NOTES:

INJECTION SYSTEM
A - Air
M - Mechanical

SCAVENGING SYSTEM
S - Separate (i.e., Pump or Blower)
CC - Crankcase (for 2-Stroke Cycle Only)

HEAT UTILIZATION
N - Not Utilized
B - To Heat Building
F - To Heat Fuel
L - To Heat Lubricating Oil
BF - To Heat Boiler Feed Water

NATURE OF FUEL OIL
API - American Petroleum Institute
BTU/lb. - British Thermal Units per Pound
"Say.U - Seconds Saybolt Universal
"Say.F - Seconds Saybolt Furol
°Eng. - Degrees Engler
S Sulphur
CC - Carbon by Conradson Method
BS&W - Bottom Sediment and Water
Spec. Grav. - Specific Gravity
Asph. Res. - Asphaltic Residue

NUMBERED NOTES
1. No deduction made for motor-driven Scavenging blower.
2. Engine speed increased and new generators installed since 1929 report.
3. Name plate ratings are 700 and 1400 K.W.
4. April 5. February 6. October
7. Nominal Rating 450 K.V.A.
8. September
9. Horizontal Engine
10. December 11. Reported 257 R.P.M. last year in error.
12. Semi-Diesel Engine
13. Cost includes import duty.
14. August 15. March - Start of 3 year period.
16. Installed in Plt. #103 in August, 1930.
17. Installed in Plt. #102 in October, 1930.

NOTES:

INJECTION SYSTEM
A - Air
M - Mechanical

SCAVENGING SYSTEM
S - Separate (i.e., Pump or Blower)
CC - Crankcase (for 2-Stroke Cycle Only)

PISTON COOLING
A - Air. W - Water
O - Oil

NUMBERED NOTES

1. Name Plates are 700 and 1400 K.W.
2. April 3. 60 Minute Peak
4. October 5. Total Labor; Operating Crew does not Maintain 6. Expense Replacing Cylinder Heads Cracked in 1928 Through Sabotage
7. Part Time on Operation; Part Maintenance 8. Rated 450 K.V.A.
9. September 10. 24 Hour Average
11. Repaired Crankshaft Broken in 1928
12. Horizontal Engine 13. December
14. Soft Water Makeup 15. Overlapping Shifts 16. Includes Water Dept. Labor 17. Further Information Requested but not Received
18. February 19. Part Time 20. Treated Last Two Years 21. Semi-Diesel Engine 22. Operator Failed to Start Oil Pump 23. Changed in July from "A" 24. August
25. Repair Parts into Stock 26. Half time Against Water Dept.
27. March, the start of the Two Year Period 28. Instantaneous 29. Same Labor Also Operates Steam Units
30. Five Year Overhaul
31. Total Labor; All Repairs in Overtime 32. Hours per Week 33. Installed in Plt. #103 in August, 1930
34. Installed in Plt. #102 in October, 1930

Gear Drives for Motorships

As Affecting the Development of an Efficient American Merchant Marine

By J. BARRAJA-FRAUENFELDER,[1] PHILADELPHIA, PA.

This paper has been written with the object of clarifying a much-misunderstood situation. While the conclusions arrived at represent the author's own deductions from current accomplishments, they are based on known facts and data, and other authorities are quoted extensively in order to present unbiased views from engineers who have no direct interest in the production of any particular type of engine and to avoid the impression of a one-man idea. Where opportunity has permitted it, reliable data have been quoted; where not so permissible, data have been omitted; but the author will gladly corroborate any statement or quotation which is thought by others to be doubtful or not sufficiently substantiated. It is suggested that the bibliography appended to the paper be carefully consulted in order that the scope of this effort may be fully digested. In substance, the paper should be considered a compendium of practically all that has been accomplished to date in this line which is, in the author's opinion, worthy of note.

THE arrival in New York of the Hamburg-American Line's new motorships *St. Louis* and *Milwaukee* opened a new era in motorship drives. The author refers to geared Diesel engines as exemplified by the power plants of those most up-to-date ships. These plants are composed of two-cycle, double-acting Diesel engines geared to the propellers at an approximate ratio of 2 to 1. Two engines per shaft are installed, or a total of four engines, the ships being twin-screw vessels. As it is believed that two-cycle, double-acting engines are the logical type to be used in connection with gear drives for large ships, and as these ships represent the latest development following a long line of successful predecessors equipped with gear drives, the author will refrain at this point from commenting on them and go back to the early days of gear drives, from whence he will trace their progress down to the present.

Historical

The earliest known commercial applications of gear drives to Diesel-propelled ships date back to 1909. Several paddle-wheel towboats were fitted with gear transmissions for service on the River Volga in Russia. The gears served to reduce the speed of the engines, of about 250 r.p.m., to that of the paddle wheels, which were to turn at 40 to 50 r.p.m. Seiliger (31),[2] p. 141, Fig. 82, shows such an arrangement, but with Krupp six-cylinder, four-cycle engines of 120 b.hp. turning at 400 r.p.m.

Table 1 gives a list of geared ships known to exist and in successful operation at the present time. This list is not complete, as very small vessels are not included because they are of no interest to shipowners engaged in the operation of large ships, and the picture the author intends to unfold to view involves only such ships. General characteristics of the ships listed are given, including those of the machinery.

As may be noted, the earliest applications, especially in Germany, involved four-cycle, single-acting engines of the high-speed submarine type. This was simply the result of an economic condition. As Dr. Dreves states (8):

> The desire for maximum efficiency in the upbuilding and operation of the new merchant marine, dictated by the economic conditions existing in Germany right after the war, was responsible for the adoption of indirect drive with oil engines for the propulsion of ships, which already had proved successful with turbines.

Also, after the war a number of German Diesel-engine manufacturers found themselves with submarine engines on their hands, either completely or partially finished or with sufficient stocks of parts, which together with existing patterns and jigs enabled them to complete those unfinished and to produce new ones of the same type at reasonable prices. So that such engines as escaped destruction at the dictum of the allied disarmament commission were thus devoted to peaceful purposes. Again quoting Dr. Dreves:

> As far as the necessity of driving the oil engine at a higher rotative speed was concerned, there could have been no fundamental objection against their use in merchant ships since their reliability has been proved, if not in continuous service, at any rate under the most difficult conditions of submarine service.

Still they possessed rather extreme characteristics for commercial use, and to suit the requirements of the merchant marine for relatively higher reliability and longer life, which is more important, both engine speed and mean effective pressure were suitably reduced. In addition, certain parts which did not require extreme lightness were made more rugged or heavier. The type nevertheless was preserved and was undoubtedly the most logical one to be so utilized at that time.

These earlier applications so showed their superiority over direct drives that at least one builder adopted them as standard, redesigning them for out-and-out commercial applications; hence the vessels which followed show this new trend, as will be seen later.

---

[1] J. Barraja-Frauenfelder & Co., consulting engineers in oil engines. Consulting Diesel engineer of the Sun Shipbuilding & Dry Dock Company. Mr. Barraja-Frauenfelder was born in Italy and was graduated from Naples Nautical College and Milan Polytechnic. He came to this country in 1901, and from 1905 to 1911, while with the Holland Torpedo Boat Company, he devoted considerable time to the study of Diesel engines. From 1911 to 1913, he was assistant to the chief engineer of the Fore River Shipbuilding Corporation, where he conducted investigations on Diesel engines and made a European investigation trip. During 1913 and 1914 he was chief engineer of the Spezia, Italy, works of the Fiat-San Giorgio Company, in charge of design and construction of Diesel engines. He returned to this country, and from 1914 to 1923 was chief engineer of the Lake Torpedo Boat Company. He has taken an active part in the development of high-speed submarine engines of both two- and four-cycle types.

Presented at the National Oil and Gas Power Meeting, held at the Pennsylvania State College, State College, Pa., June 12 to 14, 1930.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[2] Numbers in parentheses refer to Bibliography at end of paper.

From four-cycle, single-acting, we note a step forward to include four-cycle, double-acting, then two-cycle, double-acting, which seems at the present moment the ultimate type of engines to be used in gear drives.

Brief comments covering some of the most notable installations listed are in order.

The *Libby Maine*, built in 1918, represents one of the earliest attempts at gear drives in the United States. She was one of two wooden sister ships. Her mate, the *James Timpson*, was lost at sea in a storm in 1924 after covering 190,000 miles. The *Libby Maine*, as far as is known, is still operating successfully; see (13). The only difference in the *James Timpson* was in the main engines, they being Winton engines as against Dow-Willans engines in the former. Both ships had Falk gears.

The next notable application was that of the German ships *Havelland* and *Munsterland*, built in 1921 for the Hamburg-American Lines. In this connection it is interesting to note that while America pioneered in this type of drive, the Germans were the ones to realize its possibilities to the fullest extent. These ships were, to the author's knowledge, the first large motorships put in actual service at the time; the *Havelland* made her maiden voyage at the end of 1921.

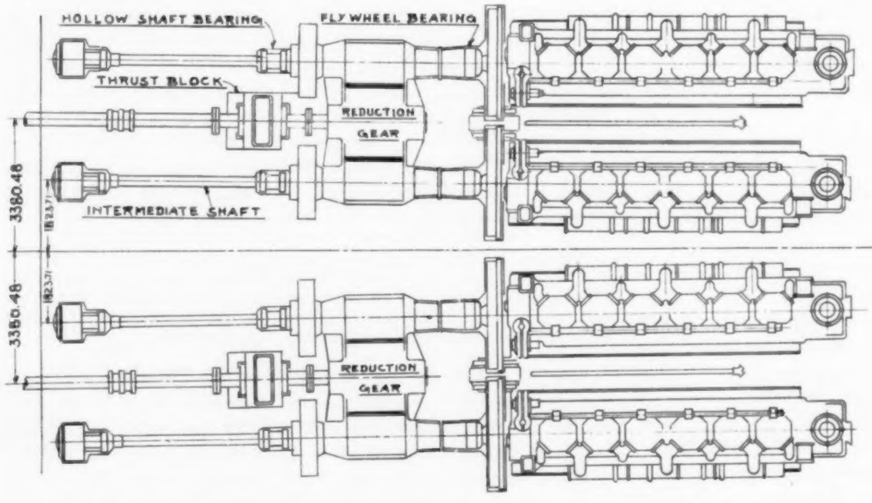

Fig. 1 Machinery of the Motor Passenger Liner "Monte Sarmiento"

Two ten-cylinder, four-cycle, single-acting engines of the M.A.N. submarine type were installed in these boats; the engines had a cylinder bore of 530 mm. (20$^{7}/_{8}$ in.) and a stroke of 530 mm. also, and were rated at 1700 b.hp. each, at 230 r.p.m. (original submarine rating 3000 s.hp. at 390 r.p.m.). Each engine was coupled to a propeller shaft by direct gear drive at a ratio of 1:2.7 (85 r.p.m. of propeller). The connections between the crankshaft and the intermediary shaft, as well as between the latter and the pinion, consisted of rigid flange couplings. The installation has become rather famous on account of a special shaft extension of great elasticity between the engines and the pinions. There has been a widespread belief that this long and flexible shaft was chosen with the idea of keeping the irregular torque of the engine away from the teeth of the gear, but this is not the case. From the beginning, the designers (Blohm & Voss) were absolutely convinced that the impulses resulting from the piston forces would have no detrimental effect on the gears. The reason for adopting the long intermediary shaft was to shift the critical range of the 5th order of the main vibrations as low as possible.

The machinery and, particularly, the gears have proved very successful. The Hamburg-American Line had ordered, at the same time, two other motorships, the *Rheinland* and the *Ermland*, of the same size and description, but equipped with slow-speed, direct-coupled, four-cycle, six-cylinder Diesel engines of the crosshead type, running at 95 r.p.m. It is the best proof of the reliability of the geared installations that the Hamburg-American Line, when further ships of the same size and for the same purpose had to be ordered, decided on duplicates of the *Havelland*. These two newer boats were the *Vogtland* and *Friesland*. The installation in the latter boat varies, however, from the original *Havelland* arrangement, inasmuch as both engines in the *Friesland* are driving one propeller shaft over one common large gearwheel. The long and flexible intermediary shafts have been eliminated in this ship, with the result that the critical range of the 5th-order two-noded vibrations is located in the neighborhood of 65 r.p.m. of the propeller, which is less convenient than in the other installations. Regarding the reasons for this alteration and regarding the couplings used in the M.S. *Friesland*, see the description of the *Monte Sarmiento* given below.

M.S. *Hans Lonehardt* (ex-*Vulcan*). This was an experimental ship built by the Vulcan Werke in order to demonstrate the Vulcan-Foettinger hydraulic reduction gear; likewise the Bremer-Vulcan Works built a tugboat for the same purpose. These ships have been successful as demonstrators, except that there does not seem to be sufficient justification for this expensive type of reversing gear, as later developments will show.

M.S. *Monte Sarmiento* and *Monte Olivia* (see 7). During the year 1923, the Hamburg Süd-amerikanische Dampfschifffahrts Gesellschaft placed an order for two motorships of nearly 14,000 British register tons with the firm of Blohm & Voss, Hamburg. The desired speed of these ships required a total of 5400 b.hp.; Blohm & Voss suggested twin-screw ships with four single-acting, four-cycle Diesel engines of six cylinders each and with 600 mm. bore and 700 mm. stroke, running at 215 r.p.m.; each propeller shaft was driven by two of these engines over one common large gearwheel, the propeller shafts running at 77 r.p.m. During the course of construction it was agreed to raise the speed of the ships to 14.25 knots, which required a total of 7000 b.hp. per engine; this increased output was obtained by installing turbo blowers for supercharging.

The first engines (for the M.S. *Monte Sarmiento*) were built as trunk-piston engines, but owing to many difficulties with the pistons, it was decided to use crossheads for the four engines of the *Monte Olivia*, cylinder bore, stroke, and r.p.m. remaining the same. At first, long and flexible intermediary shafts between the engines and the pinions, similar to the installation in the *Havelland*, were provided. The first trials showed that, at certain speeds, rather heavy oscillations took place between the two engines coupled to one propeller shaft, so that for the long intermediary shafts there had to be substituted very short shaft connections. The natural frequency of oscillations became thereby much higher, which was admittedly less convenient, but the gears worked just as satisfactorily as before. As a matter of fact, with all the gear-driven installations mentioned here, there has never been the least complaint about the gears; the wear and tear has proved entirely negligible. Fig. 1 shows the original layout of the engines, and Fig. 2 the gear set with quillshafts.

With the twin-engine arrangement, the necessity arises to provide couplings between the crankshaft and pinion that can be quickly and easily disconnected. The engineers of Blohm & Voss designed a very simple flange coupling in which a small number of very strong pins were rigidly fastened in one half of the coupling and fitted to a running fit into corresponding holes in the other half, some clearance existing, of course, in the axial direction between the two flanges. After reliable lubrication of the bearing surfaces of the pin was provided, this coupling proved quite satisfactory. It has been stated by the operators that it takes only from 8 to 10 minutes to disconnect one engine. During the trial runs and during the first voyages of the *Monte Sarmiento*, several piston seizures occurred which brought the engines to a sudden stop. Contrary to the prophecies of the advocates of the hydraulic gear, the toothed gears stood these trying tests exceptionally well; no damage whatever of the teeth could be detected. The gears are of the herringbone type, with 45-deg. angle; the diameters are 818 mm. (32 in.), with 124 teeth for the pinions, and 2295 mm. (90 in.), with 348 teeth for the large wheels; circular pitch, about 0.816 in.

M.S. *Heidelberg*. In contrast with the foregoing motorships, the *Heidelberg* is equipped with Vulcan hydraulic couplings between the engines and pinions. It must be understood that the gear here mentioned, as made by Vulcan, is not entirely hydraulic. The transmission ratio is obtained by ordinary toothed gears of the herringbone type, but the connection with the engine is made through a Foettinger-type hydraulic coupling which is an outgrowth of the old Foettinger transformer of turbine fame. When reversibility is desired, another hydraulic coupling designed to run in the opposite direction is installed at the opposite end of the pinion.

Reversing is accomplished by pumping the fluid out of the ahead coupling and into the astern coupling. This process naturally required time; hence the reversing type of hydraulic coupling is not favored.

Two single-acting, four-cycle, eight-cylinder engines of the crosshead type are installed in this ship, each driving an individual propeller shaft; the engines have cylinders of 640 mm. ($25^1/_4$ in.) bore by 700 mm. ($27^9/_{16}$ in.) stroke; they are rated at 2050 b.hp. each at 215 r.p.m. With an eight-cylinder, single-acting, four-cycle engine, the most dangerous vibrations are those of the 4th order. When a hydraulic coupling is installed, the entire shafting is divided, as far as torsional vibrations are concerned, into two independent systems; one consisting of the engine with flywheel and the primary parts of the coupling, and the other of the secondary parts of the coupling, the reduction gear composed of pinions and large wheel, the line shafting, and the propeller. The use of the hydraulic coupling, in the case of the *Heidelberg*, resulted in the oscillations of the main critical range of the 4th order being shifted above the maximum running speed, which is certainly of great advantage.

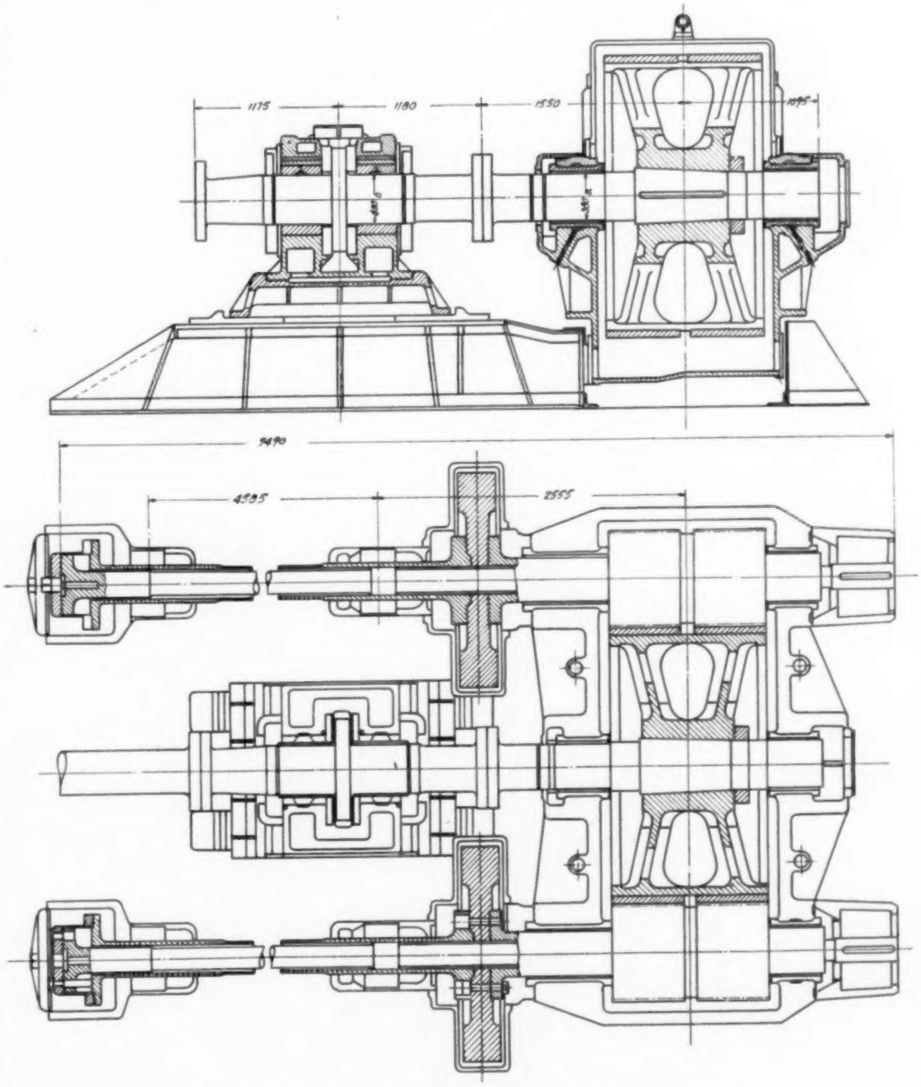

Fig. 2 Gear Set of Motorship "Monte Sarmiento"

During the first voyages, several difficulties were encountered with the hydraulic gear, mostly due to the inability to fully eject the air carried in by the lubricating oil used for filling the couplings, and further, due to defects in the auxiliary pumps belonging to the hydraulic gear. After various alterations these difficulties were overcome to the satisfaction of the owners. Two similar plants have been installed in the M.S. *Ruhr* and *Rhein*. One of the author's correspondents, who is acquainted

[b] Displacement net without fuel.

with the installation in one of these ships, expresses his opinion as follows:

> The plant works quite satisfactorily, including the hydraulic reversing part, but the space occupied, the weight, and cost of the couplings and the reversing gear, including all the auxiliaries (pump, tanks, piping), appear to be much out of proportion to the advantage obtained over the plain gear drive, whereby it can be considered today a proved fact that the simple gear drive is absolutely reliable if everything is correctly designed.

M.S. *St. Louis* and *Milwaukee.* These vessels have already made several voyages to and from New York. With the exception of the engines, their installations are similar to that of the M.S. *Monte Sarmiento.* The engines, four in number, are of the double-acting, two-cycle type with six cylinders each, and so rated that each ship will obtain 12,000 s.hp. normal rating. The difference between the two plants is shown in Table 1, to the effect that the *St. Louis*, built by the Bremer-Vulcan, has Vulcan non-reversible hydraulic couplings, while the *Milwaukee*, built by Blohm & Voss, has pin couplings. In the former the engine rating is slightly higher to make up for the losses of the hydraulic couplings. Both groups of engines have been built by the respective shipbuilders under license from M.A.N. A layout of the *St. Louis* engine spaces is shown in Fig. 3. The *Milwaukee* is slightly different in minor details.

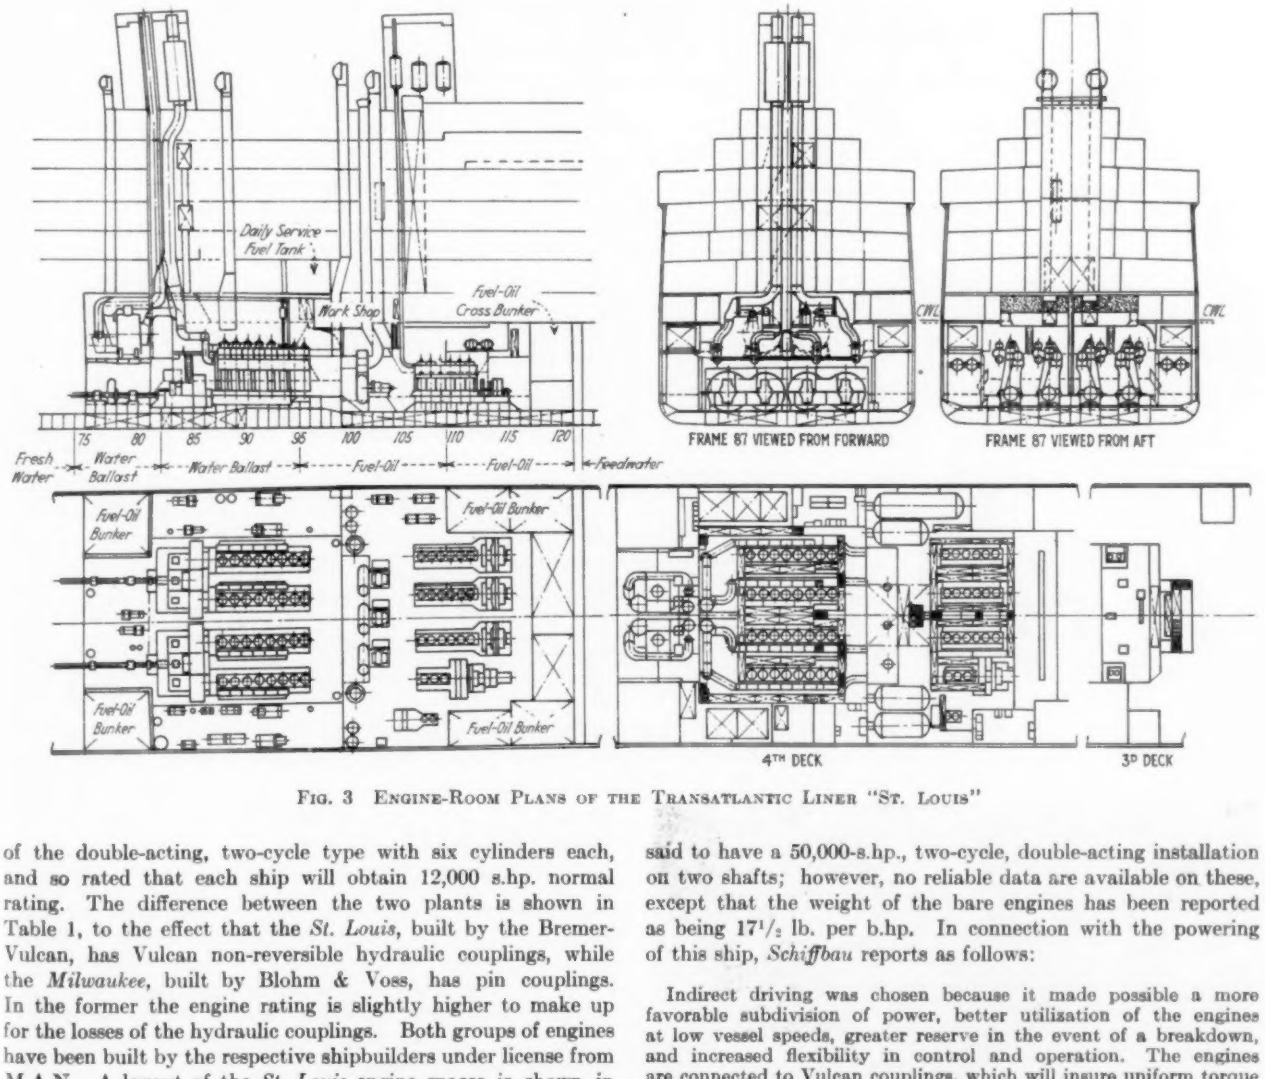

Fig. 3 Engine-Room Plans of the Transatlantic Liner "St. Louis"

Antedating the M.S. *St. Louis* and *Milwaukee* with double-acting engines is the M.S. *Wulsty Castle*, owned by the Beardmore Company and engined by the Vulcan Werke, Hamburg, with four-cycle double-acting engines of the Tosi type, and Vulcan hydraulic couplings. Reports are to the effect that this ship is functioning satisfactorily.

Another notable installation is that of the famous rotor ship *Barbara*, the power plant of which consists of four-cycle, single-acting engines coupled with hydraulic reversible gear, shown in Fig. 4.

Next in interest is the American ship *Herman Falk*, formerly *Tuxpanoil*, a very good description of which appeared in the October, 1927, issue of *Motorship* (14). Fig. 5 shows the forward end of the engines and gear. This ship has so far operated in excess of 100,000 miles, and the installation has fully justified its existence.

In addition to the merchant ships listed in the table, it is known that several naval ships have been and are being equipped with gear drives between high-speed Diesel engines and propeller shafts, among which may be mentioned the much-talked-of all-Diesel German "treaty" ship *Ersatz Preussen*, said to have a 50,000-s.hp., two-cycle, double-acting installation on two shafts; however, no reliable data are available on these, except that the weight of the bare engines has been reported as being $17^{1}/_{2}$ lb. per b.hp. In connection with the powering of this ship, *Schiffbau* reports as follows:

> Indirect driving was chosen because it made possible a more favorable subdivision of power, better utilization of the engines at low vessel speeds, greater reserve in the event of a breakdown, and increased flexibility in control and operation. The engines are connected to Vulcan couplings, which will insure uniform torque on the reduction gears and propeller shafts, besides adding the enormous advantage of enabling any one engine to be disconnected instantly without stopping the propeller shaft. The total weight of the propelling machinery, everything included, still remains less than that of a modern turbine plant of equal rating, leaving the elimination of the boilers and the saving of fuel as a clear gain to the motor vessel.

It is evident from Table 1 and the foregoing description that much history has already been accumulated on this interesting type of drive. There remains to analyze the reasons why, in

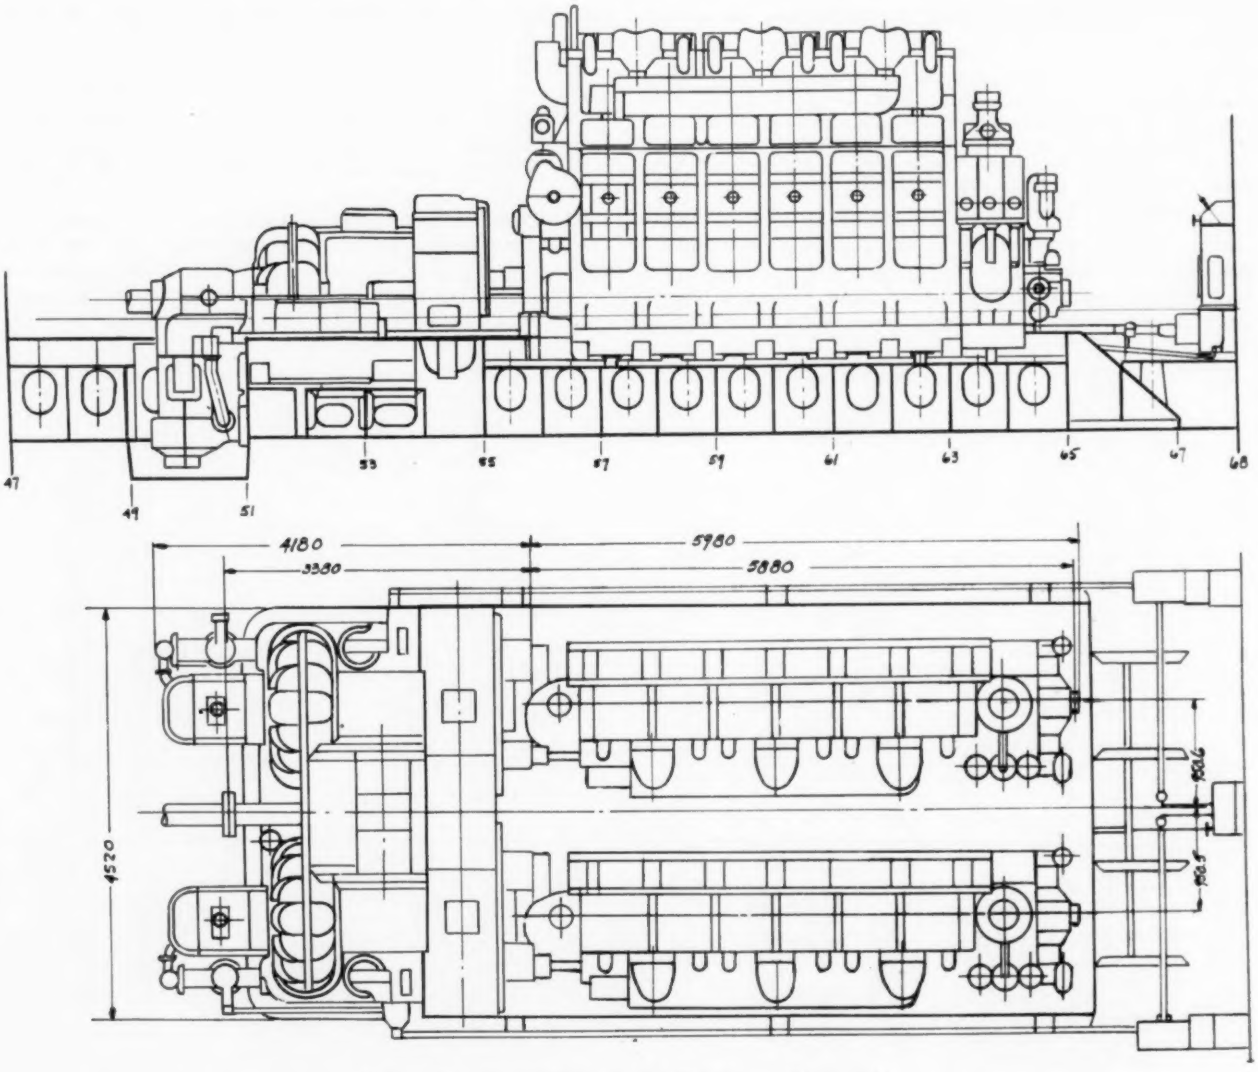

FIG. 4 PROPELLING UNIT OF THE ROTORSHIP "BARBARA"

(Two Weser-M.A.N. four-cycle, single-acting engines, trunk-piston type; bore, 14$^3/_{16}$ in.; stroke, 21 in.; r.p.m., 300; propeller r.p.m., 80; total s.hp., 1010.)

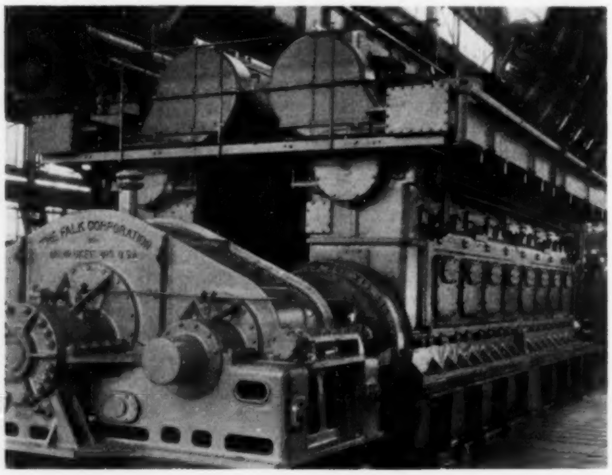

FIG. 5 FORWARD END OF ENGINES AND GEAR SET OF MOTORSHIP "HERMAN FALK"

the face of its obvious advantages, more rapid progress toward its application had not been made.

GEARS

The first and most innate prejudice is against the gears. There is a widespread misconception that the so-called pounding due to the piston impulses in a Diesel engine is detrimental to the life of the gears. It would be so if pounding existed, but since such a condition is greatly exaggerated in the minds of the critics, there does not seem to exist any real foundation for apprehension in this respect.

To begin with, gear drives of ratios approximately like those required in Diesel ship drives have been used in land industries for years, and under conditions much more severe than those encountered on board ship. To illustrate a common case, take the numerous rolling-mill installations which have been running for years without the slightest upkeep expense, as far as the gears are concerned. The owners of one such installation of about 15,000 i.hp. have stated:

> So far as we can learn, the only repairs to the bearings during the life of this engine were the replacement of some of the cushion

> springs and cross-tierods. No change was made over in the crankshaft, and the bearings ran for sixteen years without being changed. When this engine was dismantled, due to the motorizing of the mill, the gears were still in good condition. The reversing of the engine varies with the length of the bar in the rolls, but ran as high as two reversals per minute with short bars.

Any one can imagine the tremendous shocks that the gears must have withstood every time an impact was received from the ingot entering the rolls. No such condition could ever materialize in a ship unless the propeller struck solid rock.

One could keep on with this subject indefinitely, but any one with a fair knowledge of the modus operandi of various major industries can easily check up the different types of gears in use and acquire valuable knowledge.

The technique of gear manufacture has advanced considerably in the last twenty years, and especially in the last ten. The resonance troubles, due to faulty machining, experienced in the early turbine gears, are no longer present today, principally because of better workmanship. If such difficulties have been mastered with gear ratios around 1:20, then the problem becomes infinitely easier with gear ratios of 1:2 up to 1:4, such as are used in geared Diesel drives, because the stresses set up by such resonances are in the approximate order of $^1/_{100}$ of those set up in a 1:20 ratio gear set, as will be later explained.

It has been noted that many writers at home and abroad who have discussed the subject of indirect drive for motorships have considered the gear drive as unsuitable because the torque of an oil engine varies considerably and rather suddenly and the gear transmission could hardly be expected to be reliable under such conditions. The fallacy of such an assumption has been proved by many of the above-described successful installations, in some of which the torque characteristics were far from being favorable.

It is entirely up to the designer to so fix and select engine characteristics as to obtain the best possible operating conditions, the most important of which are positive torque at all times and proper lubrication. The former will be elaborated on hereafter; the latter can be easily met by very little attention to the lubricating equipment.

Comparing again turbine and Diesel gears, Mr. Banner, of the Falk Corporation, has said:

> The former operate at very high pitch-line velocities, and the number of tooth contacts per unit time is so high that shrill sounds can be generated which may become quite disturbing if resonance effect can obtain in or about the gear case. Vibrations of high, and therefore disagreeable, frequencies are also sometimes observed due to the distortion of turbine rotors.
>
> In contradistinction to those well-known and much-dreaded conditions, the oil-engine gears are operating at such low peripheral speeds and such small numbers of tooth contacts that they do not emit any noise. Balancing of pinions and gears is simple and relatively unimportant due to the low speeds. The pinions are extremely massive and do not distort.
>
> Thus inherently oil-engine units are noiseless and vibration-free, and experience with them proves this deduction to be an established fact. Such units can therefore be used with utmost advantage on passenger vessels. Since the oil engines can be made in the majority of cases vibration-free, within the running range, by design, propelling engines of this type are the given power for passenger vessels.

This is not mentioning the economic side, of which we will speak later.

The best proof of the reliability of gear-driven motorships is the fact that the Hamburg-American Line, which is in possession of most of the geared ships in operation and which therefore ought to know more about geared Diesel installations than any other concern, decided on this form of propulsion for the new transatlantic liners *St. Louis* and *Milwaukee.*

Magg (33) states:

> Direct drive means engines of extremely low speed compared to stationary engines of equal output, where, for instance, an engine of 2000 b.hp. runs at a speed of 167 r.p.m. and a 3000-b.hp. engine at 150 r.p.m. corresponding to generators of 36 and 40 poles.

There is an inherent disadvantage in direct drive where, due to propeller requirements, the maximum capability of a Diesel engine cannot be utilized; hence, *as in steam turbines, a gear transmission can even up things for the Diesel.*

Furthermore, where two engines are coupled to one propeller shaft, twin-screw safety is obtained with single-screw structural simplicity. Since modern, correctly cut gears show an efficiency of 98 per cent at least, the losses in this respect are practically negligible, while the additional expense of the gear transmission is more than offset by the reduction in engine weight and cost.

The question of vibrations must be well studied, of course, and here is where a little common-sense will steer the designer away from difficulties.

Professor Lewis (10) states:

> Just as in the steam turbine, the first condition of success may be said to lie in having good gears, accurately cut, and of sufficient size to carry the load.
>
> The second condition of the operation of a geared Diesel drive may be stated as being "the condition of positive torque." It is essential that the torque at the gear faces shall not pass through zero, otherwise the teeth will separate and pound.

The sometimes frequent and annoying troubles experienced with certain geared turbine installations, especially during and shortly after the war, have been traced back to inaccuracies in the gear-cutting process. For instance, a minute difference in pitch or in the shape of the individual teeth due either to small cyclical variations in the driving mechanism of the cutting machine or some similar disturbing factor, while of such a minute character that the resulting inaccuracies in the finished gears could hardly or not at all be found by any direct mechanical method of checking, nevertheless produced destructive effects under running conditions. It was found that force reactions of a rhythmic or pulsating nature could be produced by these small variations in the gears. If these periodically varying forces synchronized with some order of a natural frequency of the mass elastic system, which for a given installation is a fixed characteristic now easily determined in the designing stage of any machine aggregate, forces of a value many times the original ones resulted by additions of each individual vibration and caused the destruction of the gears.

While these troubles have now been eliminated in the geared turbine installations by perfection in the cutting process, wherein extremely low cutting speed and utmost rigidity are the main requirements, it will be evident from the following considerations that the geared Diesel engine is affected to a far lesser degree by possible defects in the manufacturing process. In fact, the geared Diesel drive may be considered as immune against such troubles as were experienced in the geared steam turbine.

This will be readily understood when it is considered that the forces in question will be proportional to the squares of their respective frequencies. The higher the frequency or the number of vibration cycles per unit time, the higher their accelerations and consequently their force.

A Diesel pinion running at $^1/_{10}$ the speed of a turbine-driven pinion will have acceleration forces of only $^1/_{100}$ of the latter. "Consequently," Dr. Dreves states in view of the above facts "*these exciting forces are of no practical importance in the oil-engine drive.*"

Careful and expert attention must, however, be given to the periodic torque variation inherent in all reciprocating engines.

As previously mentioned, the influence of these harmonic exciting forces emanating from the Diesel engine itself may now be evaluated for any type of installation before construction. The study of the dynamics of a mass elastic system with respect to torsional vibrations has reached a state where no excuse can be found for serious trouble of this nature, whether it may be actual breakage in the shafting system or excessive vibrations accompanied by destructive deformations in the shafting at any vital point, such as in the gear connection.

The possibility of perfect control of these conditions in the initial stages of design contrasts sharply with the uncertainty of the possible disturbing forces in the turbine gears. The latter forces being results of chance influence, preclude analysis and treatment before installation.

Finally, with regard to treatment of the two forms of gear vibrations, one characteristic of the turbine installation is more difficult, owing to the fact that the exciting forces originate in the gears themselves, whereas the characteristic pulsations in the Diesel drive have their source outside the gears, making possible various effective and easily provided means of diverting the impulses of an exciting nature from reaching the gears.

Concerning the torque variations without reference to the special state of synchronization at certain speeds, their influence on the gears is easily disposed of by fitting a flywheel having inertia according to the characteristics of the type of engine under consideration, and which will eliminate variations at the point of the gears to any desired degree.

From what has already been said it is evident that the design of a geared Diesel drive must be laid down with the exact knowledge of its characteristics with respect to critical speeds.

Practical Considerations

To quote Dr. Dreves:

> The first problem of the designer is therefore not to permit such synchronism or equality between the frequency of the exciting forces and the natural period, or if that is impossible, to place the critical speed outside of the operating range of engine speeds. It becomes necessary, therefore, to analyze the system with a given set of dimensions for cylinder bore, crankshaft, and lineshaft diameters, as well as given masses of flywheel and gear drive, for torsional vibrations, which necessitates knowledge of modes of vibration and form of excitation.
>
> It seems necessary at this time to refer to the originally projected elastic couplings of the engines of the *Monte Sarmiento* to their respective drive pinions by means of a quillshaft.

The following is by F. M. Lewis (10), p. 135, sec. 65:

> It will be found extremely difficult in many cases, while using connecting shafting of ordinary dimensions and keeping the criticals above the operating range, to satisfy the condition of positive torque. This difficulty has led to the use of the so-called "quillshaft drive." The device has been previously used for geared turbines. The pinion shaft is bored hollow and extends aft alongside the lineshaft. The reduced diameter quillshaft is fastened to the engine aft of the flywheel, passes through the hollow pinion shaft, and is connected to it by an arrangement permitting slight longitudinal motion at their after extremities. It is generally necessary to fix an extra flywheel to the pinion shaft. The effect of the arrangement is that the critical speeds are reduced far below the operating range. The engine and flywheel can respond to the torque variations by variations in the flywheel speed. The twist is taken up in the quillshaft, and the gears can run at a nearly constant speed and torque. This arrangement has met with complete success when applied to a single-engine driving gear. Examples of such a drive are the motorships *Havelland* and *Munsterland*. A quillshaft drive involving the use of step-up gears to a centrifugal pump has been recently constructed and is now in operation on the dredge *Norfolk* of the Atlantic, Gulf, and Pacific Company.
>
> The purpose of the quillshaft can be accomplished in some cases by the use of a torsionally elastic coupling. A coupling could be used in all cases were it practical to build one with sufficient torsional elasticity. As it so happens, more elasticity can be introduced by means of the quillshaft than in any other way.

In the case of *Monte Sarmiento*, however, Dr. Dreves goes on to state:

> It is characteristic of the reliability of the gear drive that during various extraordinary experiments, undertaken to broaden our knowledge of the phenomena involved and under very unfavorable circumstances, the gear teeth did not suffer the slightest damage.
>
> Fears have been also expressed for the gear drives, especially when two engines are coupled to one gear drive, in case one of the pistons seizes. Even this has been "practically tried out." Certain circumstances contributed to a seizure of one of the pistons of the *Monte Sarmiento* on its first trip. The gear drive, however, did not suffer the least. In this case the possibility of quickly disconnecting one of the engines proved to be a decided advantage.
>
> Disconnection of individual cylinders has also been repeatedly tried without the slightest effect on the gear drive.

As an example of what to expect in a well-designed drive, we may mention again the M.S. *St. Louis*, in which criticals are located as reported—one at around 45 r.p.m. on the propeller shaft and another at 170 r.p.m. on the crankshaft. The latter is exclusively confined to the primary system, comprising only the crankshaft and its masses, together with the primary parts of the hydraulic coupling. This critical has consequently no influence or effect on the performance of the gears.

It may be of interest to note that this particular critical is of the 9th order, one-noded variety, contradicting the implications of several writers on the subject of torsional vibrations that only even-numbered criticals of any noticeable magnitude are present in an installation of this type.

The critical at 45 r.p.m. in the propeller shaft receives its excitation from the four-bladed propeller. The one-noded natural frequency of this shaft system lies around 188 per min.; consequently the critical is a major one of the 4th order.

Arrangements having a more direct method of coupling engines with propeller shaft would of course have an entirely different characteristic. No such separation into two independent systems would exist. The one-noded and probably also the two-noded critical would be pushed as far down the running range as possible, while trying to keep all criticals of higher frequency above the normal speed range.

So, then, *the success of any geared Diesel drive, assuming correctly executed gears, depends chiefly upon the proper evaluation of the influence of the periodic variations in the torque from the various cylinders of the engine with regard to synchronization with one or the other of the natural frequencies of the elastic system as given by the entire engine aggregate, or in other words, with the so-called critical speeds.*

A sine qua non for a successful gear drive is the demand that at no time must the variation in torque at the point of the shafting where the gears are located reach a value of more than double the mean torque of the engine and thus at intervals produce a negative torque. This would cause periodic separations of the faces of the gear teeth, causing noisy operation and destructive pounding, with consequent rapid deterioration.

There are many and various means, as we have seen, available to conform to the foregoing conditions and insure effectivity within the operating range. It is required, however, that an exact analysis of the installation, with respect to critical speeds, be made beforehand, and the distribution of masses and shaft lengths made according to the requirements of the condition as stated. Such an analysis can be made with close approximation or even with exactness in the light of present knowledge, and a satisfactory solution may be found for almost any type of Diesel engine. In this connection, it may be noted, without going into details, that certain types of engines are inherently more advantageous in this respect than others (see Fig. 6). Thus the two-cycle, double-acting engine is most eminently suited, on account of its smooth torque characteristics, necessitating small flywheel masses, to insure uniform torque, and also because of its limited number of criticals of possible disturbing influence—the latter a valuable characteristic of this type of

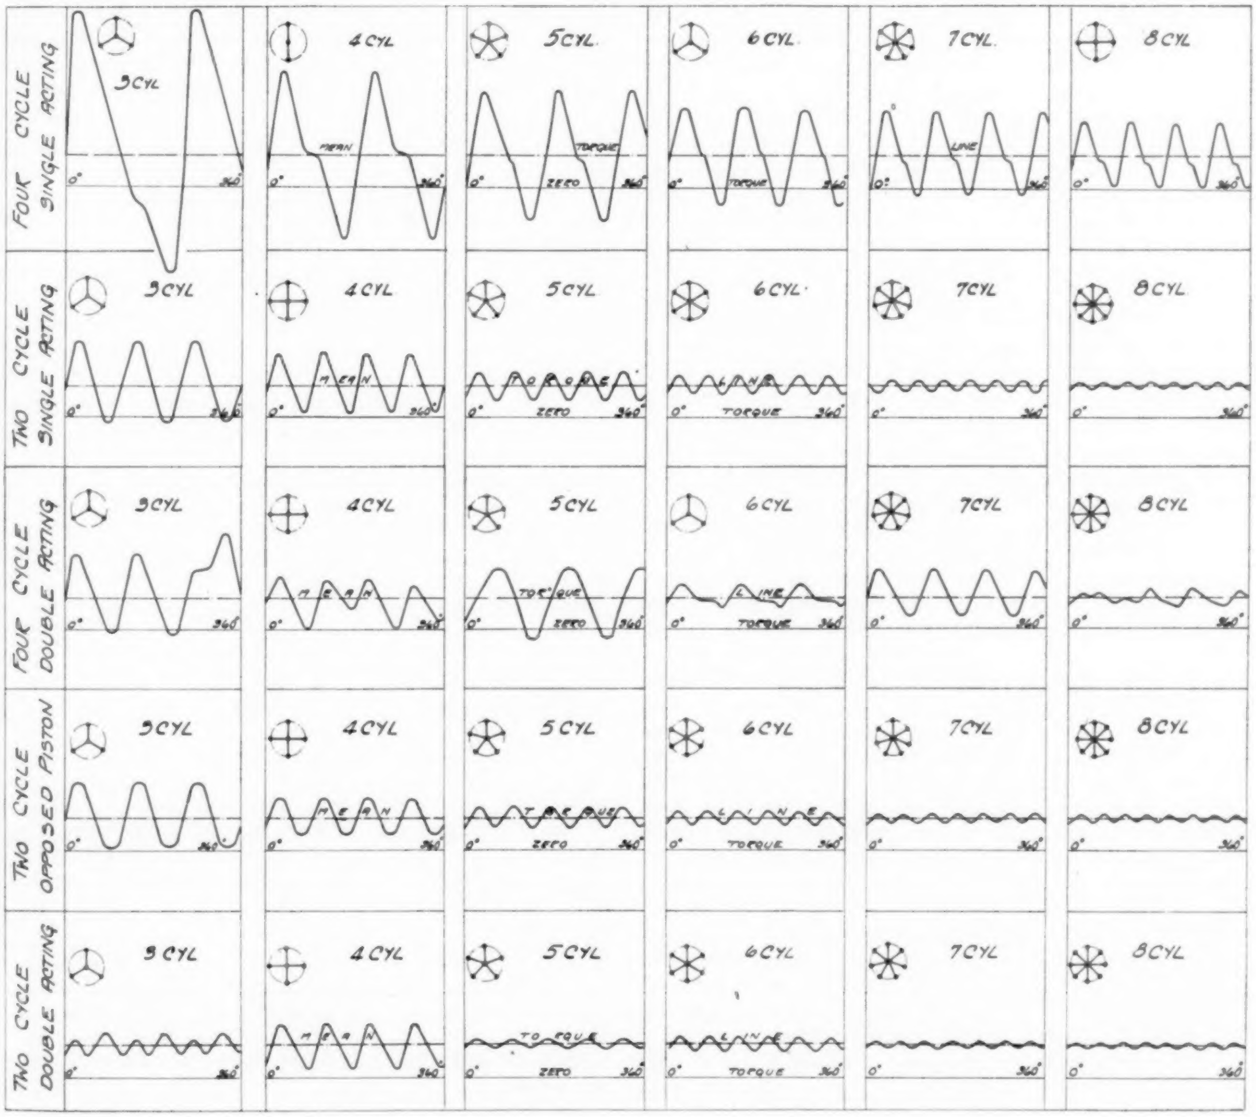

FIG. 6 TORQUE-VARIATION DIAGRAMS FOR DIESEL ENGINES OVER ONE REVOLUTION
(All engines are 100 i.hp., 100 r.p.m., and 100 lb. per sq. in. m.i.p.)

engine. Assuming approximate equal loads in top and bottom cylinders, the two-cycle, double-acting engine may have a compensating effect on many minor criticals as compared to the large number of possible disturbing points of resonance in the single-acting, four-cycle engines.

By correctly dimensioned shafts and properly arranged masses, many of the criticals of a minor order may be eliminated or reduced in such a way as to insure positive torque at the point of the gears under all circumstances. This leaves only a few more severe criticals to be dealt with. These can and usually must be put outside the operating range by a suitable arrangement of various variables.

Hydraulic transformers will eliminate the transmission of large torque variations to the gears under all circumstances, but do not act as effective damping devices in every case; at least they cannot dampen the vibrations within the engine shaft. They are, however, per se, no guarantee of successful operation, many statements in the technical literature to the contrary notwithstanding, as each case must be analyzed on its merits.

In substance, there are four ways of transmitting the power of the engines to the gears:

1 By direct rigid connection
2 By semi-rigid connection, as represented by quill-shafts and elastic couplings
3 By hydraulic or mechanical coupling
4 By damping couplings.

All of the foregoing can be supplemented by clutches or clutching features enabling the engine to be disconnected at will.

The first and second methods need no explanation, as they already have been amply discussed.

The third method includes such types of couplings as the Vulcan hydraulic, reversible and non-reversible. This coupling has the additional virtue of being capable of quick disengagement by draining the oil contained in the coupling case so that an engine can be quickly disconnected without stopping the system and can be reconnected by pumping the oil back again. This type of transmission, as we have learned, has the advantage of entirely separating the mass elastic system of the engine from that of the lineshafting, but it does not act as a vibration damper for the engine if run into the critical range except to a very small degree and under very favorable circumstances.

The fourth method includes that class of couplings which act as vibration dampers for the engine, and which also transmit power and allow disconnection when wanted. This class of coupling is necessary when it is impossible to work all major criticals out of the system. It is a comparatively new development and promises to be the most effective remedy for vibrations.

ECONOMICS

The economics of the oil-engine gear drive is not parallel to that of the turbine gear drive. In the latter high turbine speed is necessary to obtain the desired thermal efficiency, which was unobtainable when using direct connection of turbine and propeller. A compromise had to be struck before the advent of the geared turbine whereby the turbine was driven at the lowest possible speed consistent with fair commercial economy, while the resulting propeller speed was as high as compatible with the latter's efficiency. Both units were at a disadvantage. The geared turbine corrected this.

As a consequence this resulted in a smaller space being occupied by the turbine, which was somewhat offset by the space occupied by the gear, a lower weight, and consequently a lower first cost.

With the oil engine there is no necessity for increase in speed to obtain thermal efficiency. Only the questions of space, weight, and cost are involved, with certain other minor desirable features, and for these, only speeds about double those now used in direct drives are necessary. The first cost of Diesel engines is still too high for successful competition with steam installations in spite of the thermal superiority of the former. Costs must come down, and gearing offers the most desirable avenue for reduction, as not only does the higher speed bring about a greater output per unit weight, but the consequent reduction of cylinder sizes and their greater number facilitate standardization to a higher degree than with direct drive, production processes can be more readily applied, spare parts are reduced in number and bulk, and repairs are facilitated by the smaller parts which are much more easily handled.

Frahm (16) makes the comparison of Diesel drives of 8000 s.hp. at 110 r.p.m. shown in Table 2.

TABLE 2

	Cylinder			M.e.p., lb. per sq. in.	Piston speed, ft. per min.	Stroke volume, cu. ft.	Weight, lb.	Weight, lb. per s.hp.
	No.	Bore, in.	Stroke, in.					
D.A., four-cycle	8	33	59	74	1080	235	1,650,000	207
D.A., two-cycle	8	$28^3/_8$	$43^3/_8$	68	790	127	1,430,000	179
2 D.A., two-cycle geared	2x6	$22^1/_2$	$29^1/_2$	68	835	81	1,180,000	$147^1/_2$

NOTE: Two-cycle includes turbo blowers and generating sets for same. Indirect drive includes gear transmission.

The basis of comparison is a common propeller speed of 110 r.p.m. receiving the power of 8000 hp. for a single-screw ship, covering approximately the data given for the motorship *Asturias* of the Royal Mail.

Also in (4), comparative figures, referred to a single-screw ship of 2000 b.hp. and m.i.p. of 92 lb. per sq. in. for all engines, are given as follows:

(*a*) Single-acting, four-cycle, direct-drive, eight-cylinder engine, 28 in. × 95 r.p.m. (crosshead). Weight, 965,000 lb. (482 lb. per b.hp.) and cost, 418,000 r.m. ($52.25 per b.hp.).

(*b*) Single-acting, four-cycle, geared-drive, two six-cylinder engines, $21^5/_8 \times 23^5/_8$ in. × 235 r.p.m. per 70 r.p.m. (trunk piston). Weight, 480,000 lb. (240 lb. per b.hp.) and cost, 291,000 r.m. ($36.40 per b.hp.).

While these costs are not indicative of the cost in the United States, they are relative and represent a saving of 50 per cent in weight and 30 per cent in cost for the gear drive, which cannot easily be disregarded, and while they refer to single-acting, four-cycle engines, they may form a criterion of comparative values between two-cycle, double-acting engines, direct-connected and geared.

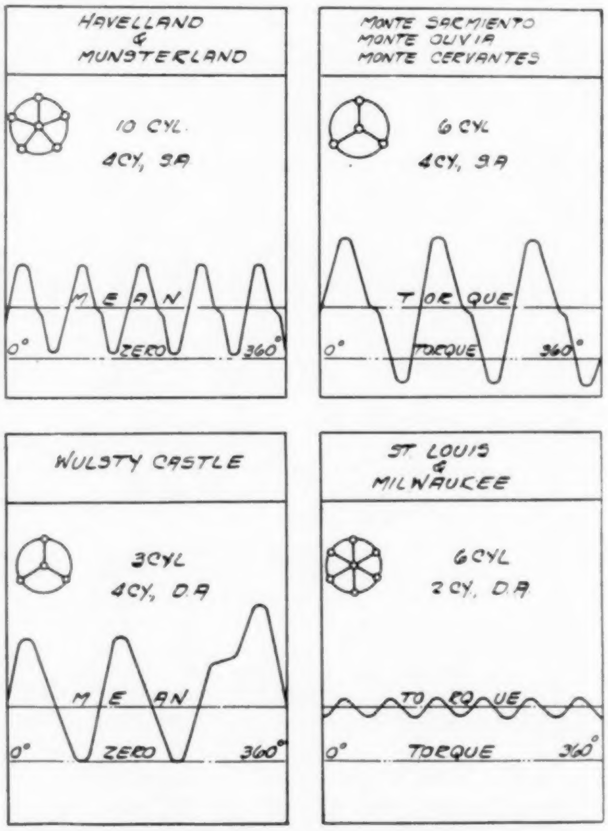

FIG. 7 COMPARATIVE TORQUE VARIATIONS OVER ONE REVOLUTION
(Based on 100 i.hp., 100 lb. per sq. in. m.i.p., 100 r.p.m. for all engines.)

CHOICE OF ENGINE

We have already seen that the most important requisite of a successful gear drive is uniformity of torque and positive character at all times. Fig. 6 shows that multi-cylinder engines, preferably of six cylinders or more, will give the desired uniformity, but above all the two-cycle, double-acting engine is the type which gives the greatest amount of uniformity with the minimum number of cylinders, and which therefore gives the least amount of fluctuation between maximum and mean torque, which in turn is the greatest safeguard against the ordinary or accidental occurrence of negative torque.

In order to bring this more in evidence, Fig. 7 has been prepared showing the torque conditions of some of the typical Diesel-geared ships in service. The *Havelland* and *Munsterland* seem almost to fulfil the condition of positive torque; the *Monte* class of ships does not. They show that theoretically there exists a small amount of negative torque; this was probably corrected by proper flywheel masses, otherwise the ships could not have performed satisfactorily. The *Wulsty Castle* shows that in spite of double action her engines are just about inside the danger line, while the *St. Louis* and *Milwaukee* show their superior characteristics by the minimum amount of torque fluctuation inherent in this class of engines.

Thus we can say that the two-cycle, double-acting engine is the logical choice for adaptation to geared drives for large ships.

But there is another quality which favors this type of engine above all others.

We must also consider the fact that the two-cycle, double-acting engine represents the logical evolution of the ideal prime mover on the basis of various practical reasons. As it is known, the simplest and cheapest type of Diesel engine is the one where a trunk piston also serves as a crosshead and depends merely upon air circulation for cooling. In modern four-cycle practice this method is used in cylinder sizes up to 16 in. and even larger, where speed and load conditions are favorable; with two-cycle engines, only the smallest cylinder sizes permit such an arrangement. In order to prevent seizure and cracking of pistons, and to always insure efficient lubrication in continuous operation under heavy loads (such as in marine practice), larger pistons require artificial cooling by oil or water circulation. The conveying system for this cooling liquid (usually telescopic pipes), while in itself comparatively simple, introduces mechanical complications on account of the ever-present danger of excessive misalignment due to the inevitable wear and deformations of trunk pistons.

On account of this, the crosshead arrangement, which virtually eliminates these complications, is more and more coming into favor in those sizes that require artificial piston cooling; this is particularly true in two-cycle practice where engines of 15 in. cylinder bore and even smaller are now more often built in the crosshead form. Experience has shown that the higher all-around reliability of such engines more than offsets the higher first cost.

With the crosshead type of single-acting engines, a form of construction is obtained which in weight and space requirements will not be appreciably exceeded by a double-acting engine of the same bore and stroke. Identically the same crosshead and guides will of course serve either type; and since it is the upper cylinder that exerts the maximum load upon the structure, the entire engine framing can also be the same. The upper cylinder end, cylinder head, valves, and valve gear will also be the same for either type, their operating conditions being in nowise affected by whatever use is made of the lower cylinder end. Likewise, in two-cycle engines the same exhaust and scavenging ports, and the control means for the latter, can be made to serve the upper as well as the lower cylinder end, so that in this respect also there need be no difference between either type.

The only outstanding feature of distinction in the double-acting engine is the lower cylinder end, with the necessary valves, the water-cooled cylinder head, and the stuffing box for the piston rod. This adds approximately 15 per cent to the height of the double-acting engine, with a corresponding increase in cost of from 10 to 12 per cent. Against this, however, we have a power output from 80 to 90 per cent greater than that of the single-acting engine, so that, reduced to a horsepower basis, both the weight and the cost of the double-acting type are at least 40 per cent lower than those of the former.

Analyzing the matter from the basis of a given capacity, it follows that, for the same number of cylinders and piston speed, the area of the double-acting cylinder reduces to about 0.55 that of the single-acting cylinder (inverse ratio of double-acting to single-acting cylinder capacity of fixed bore and stroke). Increasing this figure by 10 to 15 per cent to make allowance for the addition of the lower cylinder head, etc., gives a fair approximation of the relative weight and cost of a double-acting engine as compared with a single-acting one of equal capacity.

A smaller cylinder or a piston of shorter stroke can reciprocate a greater number of times than one of longer stroke with the same piston speed; hence the number of revolutions of the former will be greater for the same power. But the two-cycle engine has already a smaller cylinder than the four-cycle engine for the same output, so that the two-cycle, double-acting engine has the smallest cylinder of any type of engine for equal outputs. The most efficient propeller speed can now be combined with the most convenient engine speed. Conservative piston speeds compatible with sound marine practice can be adopted, thus obtaining a safe combination of engine and gear which will not be open to criticism on account of extreme conditions.

In actual practice the cylinder bore of the double-acting engine would not be arrived at by the foregoing method of reasoning. Other considerations affecting the bore-stroke ratio would enter into the problem, but the underlying idea, as given, remains; so that on the strength of careful analysis it can be stated that *the cost of a double-acting engine will always be lower in units of such capacity which in the single-acting form require to be built in the crosshead arrangement.*

Since we are only concerned here with large installations, we need not elaborate on the lower limit of size for a double-acting engine, but for the sake of defining the field, it might be stated that if a lower combustion efficiency for the lower cylinder is accepted by using one fuel valve, a cylinder as small as 12 in. bore can be used. Better combustion will be obtained with two fuel valves, and for such an arrangement more than 12 in. bore is necessary if air injection is used. From this it might be inferred that the benefits to be derived from the application of geared drives are only confined to such power units as may be obtained from the use of double-acting cylinders of 12 in. bore or more giving approximately 250 i.hp. per cylinder. Such is not the case, as where smaller powers are needed and the benefits of double action cannot be secured, the lower cost of manufacture obtainable with such engines must be secured in other ways; and this brings us back to the foregoing paragraph in which it is stated that the simplest and cheapest type of Diesel engine is the one where a trunk piston also serves as a crosshead, and depends merely upon air circulation for cooling.

In addition to the cheapness of trunk-piston construction, additional reduction in weight and cost can be obtained by the use of the highest possible rotative speed, and this can be obtained to a higher degree with four-cycle engines; hence, below the powers served by two-cycle double-acting engines, the four-cycle, single-acting, high-speed type of engine is the logical choice, except that there is an overlapping zone between 1000 and 2000 b.hp. in which trunk-piston engines with cooled pistons will very conveniently fit. The choice between the two lies primarily in space considerations.

This does not preclude the use of other types of engines so long as torque conditions are satisfied, as there may occur cases where special manufacturing advantages enjoyed by some builders may make the use of their particular type more desirable. Among these may be mentioned the two-cycle, opposed-piston type of engine, the torque characteristics of which are nearly equal to those of the double-acting two-cycle type, and which lend themselves admirably to the scheme, assuming that weight and cost conditions are met.

As to the upper limit, considering what follows, there does not seem to be any immediate need for double-acting cylinders suitable for gear drives above 24 in., or possibly a little larger. Since cylinders suitable for direct drive have been built up to 33 in. bore, we need not worry about this phase at the present moment.

TABLE 3 PROPOSED TYPICAL PLANTS. WITH GEARED TWO-CYCLE, DOUBLE-ACTING ENGINES, ATTACHED COMPRESSORS, AND SEPARATE SCAVENGE BLOWERS; GEAR EFFICIENCY, 98 PER CENT

AIR VERSUS AIRLESS INJECTION

The question of air versus airless injection is still the subject of much discussion or controversy in spite of the fact that the latter has made very rapid strides during the past few years and especially during the last two. Airless-injection engines have been growing in size very rapidly, so much so that one prominent builder, the M.A.N. company, is now ready to fulfil contracts for such engines for any size previously built in the air-injection type.

The alleged lesser perfection in atomization attributed to the airless-injection method and the limitation in fuel grades which can be utilized have had to be overlooked in favor of the greater simplicity, lesser weight, and cost of the engines built of this type. It must be admitted, however, that recent results of large airless-injection engines have shown fuel-consumption figures fully equal and in some cases superior to those of similar types of air-injection engines, which indicate efficient atomization and combustion, provided the proper grade of fuel is used.

Not wishing to enter the controversy on this subject, but fully realizing that the demands of the ship owners for simplicity and low cost will eventually force the air-injection engine to retirement, the author has computed the hypothetical plants which follow for air-injection engines, but showing the improvement to be expected from airless injection in output, reduction of weight, and cost wherever convenient.

As a general rule, by omitting the air compressor, a gain of about 7 per cent in effective output is obtained, with a reduction in weight of about the same amount. This results in a reduction of weight and cost per brake horsepower of about 13 per cent. Such a gain is certainly worth while even if the fuel consumption does not improve.

CHARACTERISTICS OF ENGINES

In order to arrive at satisfactory basic characteristics preliminary to a computation of weights and costs which will not be open to criticism, let us assume that the mean indicated pressure of a two-cycle, double-acting engine should be maintained at not more than 85 lb. per sq. in., at least until wider experience with this class of engines warrants going higher.

This coincides with present practice by the foremost builder of this class of engines at home and abroad. In the matter of piston speed, since this is a question involving only rigidity of structure and proper lubrication, the author will limit it to the highest so far obtained in high-grade single-acting engines, i.e., not over 1000 ft. per min.; say, 950 ft. per min. as a limit.

A check-up of the latest accomplishments in the matter of weight reduction of two-cycle, double-acting engines discloses the fact that a suitable structure capable of withstanding ordinary and overload stresses of this class of engine can now be built within 165 lb. per b.hp. for conservatively rated direct-drive engines of the air-injection type down to 15 lb. per b.hp. for highly rated naval types of the airless-injection type, with the value of 100 to 125 lb. per b.hp. as a good average for commercial types of engines suitable for gear drives.

The engines of the motorship *St. Louis* have been reported (20) as weighing 110 lb. per b.hp. without the blowers and 115 lb. per b.hp. with the blowers. The gears are reported as weighing 40.5 lb. per s.hp., so that the total weight of the propelling units would be 155.5 lb. per s.hp. If a plain reduction gear were used, fully 25 lb. per s.hp. could be deducted, resulting in a weight of 130.5 lb. per s.hp. and 123 lb. per s.hp. if the compressor is omitted.

The M.A.N. company offers engines suitable for direct drive, of 2000 b.hp. at 125 r.p.m., weighing 113 lb. per b.hp. (19).

On the foregoing basis, careful analyses have been made of designs which can be carried out in commercial practice, embodying all the requirements of structural strength and reliability. The designs analyzed have been correlated to existing designs as carried out by the leading builders and have been found to be in keeping with their accepted limits of strength and reliability.

The weights have been calculated from completed shop working drawings. A greater degree of refinement in execution has been allowed than in single-acting engines, avoiding, however, the use of special materials.

Costs have been calculated on the basis of these weights, allowing necessary machining wastage, but with no allowance for recovery of scrap. The man-pound-hour rate of labor has been fixed from an average drawn from a large number of factors as obtained over a period of 20 years and from a large number of commercial shops. Overhead has been fixed at 100 per cent over labor costs. Profit and contingencies have been figured in the usual way to meet present financial conditions and competition, with the understanding that the costs of drawings and patterns should be absorbed by at least ten engines.

On this basis, costs and other characteristics of propelling units of 5000-b.hp. and 10,000-b.hp. single-screw and 25,000-b.hp. and 50,000-b.hp. twin-screw have been worked out by way of examples. See Figs. 8–11 and Table 3.

It will be noted from Table 3 that the cost per pound is 20 to 25 per cent higher than that of high-grade single-acting plants, which should be sufficient guarantee of its reasonableness.

This has been checked with the costs of many existing plants of equal characteristics as well as with all bona-fide commercial quotations which have come to the author's attention, including those submitted to the Shipping Board, and except in cases where bids showed unmistakable evidence of having been fixed to the utmost that the traffic would bear, has been found to be substantially in accord with present-day practice, allowing of course for the infancy of the art.

TABLE 4

	Single-screw	Single-screw	Twin-screw	Twin-screw
S.hp.	5,000	10,000	25,000	50,000
Total weight, prime mover only, tons	374	636	1,530	2,937
Lb. per s.hp.	167.4	142.5	136.8	131.4
Airless injection	150.9	128.1	123.4	118.0
Total cost, dollars	327,732	553,640	1,258,340	2,484,680
Dollars per s.hp.	65.55	55.36	50.35	49.70
Airless injection	58.07	49.90	45.39	44.74
S.hp.	5350	11,300	28,250	56,500

In Table 3 the weights and costs of reduction gears, blower sets, and generating sets are those obtained in bona-fide quotations.

Let us now see how these data work out when concrete cases are analyzed. To begin with, Table 3 has been condensed, as shown in Table 4, to contain the same items in the same form as Table 5 for direct comparison.

Table 5 deals with two typical steam plants as described by J. Johnson in (28). The Diesel plants directly comparable to the steam plants have been evolved from Table 4 by using the 10,000-s.hp. plant factors for the 18,000-s.hp. plant and the 25,000-s.hp. plant factors for the 30,000-s.hp. plant, which is obviously a handicap against the Diesel.

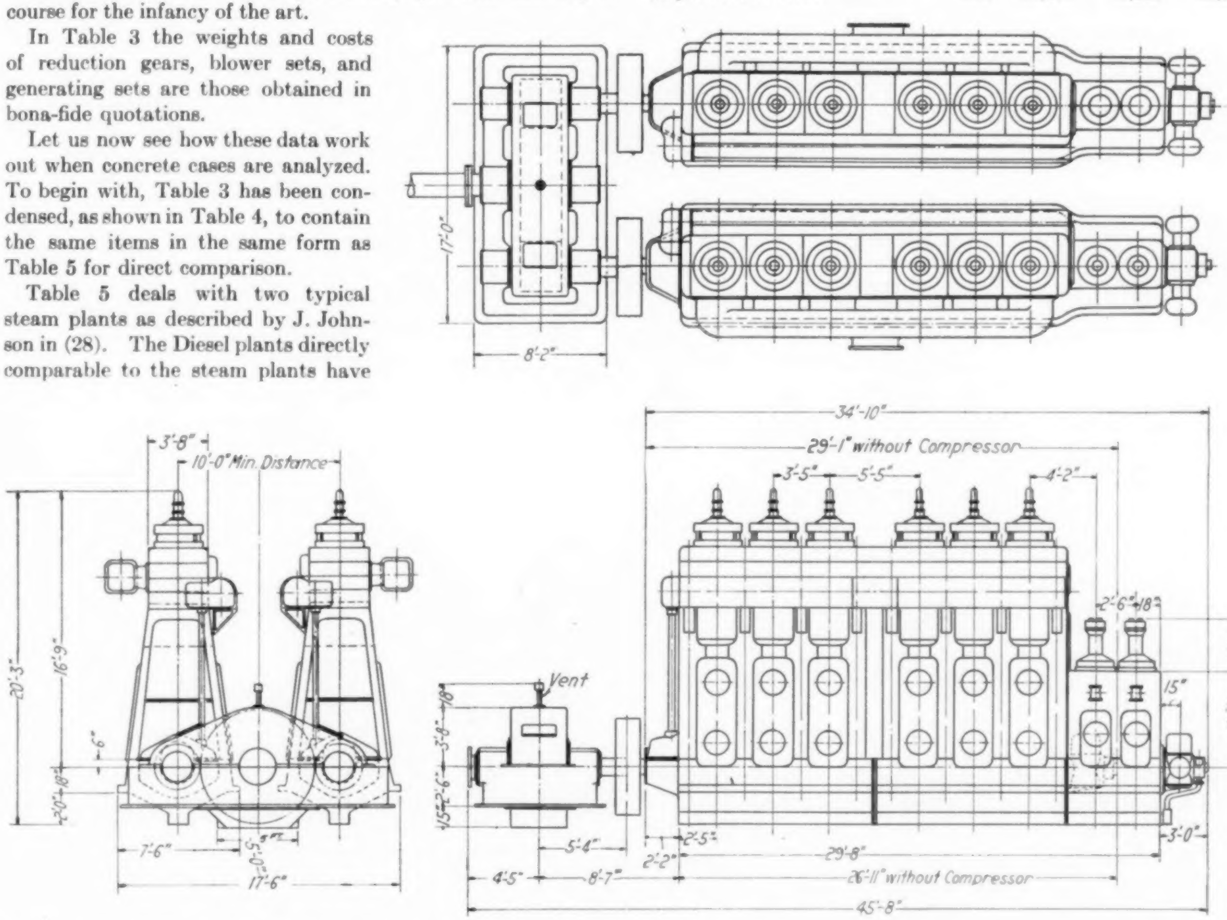

Fig. 8 Propelling Unit for Two-Cycle, Double-Acting Oil Engines With Reduction Gear, 5000 S.hp., for Single-Screw Installation

Item	Weight, lb.	Cost, dollars
Two 2550-b.hp., 6-cylinder engines, 18 × 26 in., 200 r.p.m., with compressor only	648,000	254,625
One reduction gear with thrust bearing, ratio 2 to 1	106,300	28,110
Two blowers 11,000 cu. ft. each, with dual motors	26,000	17,000
Three 110-kw. generating sets	57,000	28,000
Total power plant, prime movers only	837,300	327,735
Per s.hp.	167.4	65.55

While Mr. Johnson does not positively state the make-up of the weights quoted, it is to be inferred that they include turbines, boilers, and direct auxiliaries.

Again in Table 6, 10,000-s.hp. plants of single- and double-geared turbine sand a geared Diesel are compared, using the data for steam plants as given by *Marine Age* (28). Greater improvement could be shown with airless-injection engines.

The differential shown over the steam plants available for the balance of the machinery weights, while not definitely indicating an advantage in favor of the Diesel plant, certainly does prove that the argument is debatable and that an intelligent choice of auxiliaries may definitely swing the balance to the Diesel's favor.

In connection with the comparison between vessels propelled by geared turbine machinery and those with geared Diesel engines, it is interesting to note what Dr. Frahm (4) has to say

TABLE 5

	18,000 S.hp.		30,000 S.hp.

in regard to certain analyses made by him on bona-fide projects:

> For the purpose of comparing steam and motor propulsion for large liners, two vessels are taken, namely, the Hamburg-Amerika Line's *Hamburg*, of the *Albert Ballin* class, and the Hamburg-South Amerika liner *Cap Polonio*. Dealing first with the *Hamburg*, this is a vessel of 21,000 gross tons, equipped with turbine machinery of 13,000 s.hp., giving a speed of $16^1/_4$ knots.

Fig. 12 shows the steam machinery, Fig. 13 the same vessel with double-acting direct-drive two-stroke machinery, and Fig. 14 with double-acting two-stroke engines and gearing.

The respective weights for the different classes of machinery are indicated in Table 7.

Continuing, Dr. Frahm says:

> So far as fuel consumption is concerned, that of the steam plant is 0.385 kg. of oil per b.hp-hr. for the main turbines and 0.185 kg. per b.hp-hr. for the Diesel-driven dynamos. For the motorship the overall consumption is 0.185 kg. per b.hp-hr. The daily fuel consumption of the steamer is estimated at 122.5 tons and that of the motorship as 70 tons, it being understood that some of the heat in the exhaust gases from the propelling engines is utilized for raising steam for various purposes on the ship.
>
> The second comparison is between steam and motorship of the *Cap Polonio* class, equipped with machinery of 24,000 s.hp. [Fig. 15 shows the turbine drive as fitted to this type of vessel with two groups of four water-tube boilers, four Diesel generating sets, and geared turbine drive. The weight comparison works out as shown in Table 8, taking double-acting two-stroke machinery, both direct and with gearing.]

Three 210-kw. generating sets	108,500	53,500
Total power plant, prime movers only	1,425,500	553,640
Per s.hp.	142.5	55.36

> [The general arrangements for motorships of this class with geared and direct drive are seen in Figs. 16 and 17, respectively.] The motor drive shows itself to be distinctly more favorable, as indeed is the case in regard to machinery weight. In particular, three funnels are required on the *Polonio* vessels as steamers, whereas two would be sufficient with motor drive. The respective fuel consumptions of the vessels as steamers and motorships are estimated at 211 tons and 121 tons daily. This is based on a guaranteed fuel consumption of 0.78 lb. of oil per s.hp-hr.
>
> With both these vessels, *taking into account interest on capital, repairs, insurance, depreciation, and running costs*, it is found that the motorship would show to advantage, although it was ultimately decided to order steamers, because the machinery would be similar to that in vessels already in the owner's service, and therefore familiar to the personnel; also on account of the quiet running of previous turbine plants, the wish to learn of lengthy experience with oil engines of large power before adopting them; further, because of the possibility of reverting to oil firing and the shorter time of delivery of the steamers.

TABLE 7 MACHINERY WEIGHTS FOR TOTAL OUTPUT OF 13,000 S.HP.

	Turbine drive		Oil engines	
	Cylindrical boilers, tons	Water-tube boilers, tons	D-A, T-S direct, tons	D-A, T-S geared, tons

Average voyage weight of machinery and fuel......	7200	6530	6250	5890

From an independent check of the foregoing weights it results that the engines in the geared plants have been figured at about 150 lb. per b.hp. At the time that the Frahm analysis was made, the latest accomplishments in light double-acting engines had not been either obtained or made public.

The answer to the objections raised at that time as standing against the adoption of motorships is furnished by the motorships *St. Louis* and *Milwaukee* built for the Hamburg-American Line since then.

Let us now take some ship with which we are acquainted and see what would happen if geared, two-cycle, double-acting Diesel plants were substituted for the existing ones.

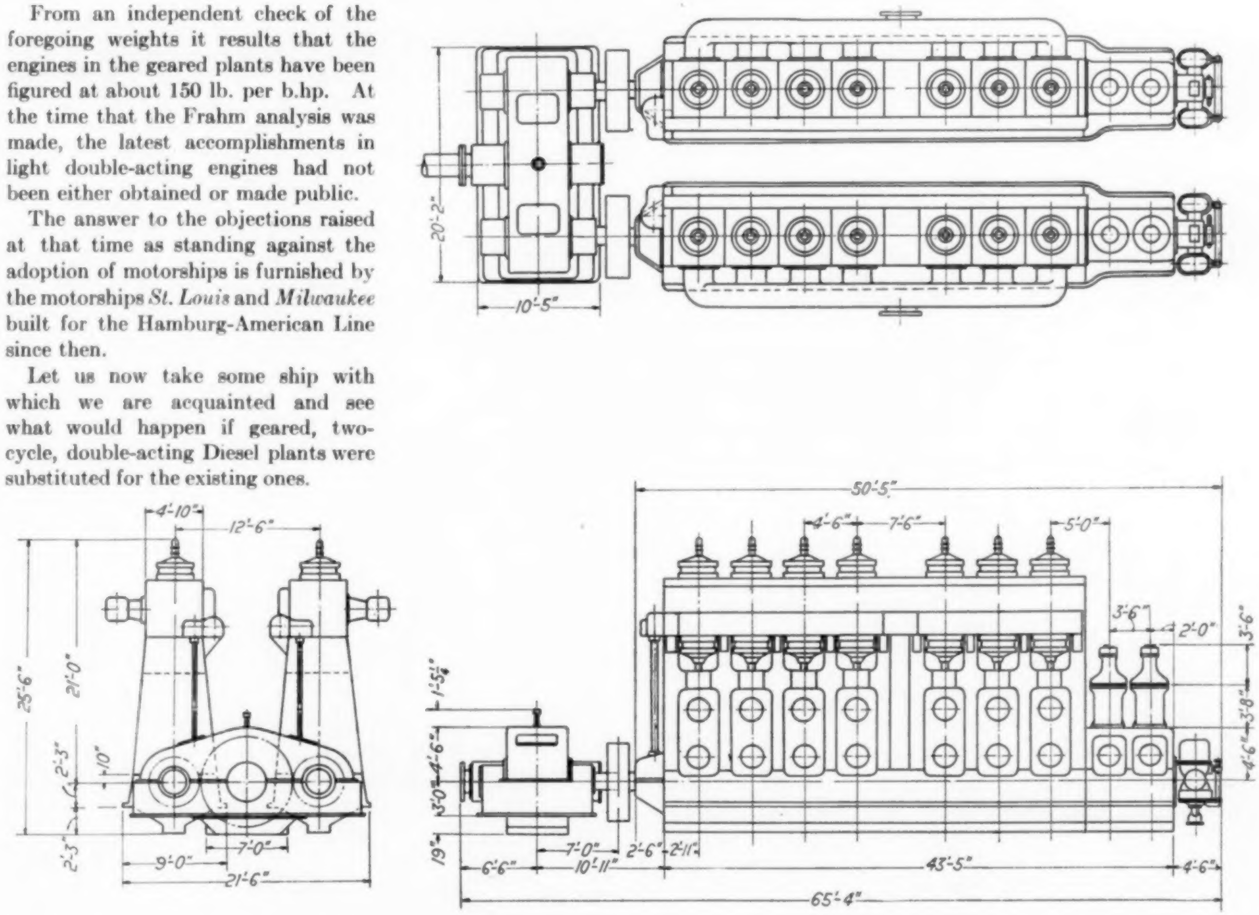

FIG. 10 PROPELLING UNIT FOR TWO-CYCLE, DOUBLE-ACTING OIL ENGINES WITH REDUCTION GEAR, 25,000 S.HP., FOR TWIN-SCREW INSTALLATION

Item	Weight, lb.	Cost, dollars
Four 6380-b.hp., 7-cylinder engines, 21 × 33 in., 175 r.p.m., with compressor only..................	2,632,000	973,840

Total power plant, prime movers only...........	3,420,000	1,258,340
Per s.hp.......................................	136.8	50.35

One of the much-argued-about vessel classes is the *Triumph* class, now equipped with Diesel-electric drive (see 35). Fig. 18 shows a layout of this vessel as it is at present and with a proposed geared plant of 5000 b.hp. The difference in space, weight, and cost is so striking that no amount of comment can bring it out any more clearly.

Another much-discussed conversion was the proposed one for the S.S. *Mt. Vernon* and *Monticello*. Fig. 19 shows the layout of these ships with geared Diesels, using the typical plant illustrated in Fig. 10 and adding two cylinders per engine to obtain the 28,500 s.hp. desired. Without arguing the matter of cost, it is seen that the weight is considerably less than that of an equivalent steam plant, and at least half of the length of the present engine and boiler-room spaces is saved. Greater savings will be obtained with airless-injection engines.

One must not lose sight of the fact, in comparing these hypothetical geared plants with their equivalent steam competitors, that in order to do so fairly, equivalent conservative characteristics must be used for the steam plants; in other words, as against 85 lb. per sq. in. m.i.p., which is at least 10 per cent under what could be done in cases not too extreme, an equivalent conservative pressure and superheat for steam must be used; and as against 850 to 950 ft. per min. piston speed, equivalent conservative turbine speed must be used. It would also be in the interest of fairness to arrive at a common understanding as to whether the high-pressure, high-superheat steam plants now contemplated or very recently put in operation are to be considered as conservative plants or not.

Turning to the *Mauretania*, the plan of Fig. 20 shows a triple-screw layout composed of three units, or a total of 75,000 s.hp., as illustrated in Fig. 14. Note the reduction in machinery-space length from 488 ft. 4 in., and that this is all accomplished with engines of only 24 in. bore and 33 in. stroke. It must be noted also that this plant represents a potentiality of at least 107,000 s.hp., because with very little increase in length the engines can be made with ten cylinders instead of seven, thus increasing the shaft horsepower in proportion. The possibilities of such an arrangement for a high-speed large liner are obvious.

For instance, if four shafts are used and engines of ten cylinders each, the potential shaft horsepower of such an arrangement would be 142,500, and this power could be accommodated in a ship of the *Bremen* size, with the added advantage that the spaces for public rooms and cabins, especially above the machinery space and in place of the boiler casings, could be rearranged and increased, thus enabling it to carry more passengers, and therefore bring in more revenue. In addition, the fuel to be carried, assuming a five-day load, would be decreased from about 4200 tons to 2400 tons one way. This is not an indifferent reduction; and if airless-injection engines are used, 153,500 s.hp. could be obtained in the same space.

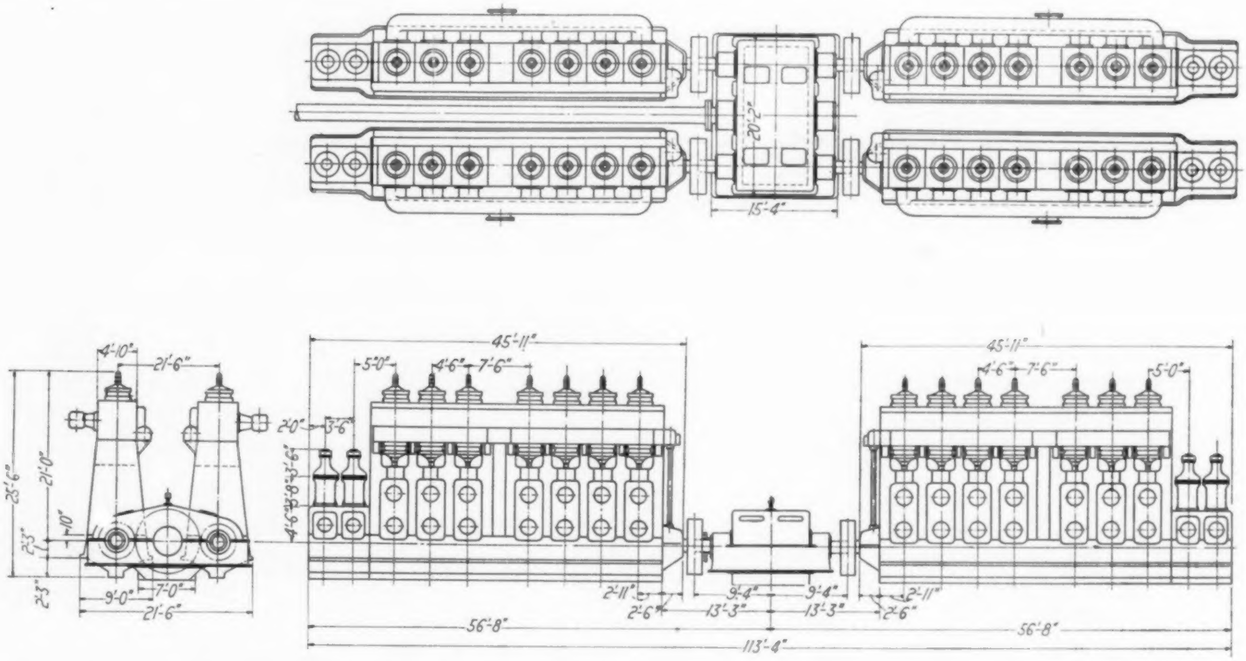

Fig. 11 Propelling Unit for Two-Cycle, Double-Acting Oil Engines With Reduction Gear, 50,000 S.hp., for Twin-Screw Installation

Item	Weight, lb.	Cost, dollars
Eight 6380-b.hp., 7-cylinder engines, 24 × 33 in., 175 r.p.m., with compressor only	5,264,000	1,947,680
Two reduction gears with thrust bearing, ratio 1.75 to 1	580,000	135,000
Six blowers 60,000 cu. ft. each (four service, two standby)	252,000	144,000
Six 500-kw. generating sets	480,000	258,000
Total power plant, prime movers only	6,576,000	2,484,680
Per s.hp.	131.4	49.70

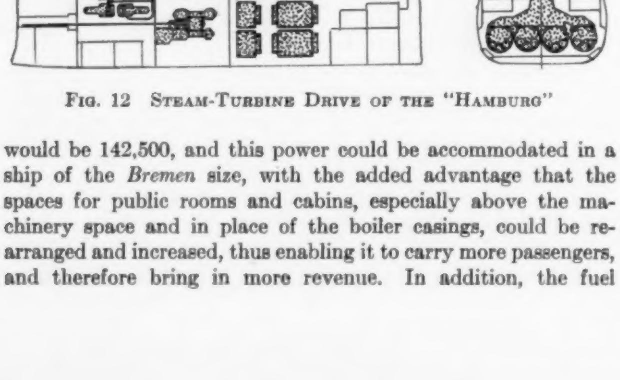

Fig. 12 Steam-Turbine Drive of the "Hamburg"

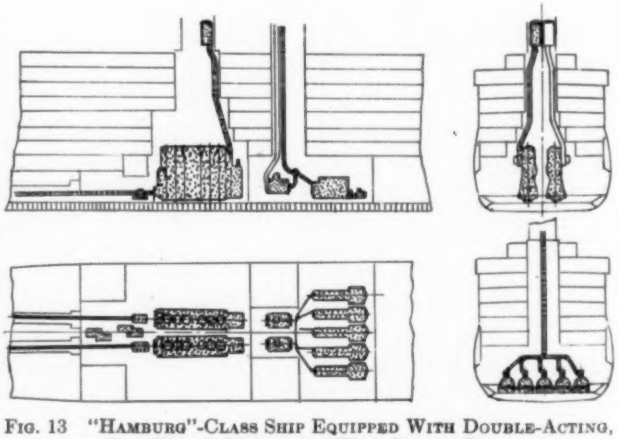

Fig. 13 "Hamburg"-Class Ship Equipped With Double-Acting, Two-Stroke Machinery With Direct Drive

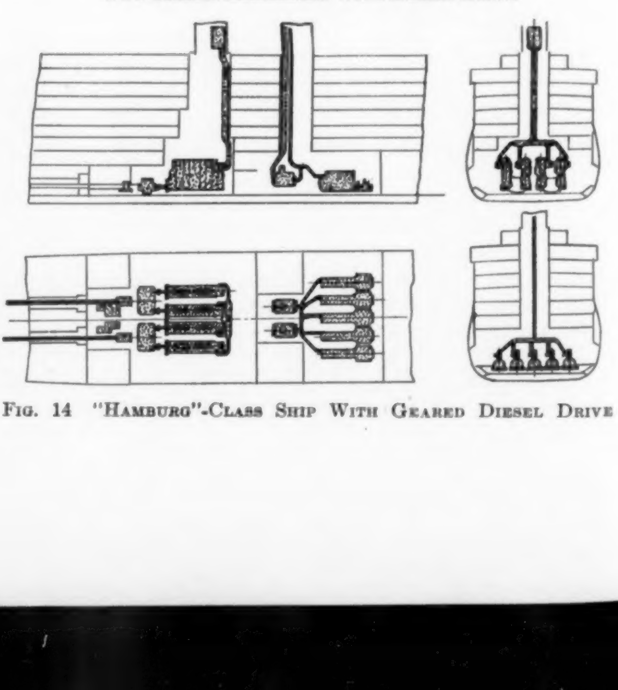

Fig. 14 "Hamburg"-Class Ship With Geared Diesel Drive

It must be borne in mind that if a ship is designed outright for Diesel propulsion, especially for geared Diesels, the aforementioned savings of space and weight can be made use of to provide a smaller ship to carry the same number of passengers at the same speed; hence the capital investment for the smaller ship and for the lesser power required will be considerably reduced (Hillhouse).

Another factor worthy of note is the element of safety of such a plant.

With four engines per shaft, coupled with readily disconnectable hydraulic clutches, the breaking down of one engine would mean only a reduction of 25 per cent of the power of one shaft, about $8^{1}/_{2}$ per cent of the total power for a three-shaft arrangement, and $6^{1}/_{4}$ per cent for a four-shaft arrangement, which would reduce the speed of the vessel by only a fraction of a knot. As a corollary, this ability to disconnect engines at will could be made use of to provide reserve power, thus obtaining an appreciable advantage over the method of obtaining reserve power by means of extra boiler capacity.

The argument is often put forward that in installations such as have been described, a large number of engines is necessary, which from the point of view of many is undesirable. Attention is called to the fact that the *Bremen* is equipped with three units per gear, which in substance are equivalent to three engines, without considering the reverse turbines. This is a total of twelve engines for the ship. Similar arrangements of three Diesels per shaft could be worked out, but they would not be convenient or desirable; hence arrangements with either two or four engines per shaft or gear must be adopted, so that in a four-shaft layout there would be sixteen engines as against the *Bremen* twelve, which is not so objectionable. In fact, the advantage is on the Diesel side, because while the turbine gear has three turbine units of different size, the Diesel unit is composed of four engines, each of the same design and size, with a number of cylinders all of the same size, which renders the spare-part and the overhauling-labor problems much simpler, and in addition full power astern is obtained.

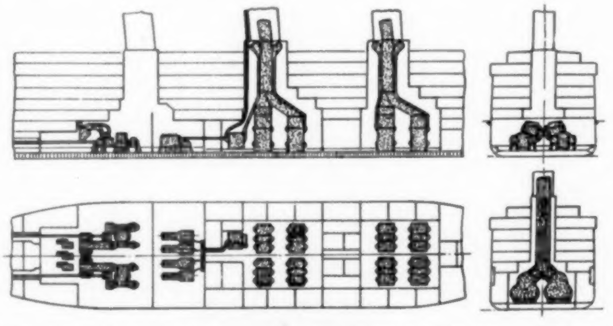

FIG. 15 "CAP POLONIO" FITTED WITH 24,000-S.HP. GEARED-TURBINE MACHINERY

Table 9 summarizes all these examples. The cost of the *St. Louis* engines has been computed by making use of the same factors used in Table 2 and the same cost per pound.

POSSIBILITIES OF THE FUTURE

Reverting to the *St. Louis* and her sister ship and to some of the accomplishments of the German builders, let us look at another situation which now presents itself.

A 15,000-b.hp., two-cycle, double-acting engine of M.A.N. design and of nine cylinders was built for the Hamburg Electric Company. This engine has been performing satisfactorily for over three years and weighs 125 lb. per b.hp., bare engine. The cylinders have a bore of 33.8 in. and a stroke of 59.1 in., and at 94 r.p.m. the piston speed is accordingly 925 ft. per min. The m.i.p. is 79 lb. per sq. in. This engine would represent a conservative direct-acting marine engine, but it would not serve our purpose except to show what has been done in the way of large power in one unit.

Recently two 11,700-b.hp. engines of a modified and lighter type have been delivered to the Berlin Electric Company and have now been in operation for some time. They represent the latest design evolved by the M.A.N. and are similar to those delivered on the second order by their American licensees to the Shipping Board, except that the latter are air-injection while the former are airless-injection engines. The cylinders are of $23^{5}/_{8}$ in. bore and $35^{7}/_{16}$ in. stroke, and at 215 r.p.m. the piston speed is 1270 ft. per min. The m.i.p. is 81 lb. per sq. in. This rating is too high for marine purposes, but if rated down to 950 ft. piston speed, but with 85 lb. per sq. in. m.i.p., they would still show a b.hp. of 8550, and since their weight is 55 lb. per b.hp. at full rating, the marine rating would bring this to about 75.4 lb. per b.hp., which is considerably less than anything the author has suggested, and is an accomplished fact. Adding to this a gear at 10.8 lb. per b.hp., the total unit weight of engines and gear would be 86.2 lb. per b.hp.

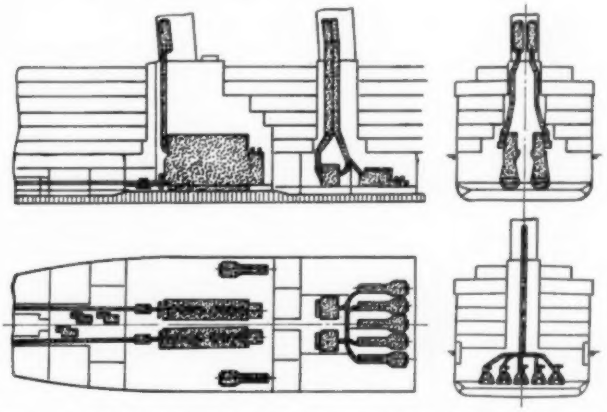

FIG. 16 "CAP POLONIO"-CLASS VESSEL WITH GEARED DIESEL DRIVE

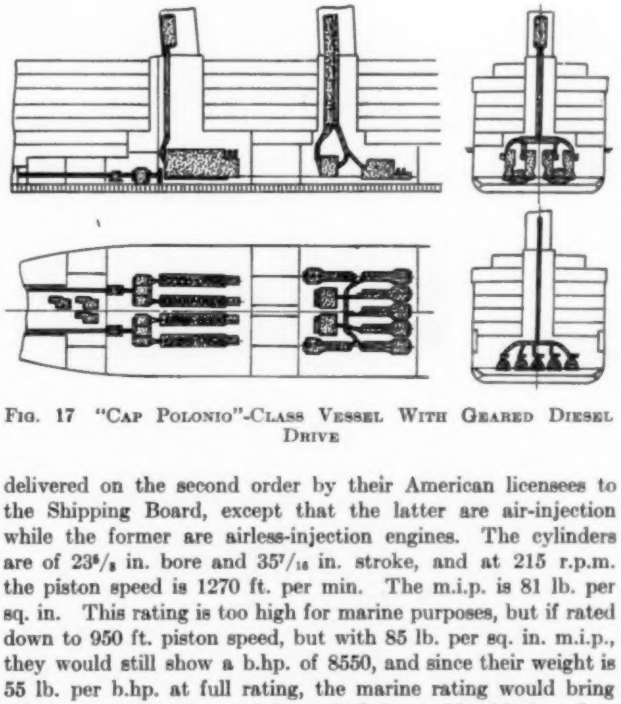

FIG. 17 "CAP POLONIO"-CLASS VESSEL WITH GEARED DIESEL DRIVE

The M.A.N. company has produced engines for naval use weighing $17^{1}/_{2}$ lb. per b.hp., which if rerated for commercial purposes would show not more than double this unit weight, but still with special materials used. If common materials are sub-

TABLE 9 TYPICAL INSTALLATIONS

	Triumph class			*St. Louis*	*Mt. Vernon*	*Mauretania*

S.hp.	4000	5000	6800	12,000	28,500	75,000
Total weight of prime movers only, tons	554	374	483	833	1,685	4,395
Lb. per s.hp.	310.0	167.4	159.0	155.5	132.4	131.4
Total cost of prime movers, dollars	458,000	327,730	447,500	630,000	1,433,655	3,726,165
Dollars per s.hp.	114.00	65.55	65.85	52.50	50.30	49.70

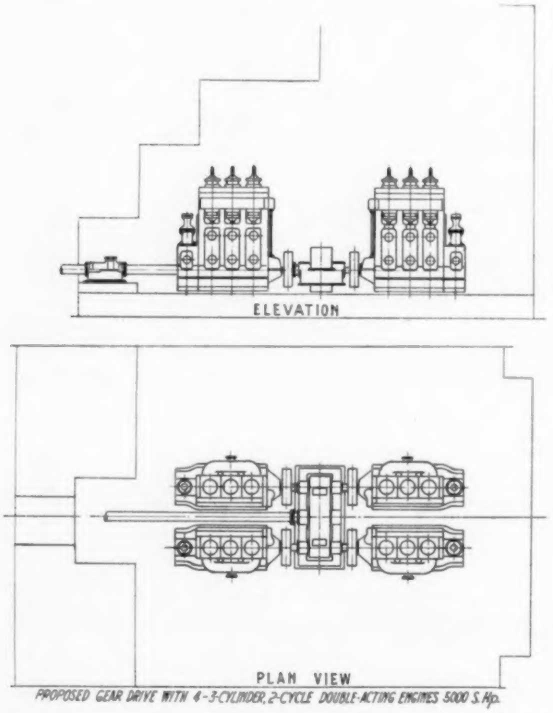
[a] This plant, described in (35), will go in same space.

stituted, the weight would then approach the aforementioned 55 lb. per b.hp., but at marine rating.

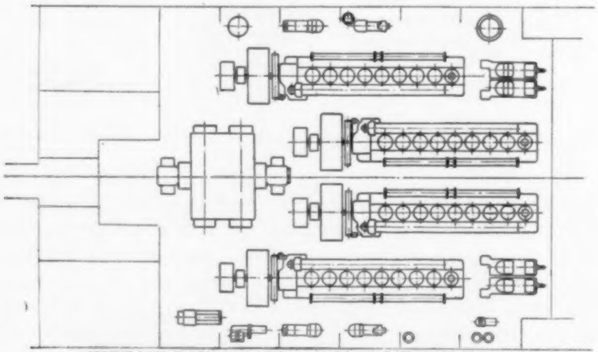
It is obvious from this that not only are the plants that have been used as examples very conservative, but that in the light of what already has been accomplished we may face in the near future more and bigger liners of the *St. Louis* type.

The aforementioned 11,700-b.hp. engines rerated to 8550 b.hp. could well be employed in a modern liner which could carry the same number of passengers at the same or better speed on a smaller displacement than the *Bremen*, assuming that the correct proportions for speed can be obtained. This is easily accomplished in view of the lesser fuel requirements and the lesser space required for machinery, which means a smaller ship, less capital investment, less cost of operation, and more profits.

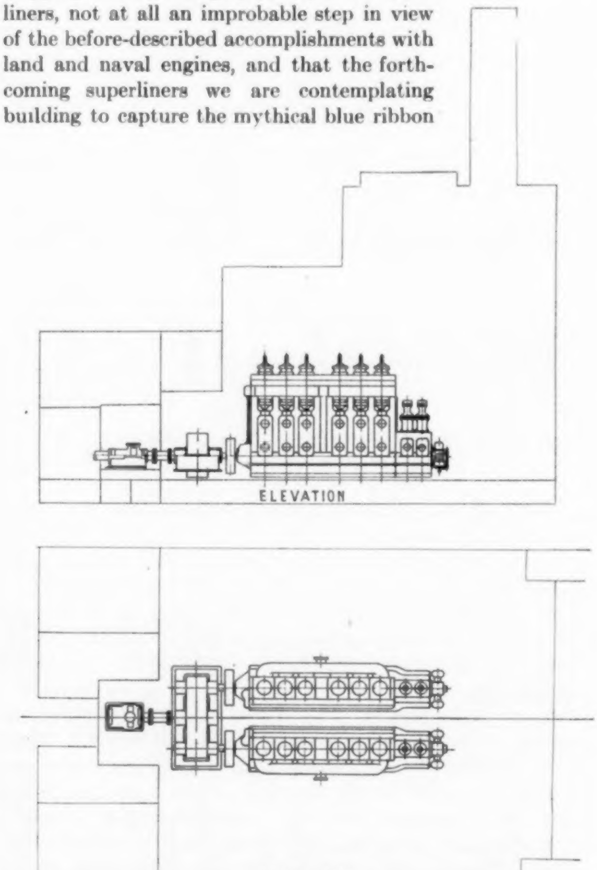
It is not to be assumed that the Germans are asleep, in view of the rapid comeback they have so far made on the sea, and the *St. Louis* should be considered only as a forerunner and as a stepping stone to larger, faster, and better liners, not at all an improbable step in view of the before-described accomplishments with land and naval engines, and that the forthcoming superliners we are contemplating building to capture the mythical blue ribbon



PROPOSED GEAR DRIVE WITH 4-3-CYLINDER, 2-CYCLE DOUBLE-ACTING ENGINES 5000 S.Hp.



PRESENT DIESEL-ELECTRIC LAYOUT WITH 4-4CYCLE SINGLE-ACTING ENGINES 4000 S.Hp.



PROPOSED GEAR DRIVE WITH 2-6 CYLINDER, 2 CYCLE DOUBLE-ACTING ENGINES 5000 S.Hp.

FIG. 18 COMPARISON OF DIESEL-ELECTRIC AND GEAR DRIVES OF MOTORSHIPS "COURAGEOUS," "DEFIANCE," AND "TRIUMPH"

Diesel-Electric

Item	Weight,[a] lb.	Cost, dollars
Four main engines, 8 cylinders, 20 × 24 in., 250 r.p.m., 1200 b.hp. each	758,000	288,000
Four generators, 800 kw. each	168,000	170,000
One propelling motor, 4000 s.hp.	300,000	
One controlling system	16,000	
Total power plant, prime movers only	1,242,000	458,000
Per s.hp.	310.0	114.00

Gear Drive

Item	Weight, lb.	Cost, dollars
Two 2550-b.hp., 6-cylinder engines, 18 × 26 in., 200 r.p.m., with compressor only	648,000	254,625
One reduction gear with thrust bearing, ratio 2 to 1	106,300	28,110
Two blowers 11,000 cu. ft. each, with dual motors	26,000	17,000
Three 110-kw. generating sets	57,000	28,000
Total power plant, prime movers only	837,300	327,735
Per s.hp.	167.4	65.55

[a] With four 3-cylinder, double-acting engines, the weight and cost increase about 5 per cent.

Total power plant, prime movers only	9,853,680	3,726,164
Per s.hp	131.4	49.70

of the Atlantic will most likely have to contend, three or four years hence, when they will be in service, with German and possibly with British, French, and Italian superior motor liners equipped with geared Diesels, which in all probability will outpoint them in operating profit if not in speed. And again, quoting *Marine Engineering and Shipping Age* (36):

> An examination of the present situation reveals the fact that in Europe, at any rate, there are far more motor passenger liners being built than steam-driven vessels. Apart from the *Bremen*, which is now completed and the *Europa*, the two 46,000-ton North German Lloyd ships, and the 40,000 tonner which is being constructed on the Clyde for the Canadian Pacific Ocean services, *all of the big passenger liners now on the stocks in British and Continental yards are to be propelled by internal-combustion machinery.*
>
> This general acceptance of the Diesel motor for passenger liners is not widely known, and most engineers and shipowners, without realizing the facts, are under the impression that the steam plant is being used quite as much in new European passenger tonnage as are oil engines. *Actually, there is four times as much motor tonnage under construction as steam tonnage, although this refers only to passenger ships.*

In the matter of reliability, the following comments in *British Motorship* are of interest:

> Recently before the Brennkrafttechnischen Gesellschaft, in Germany, a lecture was delivered on "High-Pressure Steam and Diesel Engines," in which the author was unwise enough to make the statement that "the greater reliability of steam plant in ships is of the highest importance." The author, who is a member of a turbine-building firm, quoted Sir John Biles's paper on the subject to support his case, and also spoke favorably of pulverized-coal firing in a general way.
>
> Mr. Goos, who is engineering director of the Hamburg-Amerika Line, made some interesting comments on the subject. "In general," he said, "the very numerous Diesel plants on ships are extraordinarily reliable. We have ships which have been in service many years making voyages to the Far East regularly. They come back from a five months' voyage, and in three days are ready to start again on their outward trip.... I must say we have had, with turbine ships, many unfortunate experiences.... For Diesel machinery of normal power, 3000 to 6000 b.hp., it can certainly be said that the degree of reliability is remarkable and that the regularity of operation is highly satisfactory. Up to the present time no definite statement can be made regarding the reliability of high-pressure steam machinery. We do not know exactly what type of boiler should be used."
>
> Mr. Goos also referred to Sir John Biles's paper, remarking that these lectures, "not only England, but also elsewhere, have failed to find universal approval; on the contrary, they have been very severely criticized."
>
> The author had mentioned the price of 300 marks (about $75) as the cost of Diesel generators per kilowatt, including the electrical portion, building foundations, etc. Dr. Riehm, of the M.A.N., in the discussion stated that this price is too high, as his firm was quoting 200 marks to a maximum of 250 marks ($55 to $62.50) per kilowatt, including the auxiliaries, the cost of erection, foundation, the electrical portions, and the building.

More recently, Dr. Bauer in his paper on "The Four-Day Liner," read before the November, 1929, meeting of the Schiffbautechnische Gesellschaft in Berlin (37), brings out the possibilities of motor liners of the *Bremen* size by giving an example of a 120,000-s.hp. plant with geared drive, and states that for any project involving oil engines the indirect drive is to be preferred, with gears and hydraulic coupling inserted between high-speed Diesel engines and the propeller shaft. In the discussion which followed the reading of the paper, Navy Technician Laudahn also stated:

> When considering oil engines, only high-speed ones with transmission will be considered. These can very well take up the competition with turbines.... One may say that an oil-engine plant of 130,000 s.hp. on board a liner is possible.... The first liner with oil engines is no longer an utopia.

It is to be noted that Dr. Bauer is an old advocate of the indirect drive (see 9). It is presumed, therefore, that the main reason against the adoption of such a drive for the *Bremen* was the state of the art, at the time the ship was projected, in regard to Diesel engines for such a large installation, involving considerable risk in its conception.

Since then, and since the *Bremen* was designed, the *Ersatz Preussen*, the new German treaty battleship, has been evolved, the power plant of which consists of 50,000 s.hp. on two shafts, with four engines of about 7000 hp. on each shaft. Since it is possible, without much complication, to install four engines per gear and four shafts in a ship of the *Bremen* size, the *Ersatz* power plant represents a potential 112,000-s.hp. installation.

Of course, such a plant is a naval plant, and hence highly rated, but if discounted for commercial use it could very well and with safety be considered a 68,000-s.hp. plant, with the same engines rated down to more conservative speeds, pressures, and unit weight. But such more conservative rating would still class the engines, in economy of weight and possibly cost, below anything previously analyzed in this report.

We in the United States, by reason of the higher labor costs, should further economize in the cost of Diesel installations by resorting to gear drives more than do our European competitors. The author's own feeling is that a start should be made toward some such motor liner in our own merchant marine, by first establishing the probable power plant, preferably quadruple-screw with four engines per shaft, and then constructing and equipping a twin-screw intermediate liner with identically the same engines, but only two per shaft, and if such a plant would produce 30,000 s.hp., it would represent a potential 120,000-s.hp. installation.

This is desirable in view of the fact that, at this writing, the new British intermediate motor liner *Britannic* has made its appearance, thus bringing us to a realization of the kind of competition we must meet on the Atlantic in the near future. This ship cannot be beaten in capital cost and operating expenses if built in this country, unless a geared drive is adopted to even up things from the capital-cost end.

By following this course, we could be enabled to acquire some valuable operating experience before embarking in the construction of a larger and more powerful liner.

The author presents this compendium as a probable picture of the future development of Diesel-propelled ships, and would suggest as a well-meant prophecy that he who fails to consider the geared Diesel for any large vessel, whether cargo or passenger carrier, is seemingly making a mistake.

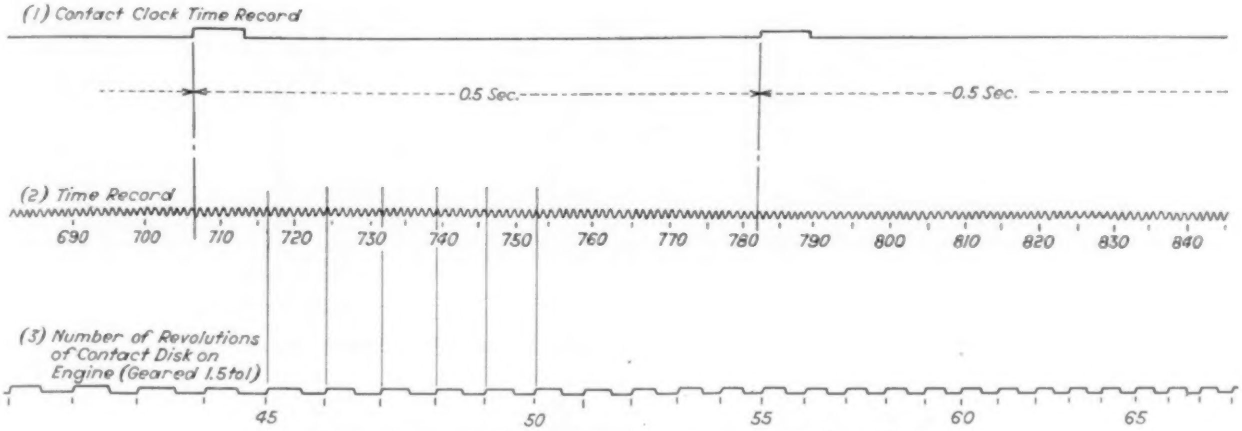

FIG. 1 PORTION OF RECORD STRIP OF ENGINE ACCELERATION TESTS

Comparative Performance of Diesel and Gasoline Engines in Motor Trucks

BY PROF. P. LANGER,[1] AACHEN, GERMANY

The results are given of tests of the comparative performance of Diesel and gasoline engines in motor trucks. The question is raised whether the carburetor is any longer justified, in view of the present high development of the fuel pump. It seems improbable that carburetor engines will ever do any better in running at low speed under load than they are now doing. The possibilities of development of the fuel pump are great. Among these is the application of the Diesel principle to light-oil engines, rendering possible a standard motor-truck engine perfect both from the thermodynamic and the automotive points of view.

THERE are in operation in the world today some 36 million automotive vehicles. These vehicles are driven by internal-combustion engines having a combined output of about 1200 million horsepower—seven times the total power developed by locomotives and nine times that of all the electric plants in existence. Indeed, a picture of the modern world would be incomplete without the automotive vehicle and its internal-combustion engine. It is a peculiar fact that the internal-combustion engine is by no means in principle the ideal prime mover for a vehicle. While it is unsurpassed for high speed and light weight, it has several serious inherent drawbacks. Above all, it is not able to start on its own power, but must be cranked before it will run, and it was only by employing an electric starter in combination with a storage battery that this disadvantage was finally overcome and the internal-combustion motor pushed to final victory over the steam engine. The modern 9 to 12 liter (550 to 730 cu. in.) capacity vehicle motor of about 100 hp. can hardly be cranked by hand at all. A further difficulty in the internal-combustion engine for vehicle propulsion is that, even at operating temperature, it is only able to pull its full or at least its approximate load upon attaining a certain minimum speed at which the fuel begins to be properly mixed and fed to the separate cylinders. The weakness of internal-combustion engines, in a word, is in operation at low speeds. The characteristic curves of both Diesel and gasoline engines show their advantages at high speeds, but these are usually limited to a minimum of about 500 r.p.m., below which the highly important range of low speeds is unprovided for.

In the investigation reported on in the present paper, particular attention was paid to the performance of engines in the lowest speed ranges.

THE TESTS

The investigations embraced Diesel automotive engines working on heavy oil with fuel pumps upon the fuel combustion principles at present most widely employed in vehicle propulsion (designated in the charts attached to this report by DSZ) for direct injection, DVK for the precombustion-chamber method, DSP for the Acro auxiliary air-chamber method, and gasoline carburetor engines (designated by VB), all of the engines considered being mounted in motor trucks. The tests were all carried out by the author at the factories, except those on engines DSZ 7c and VB 11, which were examined at the Berliner Verkehrsgesellschaft (Berlin Autobus Company) in their vehicles. All of the tests were undertaken with the engines at operating temperature.

ENGINE-ACCELERATION TESTS

With the vehicle at rest and the clutch disengaged, the engines were made to idle at the lowest speed, this being determined in the Diesel engines by the low-speed governor, and in the gasoline engines by the no-load nozzle and the butterfly-valve stop. By depressing the fuel pedal, the engine was accelerated and

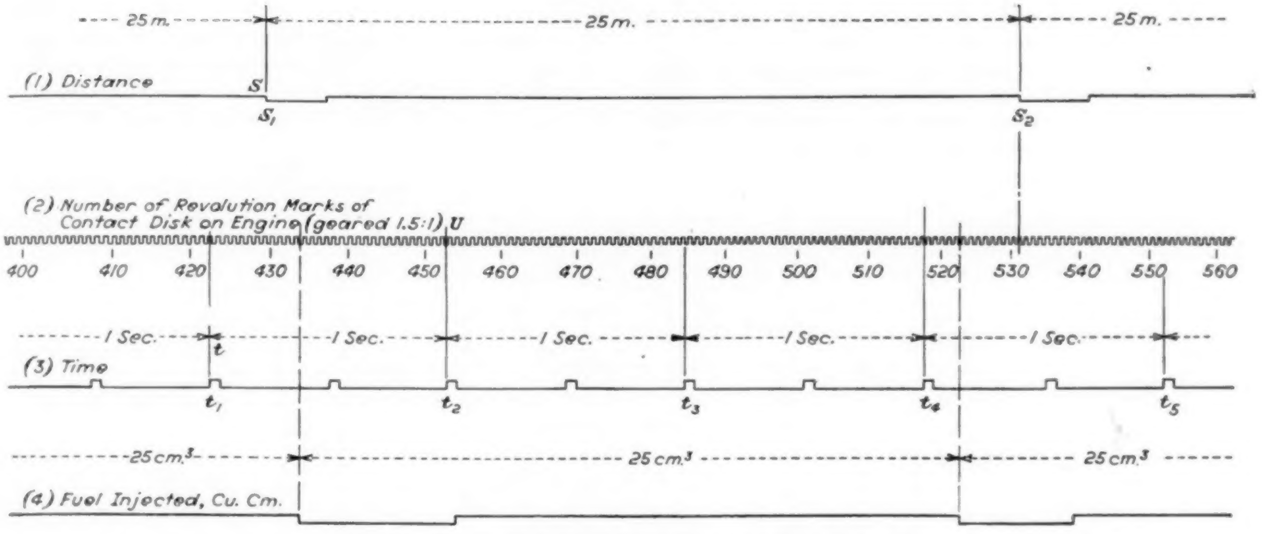

Fig. 7 Portion of Record Strip of Acceleration Tests

regulation of the fuel admission left to the speed-limiting governor.

The records were made by a magnetic recorder, shown in Fig. 1, and having three tracing points. Of the graphs registered by these points, No. 1 shows the records of a half-second contact clock; No. 2 the oscillations produced by a constant-frequency electromagnetic buzzer; and No. 3 the record of revolutions of an engine countershaft provided with rotating contacts.

The time log of the revolutions of the engine, the r.p.m., and the mean effective pressures calculated from the acceleration on the basis of the known moments of inertia of the rotating masses of the engine are recorded in Figs. 2 and 3, both for a heavy-oil Diesel engine and a gasoline carburetor-type engine of the same stroke and the same nominal maximum speed. In Fig. 2 the slow rise of the p_e curve of the gasoline engine as compared to the Diesel engine is worthy of note. Fig. 3 shows the typical carburetor holes, by which the starting time is considerably increased. In both engines the mean effective pressures were considerably lower than corresponding testing-stand values.

Maximum Pressures During Combustion

In order to obtain an idea of the maximum pressures prevailing during combustion, measurements on the engine were carried out with the truck traveling, and during the accelerating period with full fuel input by means of a maximum-pressure meter developed for the purpose and schematically illustrated in Fig. 4. Lever *a* is drawn by electromagnet *b* into contact with *c*. As soon as the pressure on piston *d* balances the attraction of electromagnet *b*, the contact pressure at *c* is relieved, and the indicating circuit is interrupted at this point. By means of a highly sensitive relay, the interruption is translated into the motion of a magnetic tracer, which thus records the interruption in graphic form. The attractive force of magnet *b*, which is located in a special circuit, is regulatable by rheostat *f*, and the pressures corresponding to the indications of ammeter *e* are denoted by marks.

A sample record is shown in Fig. 5. Of the graphs in this record, No. 1 shows the movement of the magnetic tracer caused by the circuit interruptions at *c*, No. 2 the record of the revolutions of an engine countershaft with rotating contacts, and No. 3 the registrations of a half-second contact clock.

The force of electromagnet *b* was increased until only occasional movements were made by tracer No. 1. The ammeter reading in the example under discussion gave a pressure of 30 atmospheres, which is attained and exceeded only at a few ignitions. By increasing the feed, the duration of the combustion pressures may also be exactly determined, although this question must be reserved for later investigation.

Fig. 6 is a record of maximum combustion and compression pressures measured at various full fuel inputs on Diesel engines in road operation, and in part also on the testing stand. With gasoline engines having a compression ratio of about 5.5 to 1, the pressures observed during acceleration, or in other words with wide-open throttle, were between 33 and 37 atmos. In one of the tests, made with an insufficiently knock-proof fuel, the pressure in the engine jumped to 43 atmos. with light knocking.

Road Acceleration Tests

Of the essential criteria of effective road performance, the following properties of engines were ascertained by road tests on suitable stretches:

1 The lowest running speed in high gear
2 The acceleration from the moment of giving fuel to the attainment of 90 per cent of the maximum running speed
3 Fuel consumption, as expressed by fuel input to the cylinders, during acceleration.

By the testing and measuring procedure adopted, each vehicle was started by shifting through the various speeds, and then accelerated from the lowest running speed in high gear by pushing down the fuel pedal to the limit. The recording instrument employed was the quadruple magnetic tracer. Of the four graphs shown in Fig. 7, No. 1 shows the road distance marks as registered by a hand-operated button, No. 2 the revolutions of an engine countershaft with rotating contacts, No. 3 the registrations of a half-second contact clock, and No. 4 the fuel marks as registered by a hand-operated button at the moment at which one of the consecutively arranged fuel vessels of a capacity of 15 cu. cm. (0.92 cu. in.), for heavy oil, and 25 cu. cm. (1.63 cu. in.), for gasoline, ran dry.

Comparison of the road marks with the revolution contact marks showed a clutch and wheel slippage, which was allowed for in determining the space-time curve, the velocity-time curve, and the time record of acceleration. As a rule each test was made twice, once going and once coming, in order to obtain a mean of the two runs and thereby to eliminate as much as possible the influences of grades and wind resistance.

The magnitude of the acceleration measured does not afford a direct comparison of the performance of the engine, unless piston displacement, vehicle masses, gear reductions, and wheel diameters are alike for the different engines and vehicles concerned. In addition, clutch and wheel slippage must also be considered, since these losses must be overcome by the engine with the same relative exertion as for acceleration. The mean effective pressure (p_b in kg. per sq. cm.) causing acceleration on the level road is obtained from the equation:

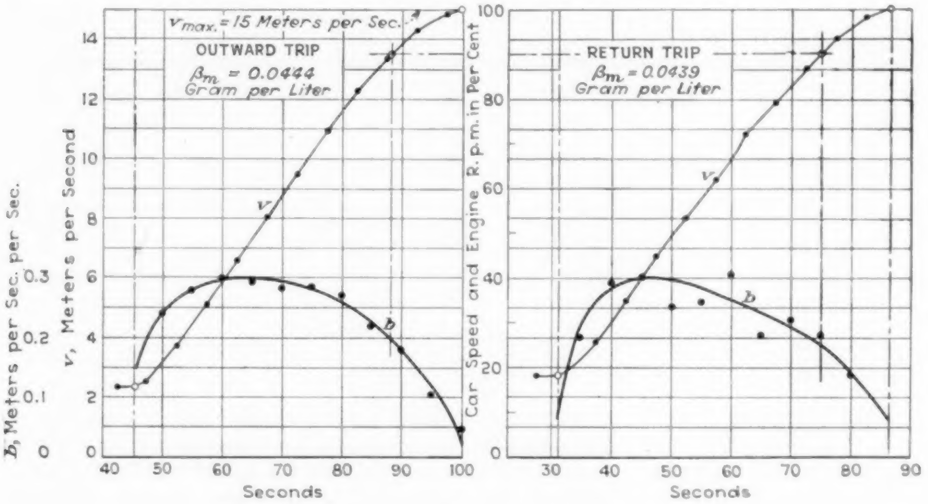

FIG. 8 CAR SPEED AND ACCELERATION IN HIGH GEAR

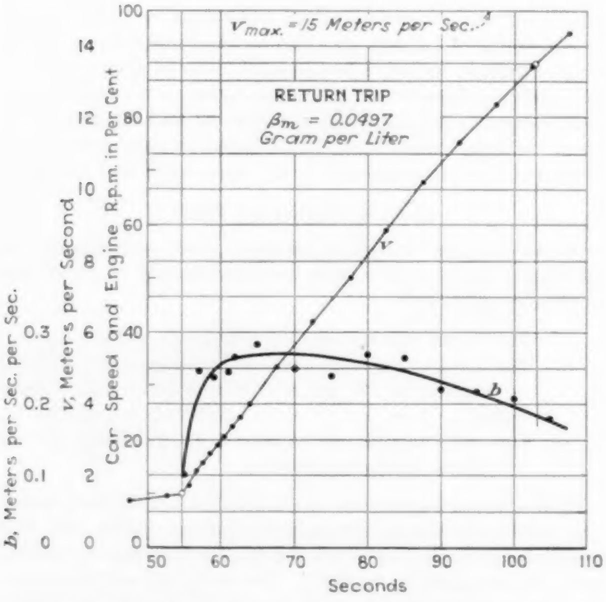

FIG. 9 CAR SPEED AND ACCELERATION IN HIGH GEAR

> Excess work of engine per revolution = work required for accelerating vehicle + wheel and clutch slippage work per revolution of engine

or:

$$10 \times p_b \times V_H \times i = m \times b \left(\frac{2R\sigma\pi}{\rho} + \frac{2R(1 - \sigma)\pi}{\rho} \right). [1]$$

where

V_H = displacement of engine in liters (1 liter = 61.02 cu. in.)

i = number of working strokes per cylinder and revolution (i = $^1/_2$ for four-cycle engines; i = 1 for two-cycle engines)

$10 \times p_b \times V_H \times i$ in kg-m. = excess work of engine per revolution

$\frac{2R\sigma\pi}{\rho}$ = distance traveled by vehicle during one revolution of engine

where

R = rolling radius in meters

ρ = driveshaft reduction figure

σ = wheel-clutch slippage

$2R\ (1 - \sigma)\pi$ = loss in travel due to wheel and clutch slippage

m = dynamic mass of vehicle —$G/g \times e$

where

g = acceleration due to gravity in m. per sec.^{2}

G = total weight in kg. of vehicle

e = number denoting rotating masses of engine and vehicle requiring acceleration in traveling

b = acceleration of vehicle in meters per sec.^{2}

From Equation [1] is found:

$$\frac{p_b}{b} = e\frac{G}{g} \times \frac{R\pi}{V_H \times \rho \times i \times 5}$$

If the value $\frac{e \times G \times R}{V_H \times \rho \times i}$ is designated by K = dynamic vehicle-engine constant, then:

$$p_b = 0.064 \times b \times K$$

The addition of the mean effective pressure p_r used for overcoming the gear friction, and rolling and air resistance on up and down grades, to p_b gives the mean effective pressure p_e of the engine during the period of acceleration:

$$p_e = p_b + p_r$$

p_r was determined by coasting tests on the various test stretches with the engine cut off, and therefore with a reduction allowed for in factor e corresponding to the elimination of the rotating engine masses. Since, in coasting, only small forces are transmitted through gears and wheels, and p_r is therefore bound to be somewhat smaller than when the full engine power is transmitted, p_e will be somewhat too small, although the error may be neglected, especially in a comparison of engines with each other.

From the equation:

> Work of engine per liter of piston displacement = fuel quantity per liter of displacement × calorific value × total efficiency

$$p_e \times 10 = \beta \times H \times \eta \times \frac{1}{A}$$

where

$p_e \times 10$ = liter work in kg-m.
$1/A = 427$ = equivalent of 1 calorie
β = fuel input in grams per liter
η (total) = total efficiency = $632/B \times H$
p_e = mean effective piston pressure in kg. per sq. cm.
H = calorific value of fuel in gram-calories
B = specific fuel consumption in grams per hp-hr.
632 = equivalent of 1 hp-hr.

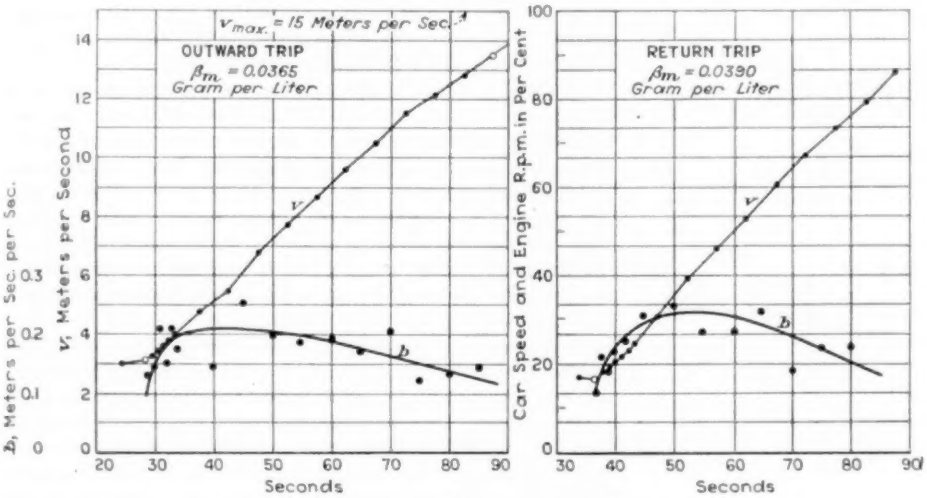

FIG. 10 CAR SPEED AND ACCELERATION IN HIGH GEAR

there follows:

$$\beta = \frac{P_e \times B}{27{,}000} \qquad \text{or} \qquad B = \frac{P_e}{\beta} \times 27{,}000$$

By this equation, the specific fuel consumption was calculated from the known mean effective pressure during acceleration and the fuel input as ascertained by measurement.

As examples Figs. 8 to 10 show the speed and the acceleration time logs of a Diesel-engine-driven truck at various fuel inputs and Fig. 11 of a gasoline-carburetor-engine-driven truck. The mean effective pressures resulting with the help of the dynamic vehicle-engine constant K are illustrated in Figs. 12 and 13. Fig. 14 presents the results of all tests performed in their relation to the average values of the mean effective pressures and the mean-specific-fuel-consumption figures as a function of the fuel input, the values of the mean effective pressures at specific-fuel-consumption figures at normal fuel input being emphasized for greater clearness by surrounding circles.

In order to obtain an idea of the average capacity of Diesel and gasoline engines in vehicle operation, the most important test results of the different engines are shown and the average values for Diesel and gasoline engines are given in Table 1.

As important from the point of view of vehicle operation, the following values were used in the comparison:

n_1 = lowest r.p.m. from which the car was accelerated in high gear in per cent of the maximum r.p.m. n_{max}
n_2 = lowest r.p.m. at which p_e = 5 kg. per sq. cm. was attained, in per cent of the maximum r.p.m. n_{max}
n_3 = lowest r.p.m. at which p_{em} was attained, in percentage of the maximum r.p.m. n_{max}
p_{em} = mean time value of mean effective pressures between n_1 and 0.9_{max} in kg. per sq. cm.
p_{emax} = maximum value of mean effective pressure between n_1 and 0.9 n_{max} in kg. per sq. cm.
β_m = mean value of fuel input in grams per liter for working-stroke volume during acceleration
B_m = mean value of specific fuel consumption in grams per hp-hr.

Fig. 15 presents the average comparative mean effective pressure as a function of the r.p.m. of Diesel and gasoline engines

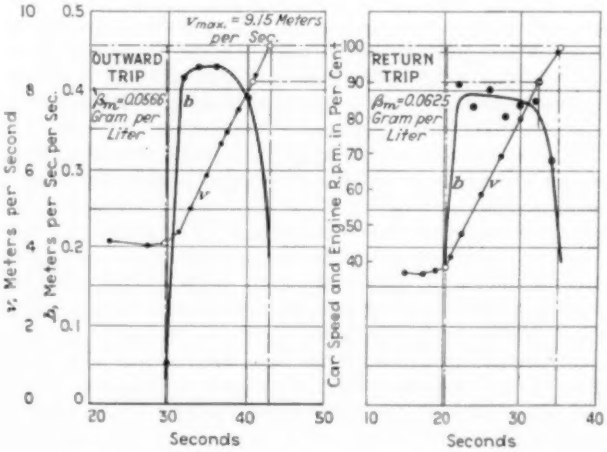

FIG. 11 CAR SPEED AND ACCELERATION IN HIGH GEAR

examined, the mean value of the maximum speed being 1475 r.p.m.

CONCLUSIONS

1 First of all it must be stated that, almost throughout, the maximum mean effective pressures occurring in the engines during acceleration of the vehicle were lower for a given fuel input than the values given in current literature and based on the results of testing-stand runs. This is true of Diesel engines, and possibly even to a greater extent of gasoline engines. The cause of this phenomenon cannot be fully explained by the fact

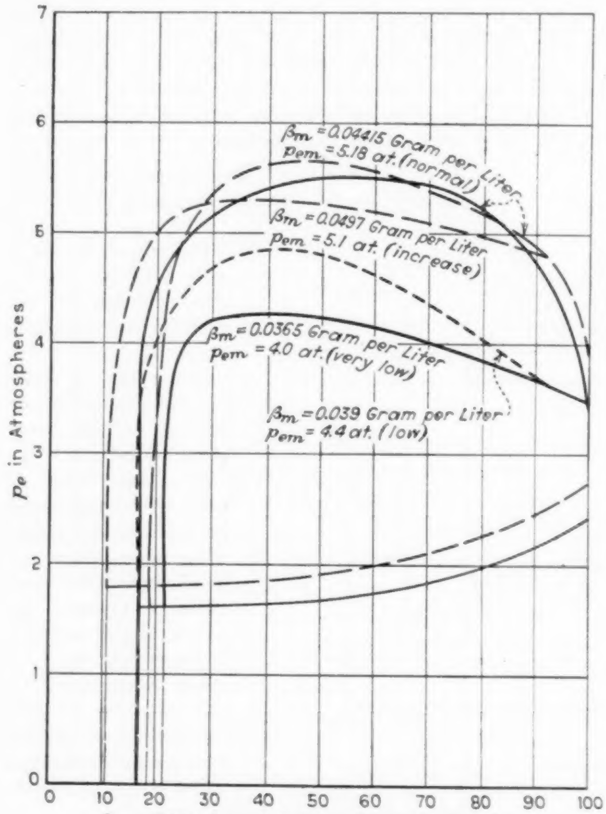

FIG. 12 MEAN EFFECTIVE PRESSURES DURING ACCELERATION

that, due to non-allowance for the losses previously referred to, the working piston pressures resulting from the present measurements on road performance are slightly lower. It would appear that engines on testing stands show a higher output at any given sustained speed than they do during operation in a vehicle, where they are subjected to rapid speed variations.

Test-stand results are of no value in judging the performance of engines in vehicles for which the fuel input is specially adjusted for each r.p.m. so as to cause the engine to be brought to the maximum output with invisible exhaust. For practical vehicle operation this would presuppose the presence of a device which would automatically adjust the ideal smokeless-fuel input for each engine speed. To the knowledge of the author such a device, which adapts the fuel input exactly to the momentary engine speed, has not up to the present been designed and introduced. It is therefore necessary to judge engine performance on the basis of the maximum fuel input giving invisible exhaust gases at the least favorable r.p.m.

2 *The maximum values of the mean effective pressures* ($p_{e\max}$) during acceleration of the vehicle are 10 per cent lower for Diesel engines than for gasoline engines, whereas *the mean values* (p_{em}) differ by only 5 per cent.

3 *The mean effective pressures at full engine speed,* therefore the excess outputs at full vehicle velocity, are the same for Diesel and gasoline engines of equal piston displacement, equal r.p.m., and equal running resistances of the vehicle.

4 Although *fuel input* is reduced by 27 per cent in Diesel over gasoline engines, the mean output of Diesel engines during the acceleration period is but 5 per cent less at full fuel input due to the thermodynamic superiority of the Diesel process. The ratio of the specific-fuel-consumption figures of Diesel and gasoline engines is as 1 to 1.27. These specific fuel consumptions which were measured during the acceleration period admit of no direct comparison of fuel consumption per 100 km. The showing is more favorable for Diesel engines, since at partial load the specific fuel consumption increases more rapidly in gasoline than in Diesel engines.

5 The strikingly quiet and slow-running characteristic of gasoline engines idling with the vehicle at rest are not in evidence with Diesel engines. On the other hand, Diesel engines attain their *stable starting torque at 21 per cent* of their maximum speed, whereas 27 per cent is required for gasoline engines, the average maximum speeds of the Diesel and gasoline engines compared being about equal—namely, about 1475 r.p.m.

6 The degree of "roughness" in the running of engines is independent of the *maximum combustion pressures.* At any rate, direct-injection engines, in spite of their higher maximum combustion pressures, do not show a greater degree of roughness than precombustion-chamber or auxiliary air-chamber engines. The cause of the rougher running of Diesel over gasoline engines may be due to the knocking properties of the gas oil, this knocking being noticeable in all known Diesel engines, though not being sufficiently marked to be heard over the vehicle noises during traveling.

In any attempt to judge the harmfulness of pressures, it is necessary to consider how and at what phase of the working process they originate. High pressures resulting from rapid though steady combustion at dead center cannot be rated as injurious. They do not cause any hard driving impacts, are controllable, and constitute an indispensable condition for minimum fuel consumption, low exhaust temperatures at full fuel input, and small cooling-water losses. These thermodynamically correct

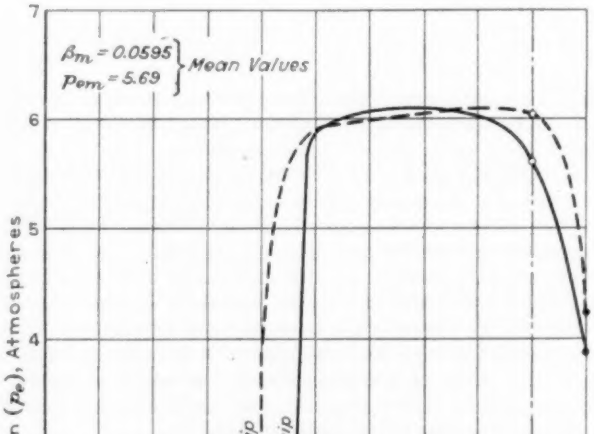

FIG. 13 MEAN EFFECTIVE PRESSURES DURING ACCELERATION

high combustion pressures might be designated as "cold high pressures," as distinguished from "hot high pressures" such as are caused by ignition through incandescence, premature ignition, or by detonation after dead center, and which are accompanied by a reduction of engine output at a given fuel input. The equivalent of the output reduction in this case becomes noticeable in an increase of the exhaust-gas or cooling-water temperature in a manner detrimental to the engine.

7 In Diesel engines the nearer approach of the average to the maximum values of the mean effective pressures, and above all the advantage, from the point of view of practical vehicle operation, of rapid attainment of the starting torque at low speeds, is not a question of the thermodynamic superiority of the Diesel principle, but of the fuel pump, which provides a sufficiently accurate fuel input to the various cylinders even at the lowest speeds.

In view of these facts, the question should be considered whether, in view of the present highly developed fuel pump, the carburetor is in any degree any longer justified. It is true that the carburetor has undoubtedly the great advantages of cheapness and practical freedom from wear. When it is considered, however, that in order to improve the running qualities of gasoline engines, especially in the low-speed range, it was found necessary generally to increase the piston displacement and simultaneously to throttle the suction, then it would seem that considerations of first cost must give way to the more important question of what is better from the point of view of vehicle operation. It seems improbable that carburetor engines will ever do any better in running at low speed under load than they are now doing. The possibilities of development opened up in this direction by the fuel pump, however, are by no means exhausted. Among these is the application of the Diesel principle to light-oil engines, which would render it possible to create a standard motor-truck engine perfect both from the thermodynamic and the automotive points of view.

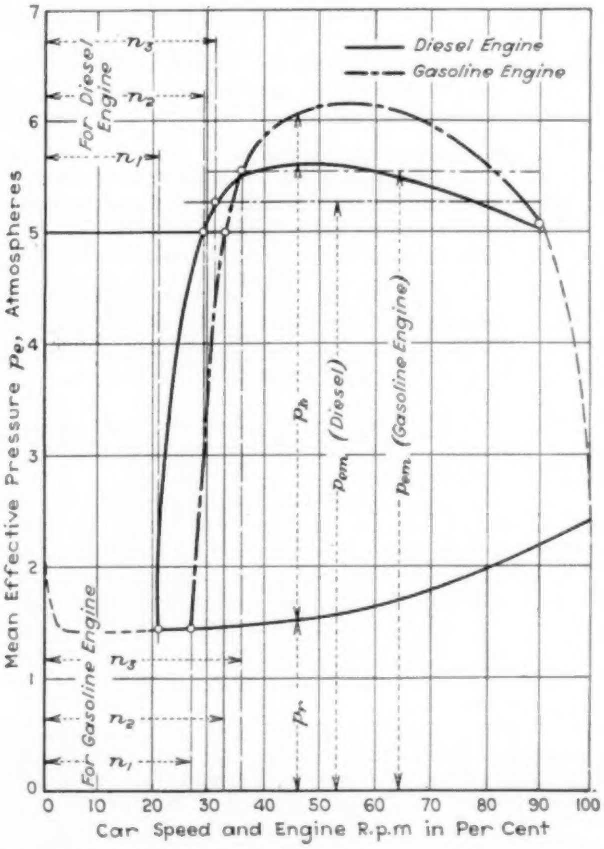

FIG. 15 AVERAGE VALUES OF MEAN EFFECTIVE PRESSURES DURING ACCELERATION

Discussion

A. A. LYMAN.[2] It is interesting to note that although Professor Langer has confined his experiments to accelerating periods, the results again demonstrate the superior fuel economy of Diesel engines and check fairly closely with general operating results with which the writer is familiar. These results cover the operation in actual service of several Diesel buses, and all show an increase in fuel mileage of 30 to 50 per cent over gasoline vehicles. This decrease in specific fuel consumption, together with the advantage of lower unit fuel costs, results in fuel savings of tremendous importance to fleet operators.

We thoroughly agree with Professor Langer's conclusions regarding the relative costs of carburetors and fuel pumps; that consideration of first cost must give way to the more important question of what is better from the point of view of vehicle operation. This difference in first cost is insignificant compared with the saving in truck and bus fuel costs resulting from the use of Diesel engines.

Our first Diesel truck engine was rather rough, but we have recently operated a Diesel bus engine that is reasonably smooth throughout the entire operating range, including idling. The slight roughness is unnoticed by the passengers and apparently does no harm. This roughness is greatly influenced by the characteristics of the fuel, and has been reduced to a negligible

[2] Automotive Engineer, Public Service Coordinated Transport, Newark, N. J.

amount by changes in the fuel that have not, however, increased its cost.

In comparing Diesel and gasoline engines, Professor Langer does not mention some of the practical advantages of Diesel automotive engines, such as:

- (*a*) Elimination of the fire hazard in vehicles as well as in the storage, handling, and transportation of the fuel
- (*b*) Appreciable reduction in road failures due to the elimination of the entire ignition system
- (*c*) Practical elimination of carbon monoxide.

These advantages, with the lower fuel costs, make the Diesel engine particularly attractive to truck and bus operators, and it is hoped that the development of light, high-speed, high-power automotive Diesel engines will be vigorously carried on.

HARTE COOKE.[3] There are a number of interesting things which this paper brings out and a number of things which would suggest further investigation.

In the first place, it should be remarked that while the comparative characteristics of the Diesel engine and the gasoline engine during the period of acceleration is an interesting phase of the use of the Diesel engine for this purpose, it does not give the full measure of the desirability of the Diesel engine for this service, for in general the operating cost of the two forms of motive power and the relative first cost of the truck so equipped would be the principal commercial factors as to which form would be the more desirable.

In connection with the method of obtaining the b.m.e.p. of the two types of engines during acceleration, it would seem that there must be some losses such as distortion of the rubber tires and the extra friction losses under the maximum loads imposed on the part doing the acceleration, which would account for the m.e.p. in actual service not coming up to what it would be on the test stand.

The difference in weight is always brought up between the Diesel engine and the gasoline engine, due to the higher pressure involved with the Diesel engine.

With modern designs the crankshaft in most cases has to be proportioned to keep the speeds at which torsional resonance occurs at a desired location, and the weight of the frame is governed usually by the ability of the foundry to cast the iron sections required, so that the lighter weights of the gasoline engines are undoubtedly due in most cases to the fact that they use an underslung crankshaft with oil pan instead of base and use a cylinder construction which permits very close center-to-center distance.

In fact, the records in the paper show maximum combustion pressures in the gasoline engines of from 550 to 630 lb., which are comparable with the pressures obtained in the Diesel engine.

Where the maximum possible acceleration is a very desirable feature, such as in local bus service, the characteristics of the different engines shown in Table 1 should be very carefully analyzed to see what the characteristics are that give some of these engines better acceleration than others.

In any case, the table shows that, as a whole, the Diesel-engine vehicles can operate in a stable manner at slower speeds than the gasoline-engine vehicles, which is a very desirable characteristic in traffic.

In regard to the roughness of the Diesel engine, it would seem that any undesirable roughness would be gradually overcome if the combustion characteristics of the engines and the fuels which they use are better understood, as it would seem to the writer that arrangements which will reduce the time lag of the ignition in the Diesel engine would make for smoother operation.

Fuel-Spray Formation

By DANA W. LEE,[1] LANGLEY FIELD, VA.

Experiments are described in which the diameters of the fuel drops in sprays from different types of nozzles were measured and the effects of fuel-injection pressure, nozzle dimensions, and the density of the chamber air on the atomization of the sprays were determined. A simple method of determining the size and form of the high-velocity parts of sprays is also described. High-speed spark photographs of fuel sprays are shown that were made with lens systems having magnifying powers of 0.5, 2.5, and 10. These photographs reveal the process by which the fuel is transformed from the solid jet to the atomized spray, and also show the effect of several factors on spray dispersion.

ONE of the most difficult problems encountered in the development of high-speed compression-ignition engines has been the proper atomization and distribution of the fuel in the combustion chamber during the extremely short time available. Rapid combustion of the fuel does not take place as soon as it enters the combustion chamber, but a certain time, known as the ignition lag, elapses during which the temperature of the fuel is raised to its auto-ignition point by the absorption of heat from the compressed air. The duration of this ignition lag and the time required for complete combustion will decrease with a decrease in the size of the fuel drops, because of the increase in the ratio of the surface area to the volume of the drops.

However, the problems of atomization and distribution are closely connected, changes in one frequently causing changes in the other. This fact should be kept in mind during an investigation of either of these characteristics, and if possible the two should be studied simultaneously.

In this paper there are presented some of the results of the experiments conducted during the past two years in the laboratory of the National Advisory Committee for Aeronautics on the atomization and distribution of the fuel in fuel sprays. More complete accounts of these experiments may be found in the first three publications listed at the end of this paper.

Spray-Atomization Experiments

The sizes of the drops in fuel sprays were determined by catching them on smoked-glass plates, and then measuring the impressions which they made in the lampblack surface. The apparatus consisted principally of a common-rail fuel-injection system so arranged that it produced only a single injection at a time, an automatic fuel-injection valve, an airtight cylindrical chamber 18 in. long and 6 in. in diameter, smoked-glass plates, and a microscope with camera attachment. The chamber was mounted horizontally, and smoked plates 5 by 18 in. were placed on a shelf below the center line of the chamber. The injection valve was inserted through one end of the chamber, so that the spray axis was parallel to and $2^{5}/_{16}$ in. above the smoked plate. The chamber was connected to a compressed-air reservoir, so that the density of the air into which the fuel was injected could be raised to values corresponding to those in the combustion chambers of engines at the time of fuel injection. The fuel used for these atomization experiments, and for all other experiments described in this paper, was a high-grade Diesel fuel having a specific gravity of 0.86, a viscosity of 38.5 Saybolt Universal sec, and a surface tension of 0.00016 lb per in. at atmospheric pressure and at a temperature of 73 F. The injection period and the effective injection pressure were determined for each experiment from photographically recorded lift-time curves of the valve stems, using the method described by Rothrock. (See reference 4.) After each injection, ample time was allowed for the smallest measurable drops to settle to the lampblack, after which the smoked plate was removed from the chamber and placed under the microscope. By using a strong side illumination, the lampblack was made to appear as a light-gray surface, while the holes made by the fuel drops were left black. (See Fig. 1.) It was found that a magnifying power of 50 easily showed the smallest impressions that the lampblack was capable of recording, its granular structure being of such a magnitude that no impressions less than about 0.00025 in. in diameter were discernible. After a careful examination of each smoked plate, photomicrographs were taken of a series of representative areas. From these photomicrographs the impressions were measured and classified into groups, the first group containing all discernible impressions less than 0.00075 in. in diameter, the next group all those between 0.00075 and 0.00125 in., etc. These groups will be referred to hereafter by their group mean diameters—0.0005 in., 0.0010 in., etc.

[1] Junior Mechanical Engineer, National Advisory Committee for Aeronautics. Mr. Lee was graduated from Cornell University in 1929 with degree of Mechanical Engineer, and has been with his present connection since that time.

Presented at the Fifth National Meeting of the Oil and Gas Power Division of The American Society of Mechanical Engineers, State College, Pa., June 8 to 11, 1932.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

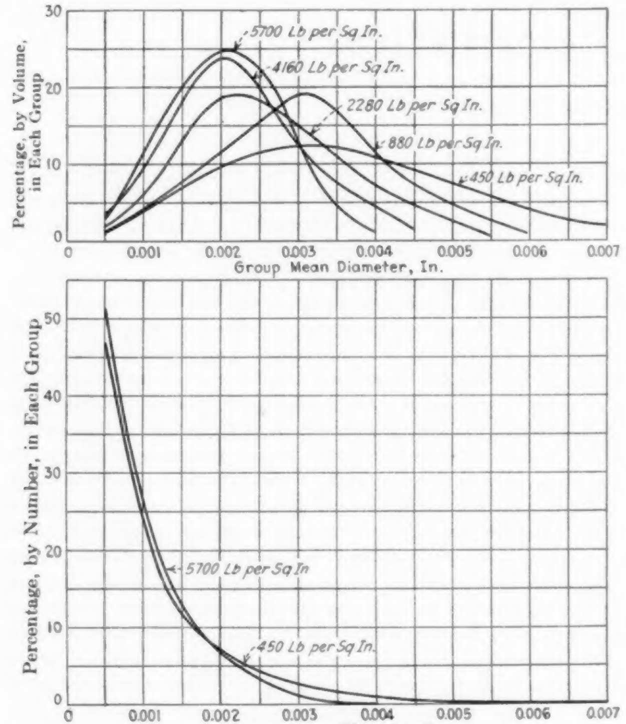

FIG. 2 EFFECT OF INJECTION PRESSURE ON SPRAY ATOMIZATION

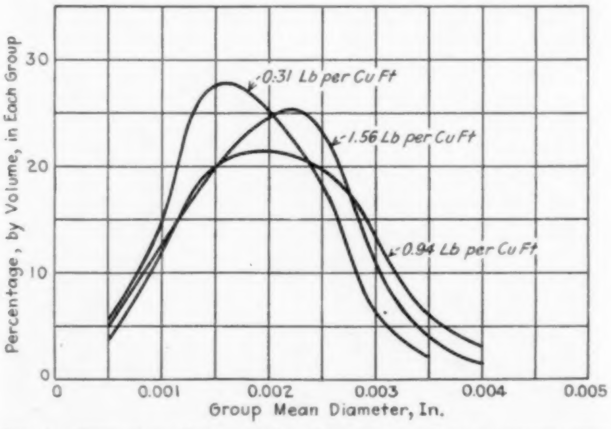

FIG. 3 EFFECT OF CHAMBER-AIR DENSITY ON SPRAY ATOMIZATION

The assumption that the impressions in the lampblack had the same diameter as the fuel drops that made them was checked by computing the weight of the fuel discharged (1) from the counted number of drop impressions and their diameters and (2) from the nozzle diameter, its coefficient of discharge, the effective injection pressure, and the injection period. The results of these computations are given in columns 10 and 11 of Table 1, which also gives the important test conditions and some of the test results. When it is considered that only about 0.1 per cent of the drop impressions was measured, the variation of about 50 per cent in the two computed weights seems surprisingly small.

The total number of drops in each spray was computed by multiplying the number of drops counted by the ratio of the area of the smoked plate to the area included in the photomicrographs. In column 12 of the table are given the arithmetical means of the drop diameters, and in column 13 are given the diameters obtained by taking the arithmetical mean of the drop volumes.

Curves plotted from the results of these atomization experiments are given in Figs. 2 to 5, and are of the type generally known as frequency curves. Group mean diameters were plotted against the percentage of the total number or total volume of the drops contained in that group. This method gave a series of independent points, rather than points on a curve, but faired curves were drawn through the points to make comparisons easier. Specific values can be obtained only at the group mean diameters. For example, at the group mean diameter 0.001 in. one may read: So many per cent of the total number (or volume) of the drops larger than 0.00025 in. in diameter were found to be between 0.00075 and 0.00125 in. in diameter.

The frequency curves of Fig. 2 show the effect of injection pressure on the atomization of fuel sprays. In the upper part of the figure the curves are based on the total volume of the fuel charge, and in the lower part they are based on the total number of drops in the spray. In the latter case the curves fall very close to each other, so that only the limiting cases were drawn, and in the following figures only the curves based on the volume of the fuel charge are shown.

Fig. 3 shows the results of the experiments made with different chamber-air densities, and Fig. 4 shows the effect of changing the nozzle diameter. In Fig. 5 the frequency curve for a centrifugal-type spray is compared with those for two sprays from plain nozzles. (Experiments Nos. 15, 3, and 13 of Table 1.)

Experiments made with a spray formed by two impinging fuel jets showed that its atomization was poorer than that of a plain spray under similar conditions, and a spray formed by a single fuel jet impinging on a metal lip was found to have the same fineness of atomization as a similarly produced plain spray. A series of tests was made using different nozzle length-diameter ratios, and the results showed no measurable differences in the atomizations.

When lip-nozzle, impinging-jet, centrifugal, and other types of high-dispersion sprays are injected into the atmosphere, they always appear to be more finely atomized than corresponding sprays from plain nozzles. However, these atomization experiments have shown that this is not the case and that spray atomization cannot be judged by visual observation.

Figs. 6 and 7 compare some of the results of the present experiments with those obtained by other investigators. The various experiments on the effect of injection pressure agree in general, although the range of drop diameters reported varies considerably. Sass found that an increase in the air density resulted in a finer atomization, whereas the N.A.C.A. experiments indicated that this factor had no effect. Wöltjen gives no data for the effect of air density, but states that his experiments showed that it had no effect on the atomization.

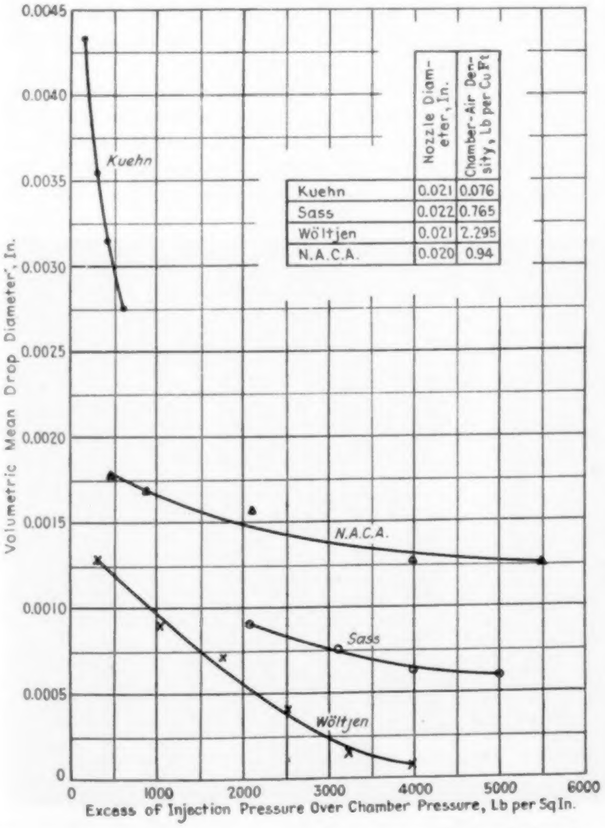

FIG. 6 COMPARISON OF RESULTS OF VARIOUS INVESTIGATORS ON EFFECT OF INJECTION PRESSURE ON VOLUMETRIC MEAN DROP DIAMETER

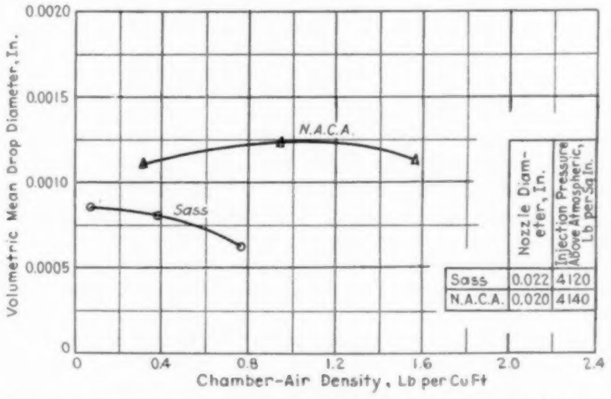

FIG. 7 COMPARISON OF RESULTS OF SASS AND THE N.A.C.A. ON EFFECT OF CHAMBER-AIR DENSITY ON VOLUMETRIC MEAN DROP DIAMETER

The results of the N.A.C.A. atomization experiments may be briefly summarized as follows:

1 Each spray is composed of several million fuel drops, whose diameters range from less than 0.00025 in. to 0.0050 in., and sometimes more. By far the greatest number of drops have diameters of 0.0010 in. or less, but those between 0.0015 in. and 0.0025 in. usually contain more than half the weight of the fuel charge.

2 Within the range of nozzle sizes and operating conditions commonly used, the variation in the mean drop diameter is small.

3 If the fuel-injection pressure is increased or the size of the discharge orifice decreased, there will be a decrease in the relative number of large drops, resulting in a more uniform atomization and a smaller mean drop size.

4 The density of the air into which the fuel is injected and the nozzle length-diameter ratio have little effect on the final sizes attained by the drops.

5 Impinging of a fuel jet against a metal surface close to the orifice results in no measurable change in the atomization.

6 Centrifugal-type sprays are less finely atomized than sprays from plain cylindrical nozzles produced at equal injection pressures.

EXPERIMENTS WITH PLASTICINE TARGETS

pieces of Plasticine, a proprietary substitute for modeling clay, mounted in the chamber that was used for the atomization experiments. Table 2 lists the diameters of the impressions made in the Plasticine targets when they were mounted at different distances from the nozzle. At a distance of 3.5 in. the impressions were very faint, and at 4 in. no impression could be seen. Two sets of targets were used, one set thick enough to completely stop the spray and the other consisting of thin slices backed by wire screening. Table 2 also lists the corresponding outside diameters of a spray produced under the same conditions, as measured from a spray photograph. The impressions in the thin targets indicate the diameter of the high-velocity core of fuel in the center of the spray, the rest of the spray being composed of fuel particles having a much lower velocity. The deepest impression made in the thick targets was 1 in., when the distance from the nozzle to the target was 0.25 in. The bottom of each impression was roughly conical in form. The deeper ones showed evidence of having been enlarged, as if by a tiny explosion, the diameters of the holes below the surface of the Plasticine being greater than at the surface. These experiments confirm the opinion that fuel sprays from cylindrical nozzles create strong blasts of air at the center of the spray, which enable some of the atomized particles to penetrate farther from the nozzle than they could in still air.

Plasticine targets were also used to determine what parts of other types of sprays had the greatest penetrating power. A centrifugal spray made a circular impression, in the center of which was a small hole similar to those made by plain nozzles, and a slit nozzle made an impression that looked like a pair of parentheses. The use of plastic targets in this manner should be useful in the development of new types of nozzles and injection systems, as it furnishes a cheap and ready means of measuring the relative penetrating power of different sprays or parts of the same spray.

TABLE 2 RESULTS OF PLASTICINE TARGET EXPERIMENTS

Distance from nozzle to target, in.	Diameter of impression at surface of target, in.		Outside diameter of spray from photograph, in.
	Thin target	Thick target	
0.25	0.04	0.08	0.25
1.0	0.08	0.20	0.50
2.0	0.14	0.25	0.75
2.5	0.18	0.20	0.94
3.0	0.16	0.12	1.10

NOTE: 0.020-in. plain nozzle; 4000-lb-per-sq-in. injection pressure; 1.1-lb-per-cu-ft air density; 0.005-sec injection period.

SPARK PHOTOGRAPHY

The study of the process of fuel-spray formation is being continued at the present time by means of spark photography, using the spark-producing circuit shown in Fig. 8. Closing the disk switch allows the small condenser *B* to discharge across the auxiliary spark gap *C*. The air in gap *C* being ionized, the main condenser *A* then discharges across both gap *C* and the illuminating gap *D*. The duration of the discharge across *D* has been estimated to be $^1/_{10,000,000}$ sec, which is from ten to a hundred times faster than the discharges that have been used with the original N.A.C.A. spark-photography equipment. An adjustable coupling connects the spark-timing shaft to the camshaft controlling the fuel injection, so that any stage of the injection may be photographed.

No attempt is made in the present paper to cover all of the work being done along these lines, but a few of the photographs are shown, accompanied by a brief explanation.

The photographs of Fig. 9 show the effect of the density of the chamber air on the formation of fuel sprays from plain cylindrical nozzles. They were made at one-half natural size and the illumination was from the side. When different nozzles were used to produce sprays in the evacuated chamber, it was found that the

spray dispersion varied greatly. In some cases, such as that shown in Fig. 9A, the sprays were nearly as well dispersed as those injected into the atmosphere, but in other cases the dispersion was very slight, even at high injection pressures. The differences are thought to be due to irregularities in the nozzles. In one case a nozzle which gave a well-dispersed spray was found to be very slightly rusted. After it was polished, the spray dispersion was much less.

Photographs like those in Fig. 9 give the general outline of the spray and much other useful information, but they do not show the structure of the spray core nor teach much about the atomization process. When higher magnification powers were tried, it was found necessary to photograph the sprays in silhouette. Such photographs reveal the structure of the core, but do not show the fine cloud of spray that surrounds it. This fact should be remembered when examining the photomicrographs of the fuel sprays.

In Fig. 10 is shown a series of spray photographs made at $2^1/_2$ times natural size. The chamber air was at atmospheric conditions in each case. Fig. 10A shows the early part of a spray from an 0.008-in. cylindrical nozzle, and Fig. 10B shows a later stage of another spray made under the same conditions. Notice that the first part of the fuel discharged was more widely dispersed than that which followed. It seems likely that the more widely dispersed fuel was that which had remained in the space between the stem seat and the orifice since the previous injection. This difference in dispersion was even more pronounced in the evacuated chamber, but in air at densities greater than atmospheric it was hardly noticeable. Fig. 10C shows a spray from a 0.020-in. nozzle, the photograph being taken during the latter part of the injection period. Fig. 10D shows a stream of fuel flowing from a 0.020-in. nozzle at a very low velocity. This photograph is included to illustrate how a column of fuel is broken into different-sized drops by its surface tension.

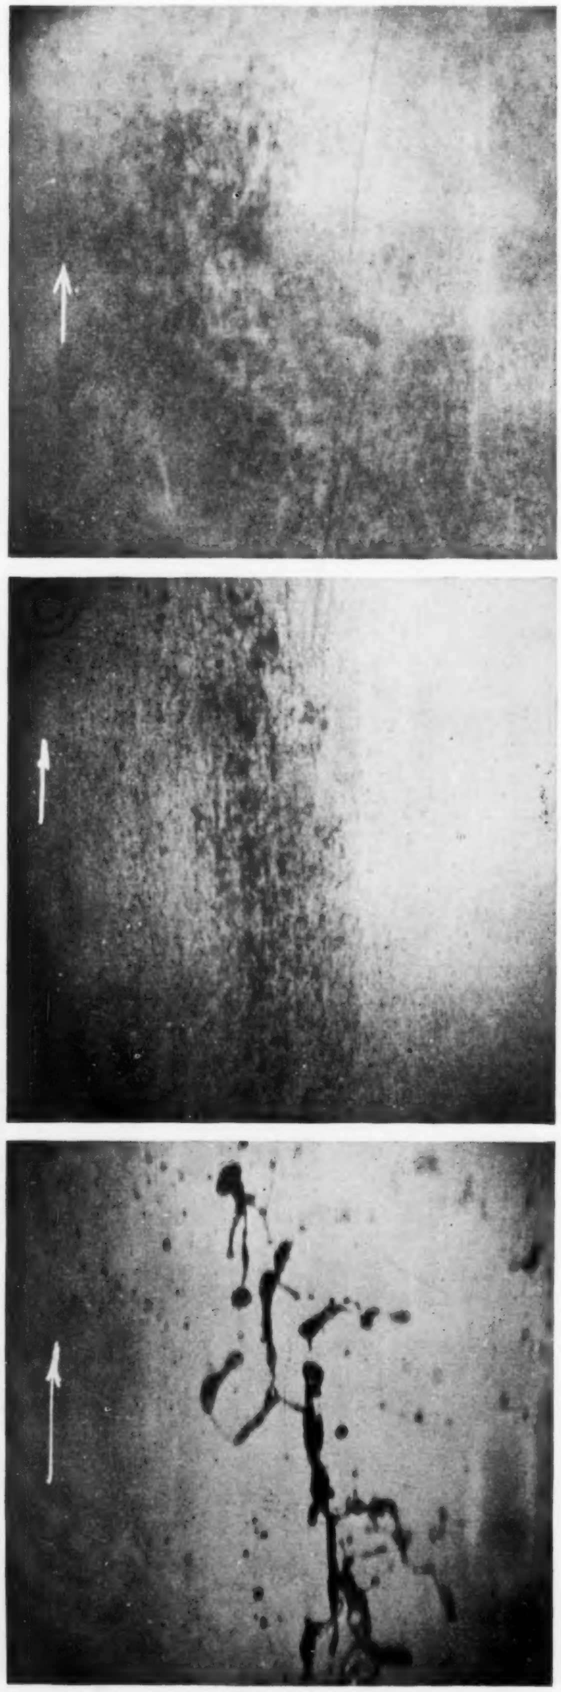

FIG. 14 PHOTOMICROGRAPHS SHOWING EFFECT OF AIR DENSITY ON FUEL SPRAYS ×10

(Nozzle diameter, 0.008 in. Injection pressure, 1000 lb per sq in. Distance from nozzle, 3 in. Air density: *A*, 0.0003 lb per cu ft; *B*, 0.076 lb per cu ft; *C*, 1.01 lb per cu ft.)

Photomicrographs of fuel sprays made at a magnifying power of 10 are shown in Figs. 11 to 14. The direction of the spray is indicated in each case by an arrow. Many of the photomicrographs are strikingly similar to the photographs made by Scheubel of fuel being atomized in a model carburetor, and indicate that the atomization processes in carburetors and in Diesel sprays are very similar, if not identical. This similarity was foreseen by R. A. Castleman, Jr., who has advanced an explanation of air-stream atomization based on the friction between the fuel and air. He says: "A portion of the large mass is caught up (say, at a point where its surface is ruffled) by the air stream and, being anchored at the other end, is drawn out into a fine ligament. This ligament is quickly cut off by the rapid growth of a dent in its surface, and the detached mass, being quite small, is swiftly drawn up into a spherical drop." All of the stages described by Castlemen may be found in the photomicrographs of Fig. 11. The ligaments are largest, and their breakdown slowest, at low fuel-jet velocities, large nozzle diameters, and low air densities.

The photomicrographs of Fig. 12 were made with different injection pressures to show the effect of fuel velocity on the disruption of the jet. In Fig. 13 the photomicrophographs show how a jet appeared at different distances from the nozzle. These two figures indicate that spray dispersion becomes greater and the size of the fuel particles becomes smaller as the injection pressure is increased or as the distance from the nozzle is increased.

In Fig. 14 a series of photomicrographs is shown for which the only variable is the density of the chamber air. They indicate that, at a given distance from the nozzle, the atomization and dispersion improve with an increase in the air density.

The atomization tests reported earlier in this paper showed that a change in the air density had no decided effect on the atomization, whereas the experiments of Sass showed that an increase in the air density resulted in a finer atomization. The photomicrographs of Figs. 13 and 14 offer a possible explanation of these different results. They indicate that the atomizing process begins as soon as the fuel leaves the nozzle and continues until the friction between the fuel and the air can no longer produce ligaments. Although at equal distances from the nozzle the atomization seems to vary as the density of the air, the total penetration of the sprays will also be dependent on the air density, so that the final atomization may be the same for all densities. Sass caught the fuel particles after they had traveled only about 8 in., and it may be that the atomizing process had not been completed at that distance, especially at the lower air densities. In the N.A.C.A. experiments, it is known that the fuel particles had lost all of their velocity relative to the air before they were caught on the lampblack.

Discussion

R. A. Castleman, Jr.[2] It has been noted by several investigators that at a small fraction of atmospheric density a jet appears to the unaided eye about the same as at atmospheric; and this has been taken to mean that the atomization is about the same in the two cases. Fig. 14 of the paper seems to advance definite evidence of the incorrectness of this deduction; for this shows that the "atomization" at about 1/250 of atmospheric is noticeably coarser than at atmospheric.

Fig. 14 seems also to throw further light on the mechanism of atomization, and to favor the ligament theory. In the first picture, the influence of air friction being almost entirely removed, the only forces left to act seem to be those due to turbulence in the jet or the tension of its bounding surface, and the result is a rather coarse disintegration. The large drops that result can be further subdivided to form the spray only when the air friction is given a chance to cause ligaments to be formed, by raising the air density to an appreciable value, as in the next picture.

The explanation that the author offers, in the last paragraph of his paper, of the discrepancy between his results and those of Sass seems quite plausible, but it should be pointed out that it is not the only possible one. Indeed, another seems equally probable (perhaps the true explanation is a combination of this and the effect pointed out by the author). Fig. 14 indicates that increase of air density from a small fraction of an atmosphere to atmospheric (pictures *A* and *B*) causes a much greater decrease in drop size per atmosphere than further increase from 1 to 13 atmospheres (pictures *C* and *D*). Both Lee and Sass made their measurements at super-atmospheric pressure, Sass ranging from 1 to 10 atm. and Lee from about 4 to 20 atm. It seems quite possible that, methods of measurement and of presenting results not being entirely comparable in the two cases, the effect might show up better in Sass' work, which seems more direct.

An analogous result was found in the case of the air-stream atomization of alcohol by F. N. Scheubel (reference 10, pictures I_6, I_5, and I_4), who found that doubling the air velocity from a comparatively low value produced a noticeable decrease in drop size, but that again doubling it resulted in little further change.

Professor Schweitzer, before the meeting, pointed out that, in a case where there is streamline flow in the orifice and therefore a parabolic velocity distribution with zero flow at the wall, it would be some distance beyond the orifice before the relative velocity at the edge of the jet would build up to a value high enough for atomization; and therefore that in such cases internal nozzle design might affect atomization. If, however, there is turbulent flow in the orifice, the mean velocity persists very close to the wall, and although the thin wall layer of zero velocity would in this case also be left behind in the orifice, the relative velocity at the edge of the jet would soon approach that given by Bernoulli's law and the coefficient of velocity. This is probably true, and pure streamline flow in the orifice should be avoided; which does not seem to be at all difficult with plain round-hole orifices of the sizes usually employed, at injection pressures customary in practice.

That such exceptional conditions can be imagined seems no argument against the general validity of the author's results. Rather this circumstance furnishes an illustration of a fact to which the writer has called attention in an N.A.C.A. report, entitled "The Mechanism of Atomization Accompanying Solid Injection," now in press. While the mechanism of air-stream atomization and of solid injection appear identical physically, in the case of solid injection it seems to be more difficult so to arrange matters that the surface of the liquid is continually exposed to an air stream of relative velocity high enough for atomization; and that therefore, under apparently similar circumstances, air-stream atomization may be expected to produce a more uniformly fine spray. By this it is not intended to imply any general preference for air-stream atomization. Circumstances (penetration, thermodynamic, and structural considerations, etc.) must determine the preferential form in each case. The two processes form useful complements.

To Professor DeJuhasz belongs the credit for first pointing out that air-stream atomization and solid injection do not necessarily yield identical results in all cases.

It may be well to briefly summarize the status of solid injection:

In 1910 James McKechnie, seeking a useful substitute for the bulky and heavy air compressor necessary in Diesel's old form of high-pressure air injection, found that a liquid could be atomized by injecting it under high pressure into comparatively still air. This invention, however, was largely undeveloped until comparatively recently, when it was found to be quite useful in the development of the high-speed compression-ignition engine.

Early in 1930 the writer suggested in *The Physical Review*, on the basis of the very brief life periods of ligaments fine enough to break up into the drops observed in atomized sprays, that the mechanism of both air-stream atomization and solid injection could be explained by the formation and collapse of fine ligaments at the liquid's surface; and in an article in *The Journal of Research* of the Bureau of Standards about a year later, he amplified this theory and pointed out a probable means of ligament formation, due to the relative motion of gas and liquid. Dr. Scheubel, of the Aachen Technische Hochschule, published (the author's reference 10) some spark photographs that he had obtained in a model of a carburetor throat, which verified the ligament theory for air-stream atomization. While he offered no explanation, his pictures fitted the ligament theory so well that he allowed the writer to reproduce some of them in his second paper (reference 11).

Dr. Sass (reference 6) reported results of drop-size measurements which could be interpreted in a manner to throw light on the mechanism of solid injection, but he also gave no interpretation. Early in 1931 Dr. Haenlein, of the Dresden Technische Hochschule, published (reference 12—English translation in N.A.C.A. Tech. Mem. No. 659) work on the influence of air friction on the disintegration of liquid jets, which he indicated would lead to atomization at high relative air speed; and soon after this Professor DeJuhasz advanced experimental evidence which he claimed to disprove the predominating influence of surface forces, and Professor Schweitzer has shown how certain conditions of flow in the orifice may delay the action of surface forces. Mr. Heldt favors the influence of turbulence in the nozzle. The writer has discussed the works of Sass, Haenlein, DeJuhasz, and the N.A.C.A., and the turbulence and ligament theories, in the N.A.C.A. report mentioned; but the author presents more direct evidence that the small drops are formed only by the formation and collapse of fine ligaments.

He is to be commended on having done a very important and difficult piece of experimental work so well.

R. A. Castleman, Jr.[3] The first picture in Fig. 11 seems to advance definite evidence against two theories: (1) Haenlein, of the Dresden Technische Hochschule, observed that a liquid jet became wavy under the influence of relative air motion, and since this waviness increased with the relative air motion, he indicated that the result of sufficiently high relative motion would be the complete disintegration of the jet into fine particles, or its "atomization." However, the author also finds waviness, but that the small drops are detached from the large drops only by means of the formation and collapse of ligaments. (2) It was pointed out by A. L. Bird, of Cambridge University, that the flow in a small orifice is intermediate between the streamline and the turbulent condition. This has been taken by some to mean that the liquid suddenly becomes turbulent when it issues from the orifice, and therefore "blows up." The author shows that this is not the case; for this would occur immediately beyond the orifice, while the author finds atomization as much as 4 in. from the orifice.

Edward Adams Richardson.[4] Colonel Allen remarked upon the necessity for considering the various factors that control combustion, a point emphasized in the writer's paper, "Heating Fuels for Injection Engines." In this connection it might be well to suggest how such an analysis applies in the particular case of the Oberhaensli engine described by Neumann in an earlier paper.

Turbulence has two purposes in an engine; the securing of better atomization or the securing of better mixing. K. O. Keller, of the Doxford Engine Company, presented a paper, "Combustion and Its Difficulties in Marine Oil Engines," before the North-East Coast Institution of Engineers and Shipbuilders at Newcastle-on-Tyne, December 7, 1928. In this paper it was shown that one complete passage of the air through the oil jets was sufficient for mixing purposes and more was undesirable. Dr. R. A. Castleman, Jr. (Res. Paper No. 281, Bur. Stand. Jour. Research, March, 1931) and F. N. Scheubel (referred to by Castleman) have shown that about the maximum practicable degree of atomization is obtained at relative velocities of fuel and air of 350 ft per sec. It is important to separate these two functions in studying combustion.

In the Oberhaensli engine, we find air velocities, according to the air-flow diagrams, of nearly 400 ft per sec, more than sufficient for a high degree of atomization. It is interesting to note that the fuel is fed at low pressure, so advantage is taken of the turbulence to reduce fuel pressures. As regards mixing, we find that the air may be expected to pass at least 10 times through the fuel jet during combustion. This is much more than is necessary.

Mr. Kuttner has seen fit to emphasize the advantages of turbulence in the Oberhaensli engine. In order to avoid possible misunderstanding, it seems well to carry the analysis further.

It must be remembered, as has been shown in the writer's paper, that excessive turbulence, from the standpoint of mixing, is undesirable. Hence, 10 times as much turbulence as is necessary cannot be regarded as a particular recommendation for an engine.

Mr. Kuttner has stated that since there is ample turbulence at high speed, the turbulence (which he assumes to have a constant angular rate irrespective of the speed of the engine) should be sufficient at any lower speed. Now it is closely true that the degree of turbulence is proportional to the engine speed. If this were not so, we should have much more trouble than we do securing combustion in any sort of high-speed engine. Hence the excessive turbulence must continue to all lower practicable speeds, remaining roughly 10 times too great.

It must be remembered that heat losses by convection vary roughly as the 0.8th power of the linear velocity. Hence, with turbulence 10 times too great for mixing, we tend to have a heat loss nearly 7 times that necessary. It would be better, we might say, to increase the fuel pressure for atomization purposes and reduce the turbulence very materially to that just sufficient for mixing purposes.

Of course, in this particular engine, the heat losses have been minimized by a particular form of construction in which the combustion chamber walls are in poor thermal contact with the rest of the engine; hence the temperature drop is lower than normal, thereby offsetting the losses due to increased turbulence. It is most important in studying this engine, or any other for that matter, to consider the question of turbulence versus heat loss. Excessive turbulence, as in this case, has forced the adoption of a detached or divided heat-storing combustion chamber. We must not attach too much importance to surface-volume ratio, the effect of which is relatively moderate, when we are taking special pains to increase fluid velocities over those surfaces. For small engines, it is not turbulence but rather the reduction of turbulence that should receive attention. Higher fuel pressures to insure proper atomization, and the limitation of turbulence to that just sufficient to pass the air once through the jets, would appear to be a proper approach to the problem. The so-called advantages of subdivided combustion chambers would be much less apparent, provided both engines were designed for the same degree, and a very moderate one, of turbulence. Surface-volume ratio, though of some importance, would then make a less imposing case. Even in this engine it is very difficult to maintain suitable ignition conditions for any appreciable time under light load, judging by the curves for surface temperature of the combustion chamber. Of course the surface-volume ratio has been accentuated by the form of construction.

Following Colonel Allen's suggestion to consider the various factors involved in combustion, we find that there is much that we can learn concerning the mode of action of a given engine and the significance of the various features of design. What is more to the point, the step-by-step method of analyzing the factors is a relatively simple procedure. If we were to take slightly more trouble in the analysis and estimate more quantitatively the various quantities involved, we should have a much clearer picture. The writer has emphasized in his paper the necessity of sticking close to basic principles in our studies.

H. K. Cummings.[5] The experimental work at Langley Field on the physical structure of oil sprays is an important contribution to our knowledge on this subject, and the author's technical report on the atomization and distribution of fuel sprays (reference 1) will be awaited with much interest.

A translation of Haenlein's dissertation (reference 12), issued by the N.A.C.A. as Technical Memorandum No. 659, includes shadow pictures of the disintegration of a gas-oil jet which resemble the spray photographs shown in Fig. 10. As the author points out, the microphotographs in Figs. 11 to 14 support the ligament-formation theory advanced by Castleman (reference 11) as explaining both air-stream atomization and the atomization accompanying solid injection. A paper by Dr. Castleman on "The Mechanism of Atomization Accompanying Solid Injection" is to be issued by the N.A.C.A. as Technical Report No. 440.

P. H. Schweitzer.[6] The writer is interested in the paper because we have been doing work along similar lines attacking the same problems by different methods. The author's results largely check with ours.

[6] Associate Professor, Pennsylvania State College, State College, Pa.

Regarding atomization, the lampblack receiver no doubt gives comparative information on the effect of various factors. In our atomization experiments, Lieutenant Thew, U. S. Navy, used a liquid receiving medium (Queol), and he found, as did the author, that the air pressure and the orifice diameter above 0.015 in. have little effect on atomization, which depends mostly on the oil pressure and viscosity. But as to the absolute magnitudes we are not convinced that the lampblack method does give correct droplet sizes, not because the diameters would suffer appreciable distortion, but because the small drops cannot be identified. The smallest drops that the author counted were taken as having 0.0005 in. diameter. We have used 200 magnification on the liquid samples, and our results were between Sass' and Woeltjen's. We found that in every case over 50 per cent of the droplets were smaller than 5 microns (0.0002 in. in diameter) and usually more than 30 per cent smaller than 2.5 micron (0.0001 in. in diameter).

It is feared that with the lampblack method these small globules are ignored. The error incurred certainly would not show up in the weight balance, as can be seen from the following example: In Experiment No. 5, 16,800,000 globules were determined as having a mean size of 0.00127 in. in diameter. If an equal number of globules (16,800,000) were present having a diameter of 3.75 micron, the difference in total weight would have been only about one-tenth of 1 per cent, which of course cannot be detected. But regarding the weight checking, one would like to know why the weight of the deposited oil drops was calculated, which involves some uncertainty, instead of determining the deposits on the lampblack by weighing.

The use of Plasticine for determining spray penetration is ingenious and commendable. Manufacturers should make use of this practical method for comparing sprays as to penetration. By the electrical balance method the writer has found that the jet velocity increases considerably from zero to about 0.4 in. distance from the nozzle and then it begins to drop. It is wondered if the Plasticine experiments gave any similar results.

The microphotographs of the oil sprays are extremely interesting. Fig. 14 shows, what we also found, that atomization and dispersion do take place even in vacuum; therefore the air friction cannot be the sole cause of disintegration. Our explanation of jet disintegration is described in Bulletin No. 40 of the Engineering Experiment Station, which has just been published.

Author's Closure

It is interesting to notice that two of the discussors refer to the photomicrograph of a spray in a vacuum, shown in Fig. 14. Dr. Castleman believes that it supports his ligament theory, and Professor Schweitzer cites it to show that air friction is not the sole cause of jet disintegration. The many additional photomicrographs of sprays in a vacuum and in air that have been taken since this paper was presented show that both of these views are correct. In a vacuum, the disintegration of the jet and the dispersion of the fuel particles depends on the Reynolds number for the fuel flow and on the nozzle characteristics. If the flow is turbulent, the jet spreads out into thin sheets, which later split into parts and the parts are drawn up into large drops by the force of surface tension. If the flow is non-turbulent, the jet remains as a smooth, round column for at least 3 in., even though the injection velocity be as high as 550 fps. In no case were the drop sizes small enough in vacuum to warrant consideration of fuel turbulence as a primary factor in the atomization process. When the density of the air is atmospheric or greater, the effect of turbulence is dwarfed in comparison with that of air friction. The jet is torn by the air into smaller and smaller irregular particles, and the final atomization is accomplished by ligament formation and collapse. The results of the experiments made since the presentation of this paper will be included in an N.A.C.A. technical report now being prepared.

The discussion by Mr. Richardson does not seem to be very closely connected with fuel-spray formation. The author believes that Mr. Kuttner is in a better position than he to defend the advantages of air turbulence in the Oberhaensli engine.

As Professor Schweitzer points out, the lampblack receiver method ignores all drops less than about 0.00025 in. in diameter. On the other hand, when a fuel spray is caught by a liquid receiver while it is still traveling at high velocity, as was done by Lieutenant Thew, there is probably some further atomizing action in the receiver, the extent of which may be much greater than would have taken place in air. The decision to use the lampblack was made only after a consideration of both methods, with some preliminary experimentation with each.

To check the discharge weight by weighing the plates would have been very difficult. The weight of the fuel was a very small part of the total weight, and large corrections for fuel evaporation and for absorption of moisture from the air would have been necessary. The accuracy of the calculated fuel weights was checked by catching 10 similar injections in a cup and weighing. The two values usually differed by less than 10 per cent.

No Plasticine records were made at close intervals near the nozzle, so that the changes in spray velocity found by Professor Schweitzer could not have been observed.

OGP-54-5

A Proposed Speed Characteristic for Oil Engines

By V. L. Maleev,[1] Stillwater, Okla.

The author proposes a method of readily classifying oil engines as low, medium, high, or super-high speed, by means of a "speed characteristic" equal to the square of the revolutions per second multiplied by twice the stroke in feet. To show that it provides a consistent and practical means of classifying engines, he applies it to the data of some 84 modern engines covering a wide range of sizes, speeds, and powers.

WITH the advent of high-speed oil engines it seems timely to ask where to draw the dividing line between low and high speeds. In searching for a proper yardstick, the best name for which seems to be "speed characteristic," let us briefly enumerate the respects in which an increase in rotative speed influences the behavior and hence the design and construction of an oil engine.

The principal results of an increase in rotative speed are: (1) an increased number of reversals of the reciprocating parts; (2) shortened periods for the different cycle events, such as intake of the air charge, exhaust, and particularly the injection of fuel oil; (3) an increase in the acceleration imparted to reciprocating parts; (4) the reaction of these increased inertia forces upon the rotating parts; (5) increased noisiness as a result of increased inertia forces and velocities; (6) increased danger from torsional vibrations and critical speeds; (7) increased peripheral speeds (bearings, gears, chain drives); (8) increased linear speeds of reciprocating wearing surfaces; (9) increased piston displacement per time unit, hence increased gas velocities through the intake- and exhaust-valve openings.

There are two characteristics by which engines are commonly classified in respect to speed: the rotative speed, expressed in revolutions per minute, and the so-called piston speed, in feet per minute. However, it is easy to show that neither of these characteristics can be used satisfactorily for that purpose.

Undoubtedly, the rotative speed is a very important factor influencing the majority of the results enumerated; however, it has little connection with results (8) and (9). Without going into any computations, it is easy to see that an engine of 10 hp. per cylinder of $4^{1}/_{2}$ in. bore and 6 in. stroke and running at 1000 r.p.m. presents a less difficult problem and is less of a high-speed engine than an 80-hp. engine of $8^{1}/_{4}$ in. bore and 12 in. stroke, running at the same speed of 1000 r.p.m., and that an engine builder would encounter insurmountable difficulties, at least at present, if he attempted to build an engine of 650 hp. per cylinder of 18 in. bore and 24 in. stroke, running also 1000 r.p.m. These examples show that the size of an engine must be taken in consideration when speaking of its speed.

Let us see now whether the average piston speed, usually designated by c, may not be better suited for use as a speed characteristic. Its expression

$$c = \frac{ns}{6} \qquad [1]$$

where n is the rotative speed in r.p.m. and s the length of the stroke in inches, shows that piston speed is directly proportional to s, which in turn, other things being equal, is proportional to the size or power of an engine.

Again let us compare three engines, this time with the same piston speed (e.g., 1000 ft. per min.): the aforementioned engine, $4^{1}/_{2}$ in. × 6 in. × 1000 r.p.m., a 220-hp.-per-cylinder engine, 17 in. × 23 in. × 260 r.p.m., and a 450-hp.-per-cylinder engine, 32 in. × 60 in. × 100 r.p.m. It is evident that these three engines cannot be put in the same class in respect to speed. They behave differently in regard to results (1)–(7) previously enumerated. In spite of equal piston speeds these engines belong to three different classes: the 10-hp.-per-cylinder at 1000 r.p.m. is a high-speed, the 220-hp.-per-cylinder at 260 r.p.m. a medium-speed, and the 450-hp. at 100 r.p.m. is decidedly a low-speed engine.

Thus it is evident that the piston speed c is not suitable as a speed characteristic, although it contains the two necessary basic features—the primary speed factor n and the influence of engine size s. The trouble is that multiplying n by s, formula [1], practically obliterates the influence of n. A simple means of restoring the proper influence of n and retaining the influence of s is to take the speed characteristic in the form of a product of c and n. Large numbers with many digits not being suitable as characteristics, it is better to use revolutions per second instead of revolutions per minute. Designating this speed characteristic by c_s and using for c its expression [1], we obtain

$$c_s = \frac{n^2 s}{21{,}600} \qquad [2]$$

The factor $n/60$ of [2] being revolutions per second and $2s/12$ being feet, the expression for c_s becomes feet per second per second, which is that of acceleration and very appropriate for a

speed characteristic. Another argument in favor of [2] as a speed characteristic is the fact that the factor limiting the speed of a reciprocating engine is the so-called inertia loads which vary directly as the square of rotative speed and as the first power of engine stroke, or exactly according to formula [2].

For the sake of convenience in practical use, [2] can also be presented in the form

$$c_s = \frac{nc}{3600} \qquad [3]$$

which saves one slide-rule operation if *c* is already known.

It may be also useful to consider why the other dimension determining the size of an engine, namely, the cylinder bore *d*, has no direct relation to the speed characteristic. Although with an increase of *d* the weights of the reciprocating parts and the inertia forces increase, and in the same proportion, the dimensions of the parts subjected to these forces also are increased in a correct engine design, so that the stresses and unit pressures remain the same and are independent of *d*.

After having established tentatively a method of computing a speed characteristic, the next step is to determine the limits between which an engine should be classified as a low- or high-speed one, and to prove from a sufficient number of examples that the speed characteristic and scale of limits selected are correct and sound from all viewpoints.

The standard practice in classification where a certain feature or characteristic changes gradually from a low to a high value is to insert a medium group between the two main groups and additional groups with a prefix "extra" or "super" for values outside the main groups. A classification of engines selected with these points in view and the corresponding speed characteristics are given in Table 1. The speed-characteristic limits were determined by computing the characteristics c_s from expression [2] for a large number of actual oil engines and taking in consideration their behavior in regard to the nine effects of speed increase outlined at the beginning of the paper.

Obviously the dividing lines between the speed-characteristic limits for the different groups are more or less arbitrary. On the other hand, there must exist a certain regularity between these figures. The best results were obtained with an increase of the characteristic limits in a geometrical progression with the ratio 3, which, with a slight rounding off of the figures, gave the values in the third column of Table 1.

TABLE 1 SPEED CLASSIFICATION OF ENGINES

Classification of engines	Abbreviated designation	Speed characteristic limits (c_s), ft. per sec. per sec.	Limit figures in existing engines	
			n, r.p.m.	*c*, ft. per min.
Low speed	L	25– 74	95– 350	687–1000
Medium speed	M	75– 229	300– 800	750–1333
High speed	H	230– 699	600–1450	1000–1867
Super high speed	S	700–2100	1500–2500	1755–2329

The proposed method of speed characteristics, expressions [2] and [3], retains its value even if the system of classification and engine designations presented in Table 1 is changed either in respect to limits, to number of subdivisions, or to both.

For the sake of comparison, the limits of *n* and *c* of the various oil engines listed in Tables 2 and 3 and classified according to the author's proposal are given in the last two columns of Table 1. These figures follow the trend of the speed characteristics given there very well, but with considerable overlapping—which was the reason for the present investigation.

To check the method of classification described in respect to its usefulness, data for a number of existing oil engines were compiled in Tables 2 and 3. Table 2 comprises data on a number of oil engines of the latest design, and commonly regarded as high-speed engines. In its compilation a table of high-speed engines, published by E. C. Magdeburger,[2] was used as a basis, with a few changes and additions, the latter being suitably indicated; and out of several engines with the same bore, stroke, and r.p.m., only one was taken in each case. Two new columns were added: the speed characteristic c_s, and classification as to speed according to Table 1. Similar data for engines usually considered of low or medium speed are presented in Table 3. In order to obtain a short, clear table only a limited number of mechanical-injection vertical engines were considered. In several instances the choice was decided by the availability of the necessary data. The chief object was to select representative engines differing in speeds, cycles, and sizes, avoiding duplication of engines of the same bore, stroke, and r.p.m. Table 3 in connection with Table 2 makes it possible to check the consistency and soundness of the proposed speed characteristic c_s over the whole range of oil engines at present constructed.

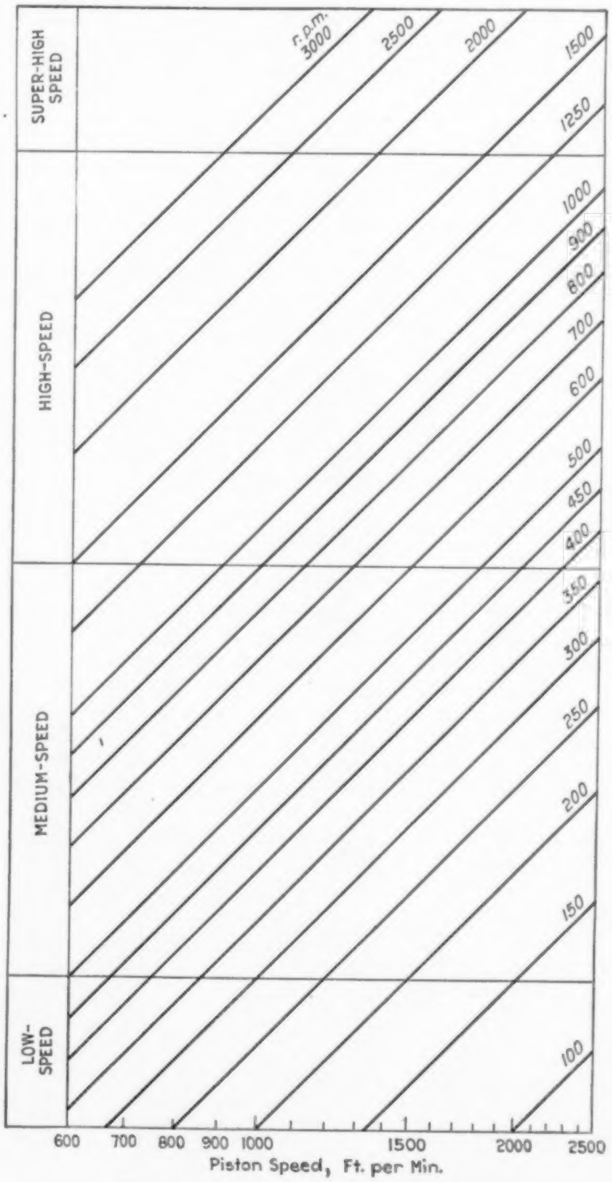

FIG. 1 SPEED CLASSIFICATION OF ENGINES

---

[2] *S.A.E. Journal*, February, 1930, p. 204.

From Table 2 the following conclusions can be drawn: That not all engines commonly considered as high-speed can be classified as such, and therefore it is desirable to have a positive means of classifying them; that the introduction of a "super-high" classification makes it possible to pick out at a glance engines showing greater departure from a conventional design and that therefore this designation is desirable.

Table 3 shows that engines of certain makes have very close speed characteristics in their respective groups; for instance, the three Deutz engines, the three Standard Motor Construction engines, and the four low-speed Western-Enterprise engines. Engines of other builders show less regular speed characteristics. The speed characteristics generally fall off considerably with increase of engine size, showing clearly an excessive lowering of the rotative speed with increase of stroke and output per cylinder. This shows how an engine designer can benefit from the use of a list of speed characteristics of oil engines actually built and satisfactorily operating, as given in Tables 2 and 3.

The author believes that as a result of this discussion the following general conclusions can be drawn:

1 The use of the proposed speed characteristic c_s gives a consistent and correct means of judging oil engines in respect to speed.

2 The system of classification as presented in Table 1 is sound, and without irregularities.

3 The system of classification proposed is practical and general; it presents a means of showing in a concise way what has been done by other engine builders, and can be used as a guide by engine designers, regardless of whether the engine to be designed is a high-, medium-, or low-speed one.

Discussion

E. C. **Magdeburger.**[3] The observations of the author on the desirability of establishing a yardstick for classifying oil engines are thoroughly concurred in, and the deductions leading to his "speed characteristic" appear logical enough to make it a satisfactory means for differentiation of type of engines. There is only one suggestion that is believed to be pertinent. It would make the practical application of the proposed classification quick and easy and may thereby contribute to the adoption of the idea itself. The various division lines, as the author himself suggests, are perfectly arbitrary, but there appears to be no good reason why the width of ranges of the different classes should be so arbitrarily chosen as Table 1 would indicate.

It is therefore suggested to use for speed classification a unit, proportional to that proposed by the author, which has the advantage that it will require no slide rule or any other constants to memorize and can be obtained by a bit of mental arithmetic in all but the few cases close to the border line. The proposed "speed characteristic" is to be

$$\frac{\text{R.p.m.} \times \text{piston speed}}{100{,}000}$$

For the division lines of the various classes, which can be easily remembered, it is proposed to establish the powers of number 3, so that for low-speed engines the speed characteristic is below 3, for medium-speed engines it is to be between 3 and $3^2 = 9$, for high-speed engines it is to be between $3^2 = 9$ and $3^3 = 27$, and engines having a speed characteristic above $3^3 = 27$ are to be classed super-high-speed.

An easily made diagram which further simplifies the classifying process, once the speed in r.p.m. and piston speed in feet per minute are known, is given in Fig. 1. If the vertical line of the piston speed is followed to the inclined r.p.m. line, their intersection will give the proper classification of the engine.

It may be of interest to add that the first submarine Diesel engine of our Navy had cylinders of $12^3/_4$-in. bore and $13^1/_2$-in. stroke and ran at 400 r.p.m. (piston speed, 900 ft. per min.). It belonged, therefore, to the medium-speed class (400 × 900/100,000 = 3.6), and, in fact, all of our submarine engines are in the same class.[4] It is only with the new "experimental" Diesel engine, having cylinders of 11.024-in. bore and 14.961-in. stroke and a maximum speed of 700 r.p.m. (piston speed, 1745 ft. per min.) that the Navy ventured into the high-speed class (700 × 1745/100,000 = 12.2).

Author's Closure

The author agrees with the practical usefulness of Mr. Magdeburger's suggestion of changing the divisor in expression [3], and expresses the hope that this change, in connection with other advantages, will help in the adoption of the speed characteristic c_s by designers of oil engines in their work.

PME-54-1

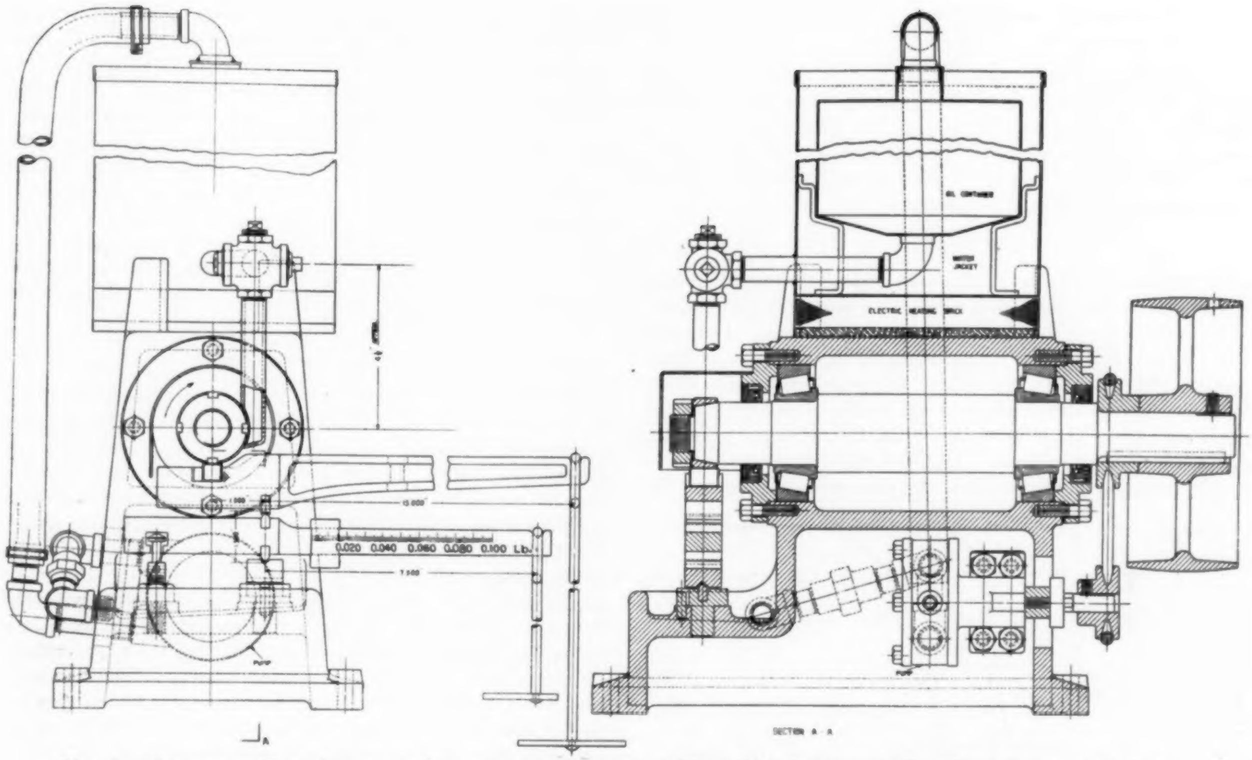

FIG. 1 MACHINE TO TEST ABILITY OF LUBRICANTS TO WITHSTAND HIGH UNIT PRESSURES WITH HIGH RUBBING SPEEDS

Lubricant Testing

By E. G. BODEN[1] AND O. L. MAAG,[2] CANTON, OHIO

A simple machine is described which was developed for the purpose of testing the power of lubricants to withstand high unit pressures with high rubbing speeds. The results of these tests are shown in photos of test blocks indicating the effect of pressure and speed when using oils of varying viscosities and varying composition.

THE complex nature of lubricants used in engineering, even in their simplest form, gives physical results which will vary, depending on their composition. A great amount of information is available on the effect of lubricants used for plain journal bearings, but this paper will be limited to the lubricants used for gearing and in conjunction with anti-friction bearings.

The ever-increasing demand for higher speeds in all forms of engineering has resulted in a limit being placed on speeds due to the lack of efficient lubrication. Considerable advancement has been made within recent years in the metallurgy of steel, and today we can, with fairly definite knowledge of the properties of metal, develop machinery which can be depended upon to produce certain given results. This development has reached its present stage by repeated physical testing and by designing the special testing means to obtain desired characteristics of the material.

GENERAL TESTS

Until quite recent years the testing of lubricants was confined to the general physical constants determined by A.S.T.M. and S.A.E. standard methods. The objects were to determine:

1 The viscosity of the lubricant, which is usually taken by means of the Saybolt viscosimeter
2 The cold test, which is to find the point at which a lubricant becomes non-fluid
3 The flash test
4 The fire test
5 The gravity test
6 Determination for ash
7 Determination for carbon residue

[1] Experimental Engineer, Timken Roller Bearing Company. Mr. Boden's technical training was obtained at the Manchester College of Technology and in mechanical engineering and apprentice work at Crossley Motor Company, Manchester, England. Later he was design engineer for Sizaire Berwick Automotive Engineers in London, and next with the Chandler Motor Car Company in Cleveland as quality and research engineer.

[2] Lubricating Engineer, Timken Roller Bearing Company. Mr. Maag's technical training was obtained at the University of Kansas in chemical engineering and the teaching of chemistry. In the commercial field his experience has been as a chemical engineer with the Kansas City Industrial Laboratory, the U. S. Bureau of Standards, Washington, and the Galena Signal Oil Company, Franklin, Pa.

Presented at the Lubrication Research Session of the Lubrication Engineering Meeting, Fifth Oil Power Conference, State College, Pa., May 22, 1931, under the joint auspices of the Pennsylvania State College and the Lubrication Engineering Committee of the Petroleum Division of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

8 A channeling test
9 A corrosion test.

With these tests, only the effects of the viscosity of the lubricant in regard to the load-carrying capacity could be used as an indication of the relative merits of different lubricants for withstanding varying degrees of unit pressure. Within certain temperature ranges the effect of viscosity will be to carry higher unit loading with increase in viscosity.

GEAR LUBRICANTS

Lubricants suitable for gearing will depend on the unit loads, gear material, and tooth design reflecting on the slippage speed, which appears to be one of the main causes of failure. Gears are generally lubricated from a fluid-oil bath, the quantity of lubricant passing the point of mesh of the gear being quite small, depending on the adhesiveness of the lubricant and the effect of centrifugal force tending to throw off the lubricant from the power-transmitting surfaces. The lack of lubricant, which has a double function in maintaining the separation of the metallic surfaces and the conduction of heat generated by the inevitable friction between parts highly loaded or subject to high rubbing speed, gives rise to scoring or a welding action due to the breakdown of the separating film.

SPECIAL TESTS

Several devices for determining the film strength of lubricants have been developed, among which may be cited the Amsler, Hershey, Mougey, McKee, Kingsbury, Herschel, and Dickinson. Most of these machines were designed for testing lubricants on plain bearings. Exception to this would be the Amsler machine, which is made in the form of rotating disks having their edges sliding against each other, and the McKee machine, utilizing balls in grooved shafts.

Owing to the lack of public information on the ability of lubricants to withstand high unit pressures with high rubbing speeds, our company developed a simple testing machine for this purpose.

DESCRIPTION OF SCUFFING MACHINE

Fig. 1 shows the cross-section and end view of this apparatus. A mandrel is mounted on two Timken bearings held in a cast-iron base and having on one end of the mandrel a tapered end to receive a standard Timken bearing cup, which is used as one of the test members. A nut having a left-hand thread securely locks this tapered bore cup to the mandrel, with no possible tendency for it to rotate. Directly beneath the revolving cup a test block $^{1}/_{2}$ in. square by $^{3}/_{4}$ in. long is mounted in a lever, shown in the end view of the apparatus. This lever is supported on a knife edge which is carried on the top of a second lever, which also is carried on a universal knife edge on the base of the machine. This arrangement assures that the test block will at all times be parallel to the revolving cup, so that the unit loading will be maintained constant over the length of the test piece. The top lever is loaded by means of weights on the end, which produces a pressure on the revolving member ten times the amount of load added to the lever.

TEST PROCEDURE

The lubricant to be tested is placed in the 1-gal. tank mounted on the top of the base casting, and brought to the required temperature by means of the electric heating pad directly beneath the oil tank. The oil is flowed by gravity from the tank over the test piece, the flow being controlled by a valve, shown in the illustration. The arbor is then driven at any desired speed, depending on the conditions to be met, either by means of a belt or by being coupled directly to an electric motor. It can be readily seen that the revolving test piece in contact with the stationary square test block will produce a frictional force in a horizontal direction, tending to move the top lever horizontally toward the left. This tends to rotate the bottom lever in an anticlockwise direction, and is resisted by means of a conical stop pin on the base of the machine. The bottom lever, known as the frictional lever, is counterbalanced with its scale pan, so that to balance the friction created by the load, it is necessary only to add weight to the pan so that when the lever just leaves the stop pin the frictional force has been counterbalanced. It is then possible to determine the coefficient of friction. The oil is returned to the tank by a pump inside the base of the machine and driven from the mandrel by a small round belt, as shown in the diagram. The machine is therefore a self-contained assembly. The test pieces can be any desired material, but for checking ordinary gears such as are found in automotive rear axles, the test pieces are made from carburized steel, case-hardened and ground, the standard cups having a Rockwell hardness of 60 on the "C" scale.

The machine, as run for checking lubricants suitable for gears, uses a square test block which gives a very high initial loading. The test is comparative as the initial areas are the same. The abrasives in the lubricant, however, will change the ultimate area of contact during test depending on the severity of the abrasives. It is more convenient and cheaper to prepare specimens having flat faces than to prepare specimens having two curved surfaces in contact. If it is desired to maintain constant unit pressure, then test pieces can be made having curved surfaces to correspond with the round test block to be used as the stationary test member.

TEST RESULTS

The results outlined in the following tests were obtained when running the machine at a rubbing speed of 320 ft. per min., using specimens of carburized steel hardened to 60 Rockwell on the "C" scale.

Curve *E* in Fig. 2 is a friction curve for a straight mineral oil of 150 seconds viscosity at 210 deg. fahr., which shows a rapid increase in friction at a load of 6000 lb. per sq. in. This is the point at which scuffing starts and is the maximum load this oil will carry at this particular speed.

Curve *U*, for a straight mineral oil of 800 seconds viscosity at 210 deg. fahr., also shows a minimum friction and then a rise to

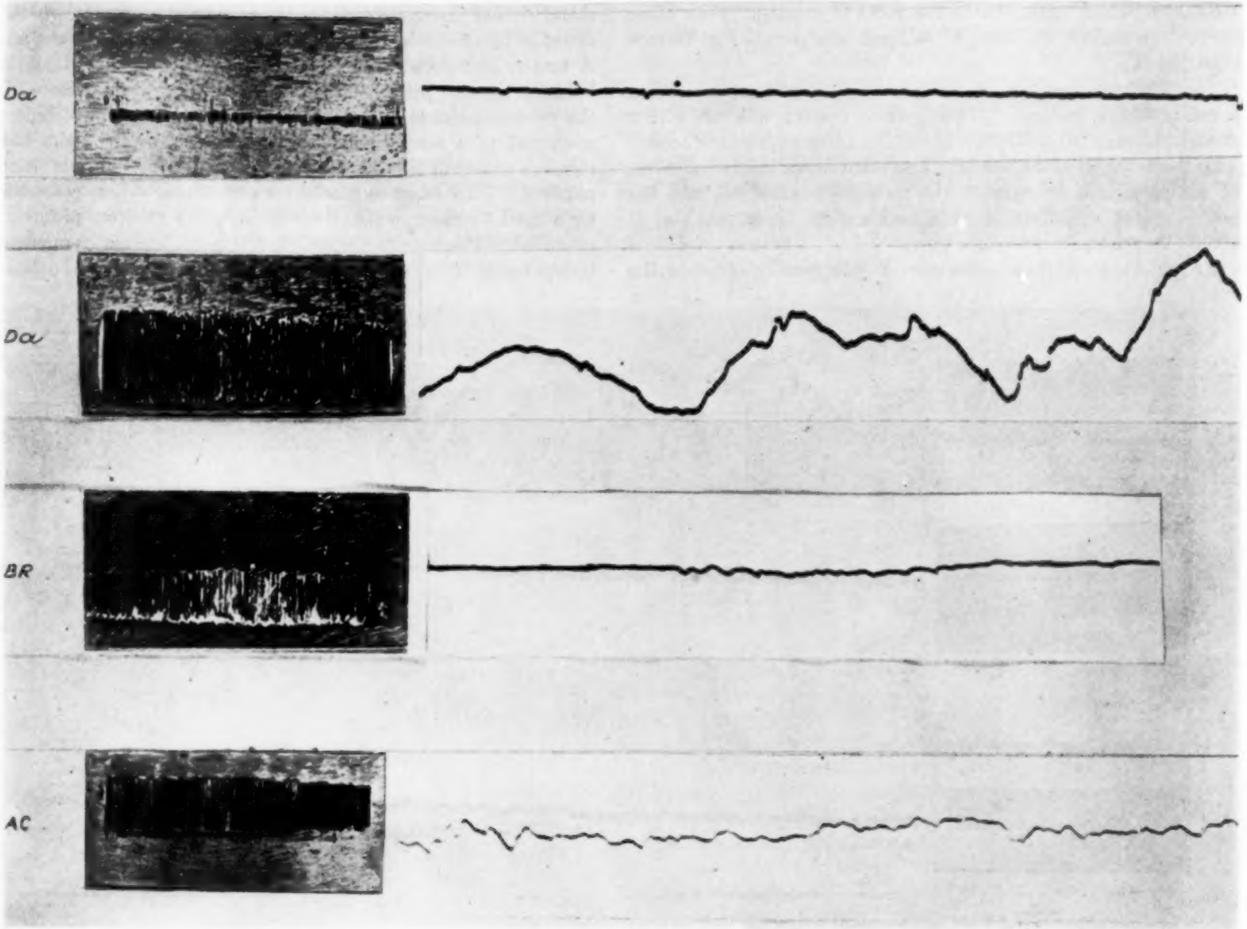

Fig. 3 Four Typical Test Blocks

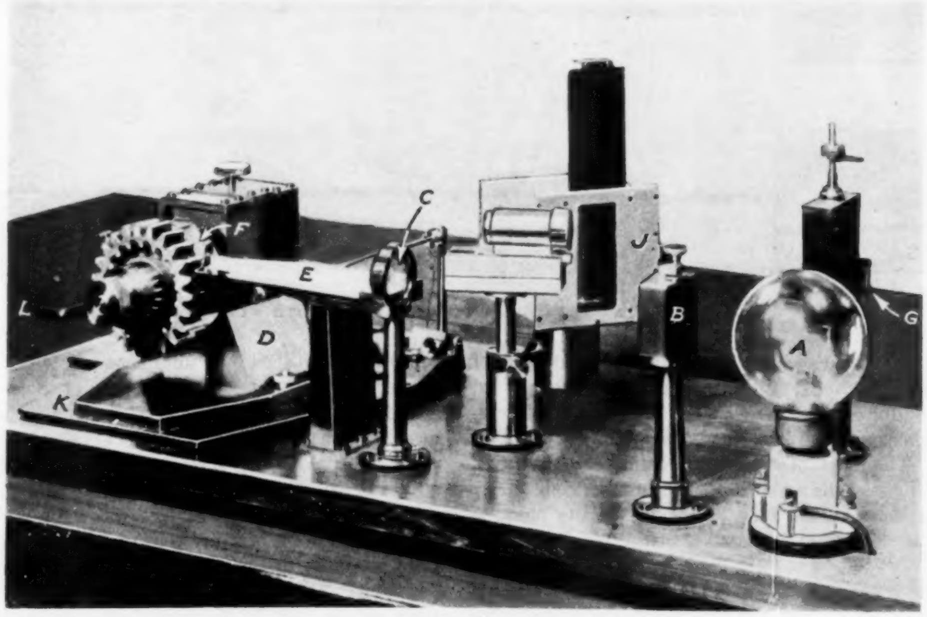

Fig. 4 Roughness-Recording Machine

15,000 lb., which again checks the point of scoring. Four other curves are shown for straight mineral oils containing various ingredients.

Fig. 3 shows four typical test blocks after test, at a rubbing speed of 320 ft. per min. The block at the top was run with a straight mineral oil at 5000 lb. per sq. in. pressure, and the second with the same oil at 10,000 lb. The third block shows the effect of adding aluminum soap to the straight mineral oil, and the bottom block the effect of adding soda soap, these two also at 10,000 lb. per sq. in. pressure.

As can be seen, these additions do not greatly improve the carrying capacity of the lubricant. The curves to the right of the block show the roughness of the face as determined by an apparatus designed for our company by the University of Michigan which can check the surface roughness of either plain or curved surfaces. The magnification is approximately 500 times, so that $^1/_4$ in. in height of the actual size of the curve produced by the machine represents 0.0005 in. The width of the block is $^1/_2$ in., so it will be seen that the scuffing of the block is rather severe.

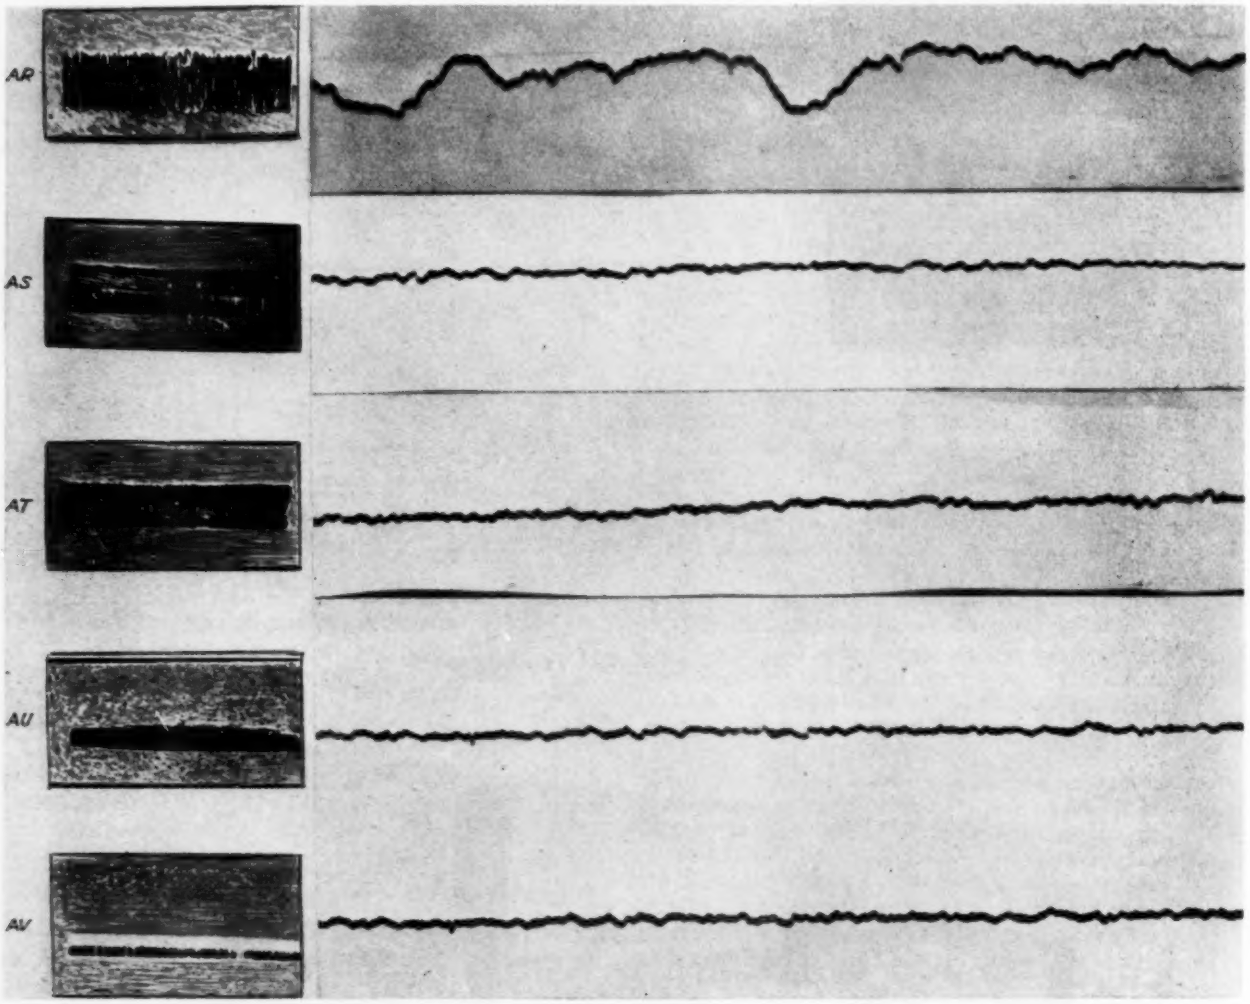

Fig. 5 Results of Tests of Straight Mineral Oil, With Various Additions

Operation of the roughness-recording machine, which is shown in Fig. 4, is as follows:

Light from a source *A* is projected through a small hole in the stand *B*, and through a lens *C* against a small mirror *D*, which is fastened to a razor blade attached to a lever *E* hinged to a stand. A master surface *F* supports this lever, so that any deviation between the test pieces and the master piece will be reflected by the movement of the mirror *D*. This reflected beam of light is projected to a second mirror *G*, which reflects the light back through a second lens *H*, not shown, on to a piece of sensitized paper *J*. This paper is placed on a revolving drum, connected by a cord to the movable base *K* on which the test pieces are mounted. The base moves only in a straight line and is operated by the handle *L* at the rear of the fixture. To test plane surfaces the arbor is replaced by a suitable stand, which also must carry a master test piece.

Fig. 5 is a photograph of test blocks after a run with experimental Pennsylvania oil, which is extremely low in natural sulphur. Oil "AR" was a straight mineral oil of 150 seconds viscosity at 210 deg. fahr. At a pressure of 10,000 lb. per sq. in., it scored very badly. Oil "AS" was the same oil as "AR," but with the addition of 2 per cent of free sulphur. Fine scratches were produced in this test. The load was carried to 20,000 lb. per sq. in. Oil "AT" had 2 per cent of lead oleate added to the same oil as "AR." No scratches were evident with this oil. The load was carried to 20,000 lb. per sq. in. Oil "AU" had

10 per cent of lead oleate added to "AR," and the load was again carried to 20,000 lb. per sq. in. Again no scratches were observed. Oil "AV" was made by adding together oils "AS" and "AT," and it therefore contained 1 per cent of lead oleate and 1 per cent of sulphur. Fine scratches were noticed, which shows that the sulphur was the cause of the scratches.

Curves of the coefficient of friction for these same oils, Fig. 6, show that the friction increases with the increase of lead oleate.

Temperatures reached by these oils in the tank are shown in Fig. 7. The sulphur oil shows the lowest temperature, as might be expected from the well-known cooling action when adding sulphur to hot journals.

Highest temperatures were reached with the high-lead-oleate oil. The friction curves in Fig. 6 followed the temperature curves in Fig. 7 in the same order.

Many oils compounded in various ways have been tested, but the most promising as regards load-carrying ability are sulphur oils, chlorinated oils, and lead-soap-base oils. Test results obtained with lead-soap oils are shown in Fig. 8. The rubbing speed was 320 ft. per min. Oil "AX" is a well-known brand of lead-soap oil containing sulphur. Oil "AJ" is a similar lead-soap oil. Oil "BF" is another containing approximately 7 per cent of lead-soap and no sulphur. All of these were tested up to 20,000 lb. per sq. in.

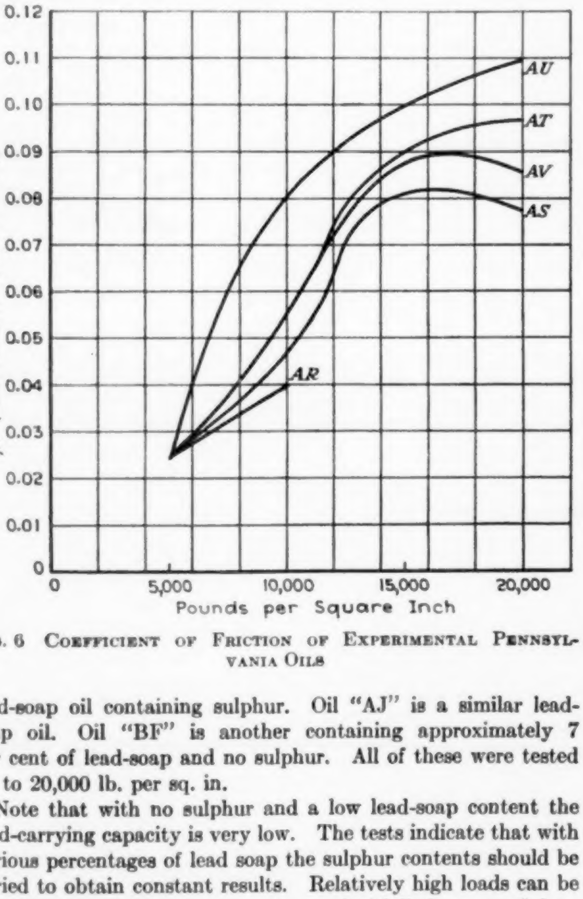

FIG. 6 COEFFICIENT OF FRICTION OF EXPERIMENTAL PENNSYLVANIA OILS

Note that with no sulphur and a low lead-soap content the load-carrying capacity is very low. The tests indicate that with various percentages of lead soap the sulphur contents should be varied to obtain constant results. Relatively high loads can be carried with a high lead-soap content and with little or no sulphur, but to hold high percentages of lead-soap in permanent suspension is very difficult, if not impossible.

Test results obtained with sulphur oils are shown in Fig. 9. Oil "BT" had 20 per cent of added sulphur. Oil "BU" had 10 per cent of added sulphur. In this case the sulphur supposedly was added on to the hydrogen atom. Oil "BV" contained 10 per cent combined sulphur, the sulphur atom replacing the hydrogen and therefore being a chemical combination. All of these were tested up to 20,000 lb. per sq. in.

The results of this test are interesting, showing the abrasive qualities as well as the carrying capacity of an oil high in free sulphur ("BT"). This is shown by the extreme width of contact surface that has been very badly lapped. Most chemically combined forms of sulphur score badly at 20,000 lb. per sq. in. and would carry loads of only 10,000 to 15,000 lb. Sulphur oils that are high in free sulphur separate badly in test.

Of the three oils represented in Fig. 9, oil "BT" separated badly in test and oil "BU" separated slightly after standing approximately one month. No separation occurred in oil "BV," which was chemically combined.

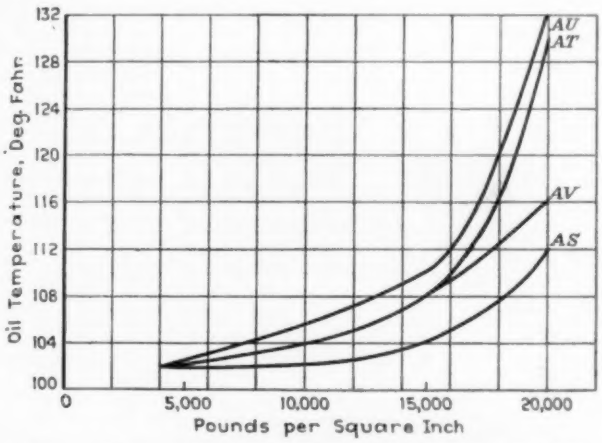

FIG. 7 TEMPERATURE OF EXPERIMENTAL PENNSYLVANIA OILS

The effect of castor oil under a load of 10,000 lb. per sq. in. is shown in Fig. 10, oil "O." It was surprising to find that this oil did not stand any more load than a straight mineral oil of approximately 150 viscosity at 210 deg. fahr. The advantage of this oil is a low coefficient of friction and low cold-test value. The result obtained with an oil having an addition of 10 per cent of a cutting oil to a straight mineral oil of 150 viscosity is also shown, oil "CL." This cutting oil is a sulphur chloride of chemically combined form. The results obtained were very surprising, as the sulphur contents of the mixture did not exceed 0.5 per cent.

The effect of rubbing speed in relation to pressure per square inch before scuffing occurs has been determined for three different oils, as shown in Fig. 11. The oils tested were: (1) Lead-soap oil "CX" (curve *A*); (2) straight mineral oil of 150 viscosity at 210 deg. fahr. (curve *B*); (3) oil *B* with 3 per cent of flowers of sulphur (curve *C*).

The curves are extremely interesting as showing the importance of rubbing speed with relation to pressure. This brings up the question of whether a standard means of testing the load-carrying capacity of an oil is desirable. It is our opinion that this is very essential in analyzing an oil for its load-carrying capacity and is perhaps more important than the usual physical test made on lubricants in the past.

Fig. 12 shows a test conducted on a bronze block of 80 per cent copper, 10 per cent tin, and 10 per cent lead, using a steam-refined straight mineral oil of 150 viscosity at 210 deg. fahr. at a rubbing speed of 320 ft. per min. It is to be noted that the point of minimum friction falls at the same place as it did when steel was used—namely, approximately 6000 lb. per sq. in. In the case of the bronze, however, instead of a scoring taking place, rapid wear begins to set in beyond this pressure, and as seen at 20,000 lb. per sq. in., the surface is relatively smooth, but the specimen has been badly worn away.

An attachment to this machine can be installed to enable non-

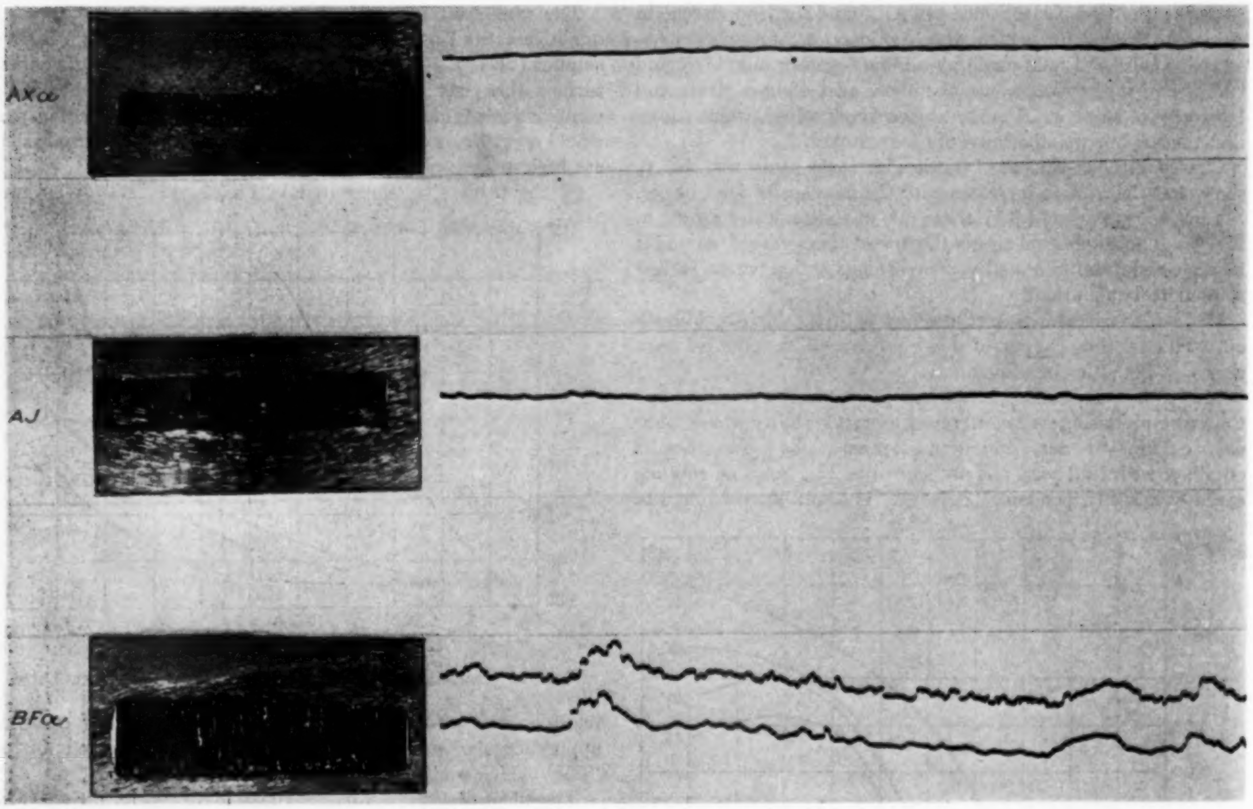

Fig. 8 Test Results Obtained With Lead-Soap Oils

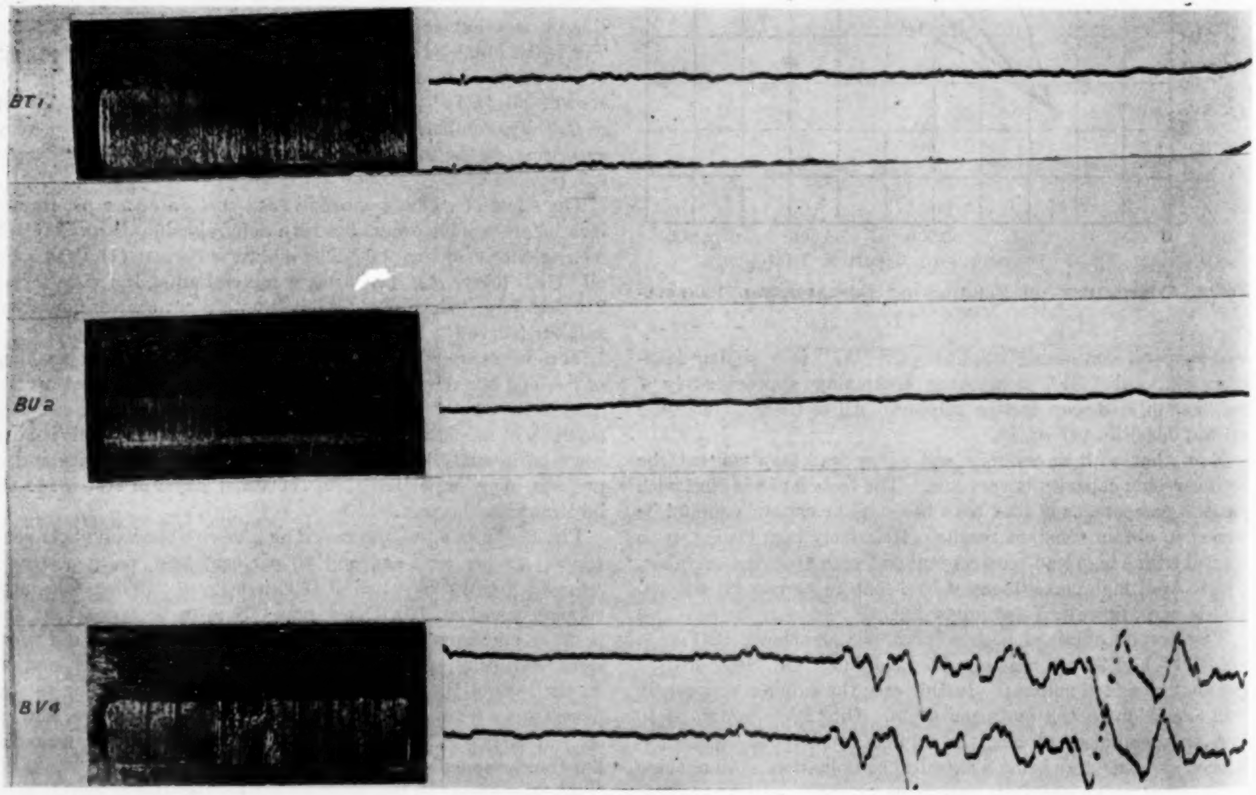

Fig. 9 Test Results Obtained With Sulphurized Mineral Oils

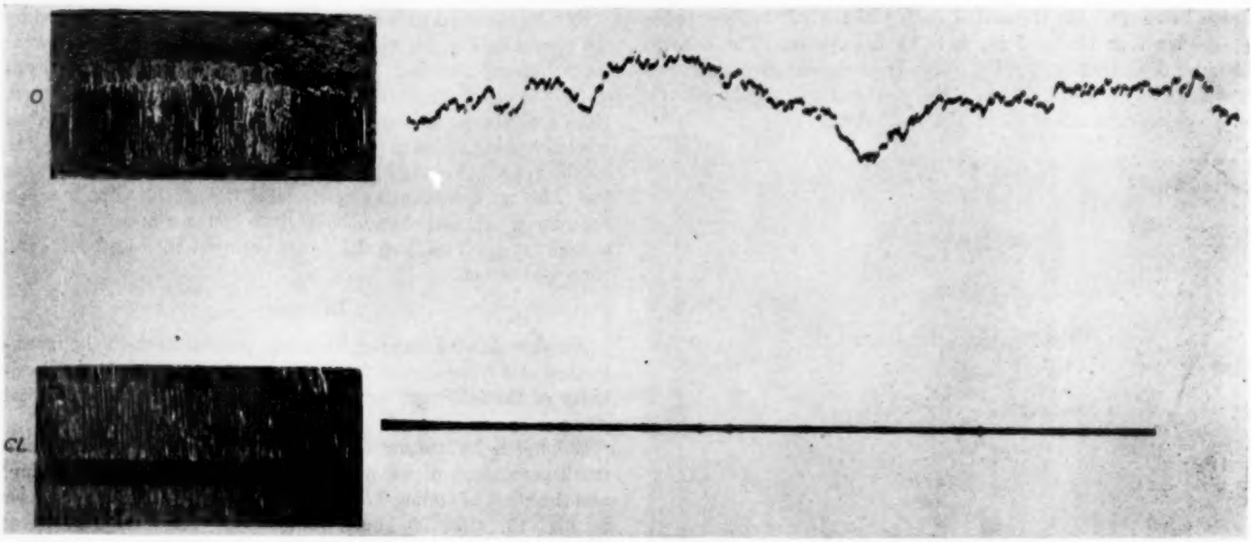

Fig. 10 Effects of Castor Oil and of a Straight Mineral Oil With Cutting Oil Added

fluid oils or greases to be tested for load-carrying capacity.

It is interesting to note the difference between greases on the adhesiveness of the grease to the test pieces. This shows up in the increased carrying capacity and appears a very important item in the selection of a grease for heavy loads.

Greases that readily channel and will not be drawn into the load zone will not carry very high pressure and will score very readily.

It should be noted that the temperatures of operation within certain limits do not give a true indication of the lubricating value of the grease, which, after all, is important only in keeping down the local temperature of the parts subject to loading.

A desirable feature of any lubricant is its heat-dissipating quality, and for this reason lubricants of high viscosity are not suitable for high-speed lubrication.

Abrasive Properties

Coupled with the efforts to obtain lubricants which will stand high unit pressures is the problem of abrasiveness of the compounded lubricants.

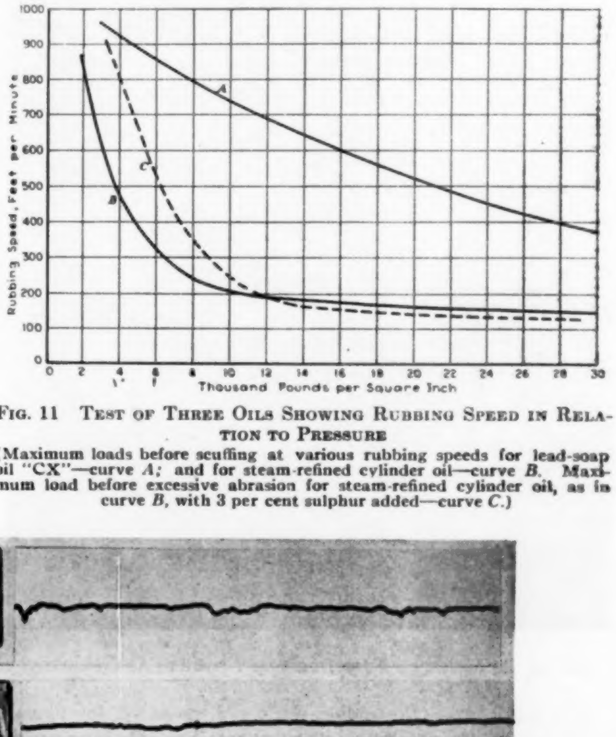

Fig. 11 Test of Three Oils Showing Rubbing Speed in Relation to Pressure

(Maximum loads before scuffing at various rubbing speeds for lead-soap oil "CX"—curve *A;* and for steam-refined cylinder oil—curve *B.* Maximum load before excessive abrasion for steam-refined cylinder oil, as in curve *B,* with 3 per cent sulphur added—curve *C.*)

It might be stated that in these investigations of lubricants there has not been found a lubricant which would permit higher unit pressures to be carried which did not at the same time have an increased abrasive action on the load-transmitting members.

To test a lubricant for its abrasiveness, a machine was built to make comparative tests, and is illustrated in Fig. 13. It embodies four pinions, each mounted on two bearings and driven by a single ring gear. This machine is mounted in a vertical position and driven by a vertical electric motor through a belt drive.

The pinions are run at 2000 r.p.m., and the lubricant is supplied to the gear box and circulated through pipes to the four

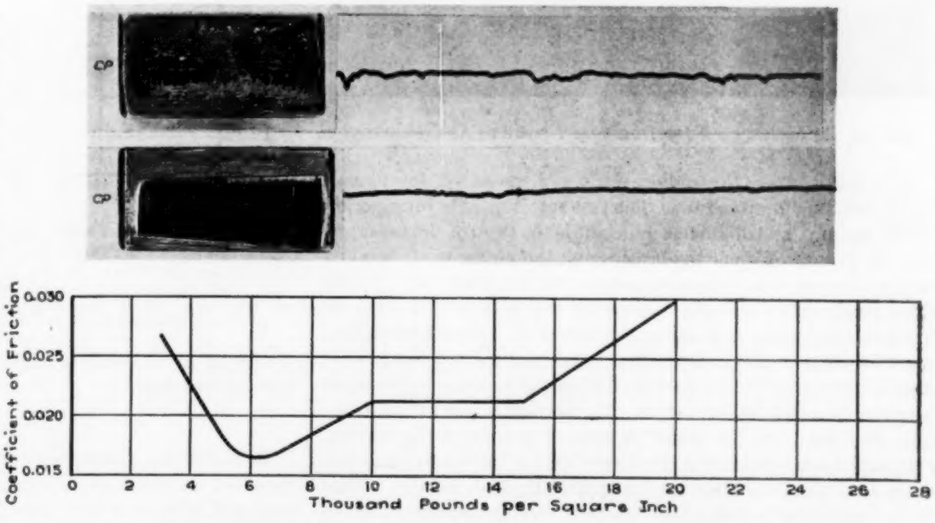

Fig. 12 Test on Phosphor-Bronze Block, Using Steam-Refined Straight Mineral Oil

pinion housings. On the end of each pinion shaft is mounted a fan having four blades 5 in. wide by 6 in. long. The outside diameter of the fan is $16^1/_2$ in. This arrangement gives a load of approximately 8 hp., and is also the means of cooling the oil to a constant temperature of about 150 deg. fahr.

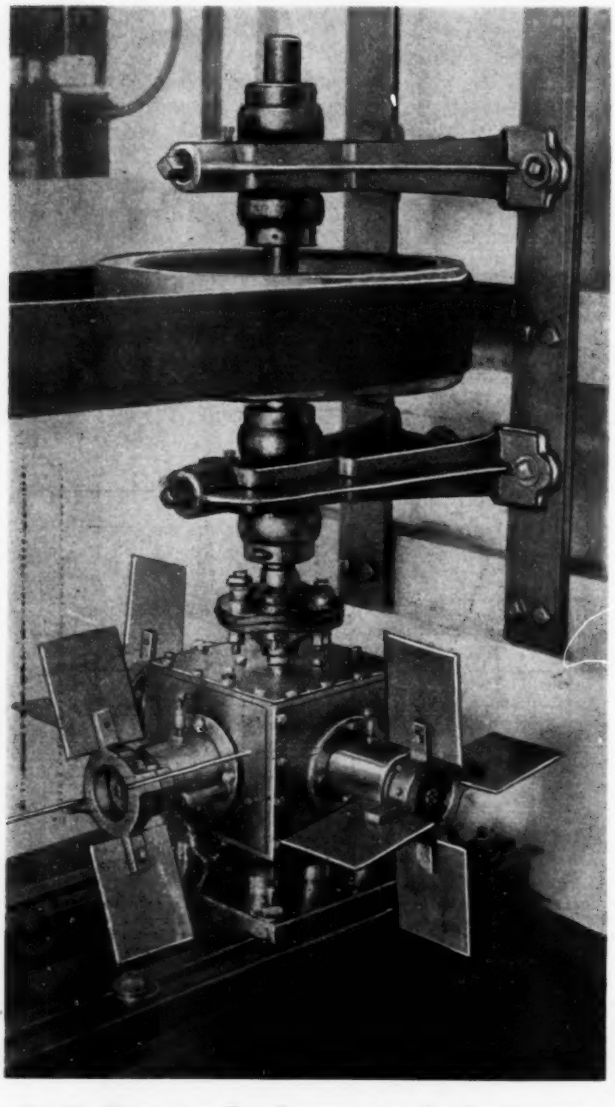

FIG. 13 MACHINE TO TEST LUBRICANT FOR ITS ABRASIVENESS

The bearings on the pinion shaft are measured for overall height before and after test. The test run is usually for a period of 200 hours. The difference in height is the drop of the bearings, and the average drop of the bearings on the pinion shaft is taken as the measure of the abrasive property of the lubricant. Under these conditions a straight mineral oil will give a total wear on Timken bearings of approximately 0.0015 in. on the two pinion-shaft bearings in 200 hours. It is important when testing bearings for wear that the load be applied on the bearings in the same way that it is applied in service. In the case of the pinion bearings the load from the pinion is applied outside of the bearing axis, and when considering the thrust load in particular produces more wear than when the load is applied through its axis. This is the reason for building this machine, and the results obtained have justified its development.

Results obtained with some of the oils tested are represented by the curves in Fig. 14, which show comparative amounts of wear for 200 hours' duration. These reveal that straight mineral oils of 150 viscosity, which was the lowest viscosity of the oils tested, gives a minimum amount of wear. Abrasion is increased when ingredients are added to the oil, the amount of abrasion depending on the type and quantity of the substances present. Note that the chemically combined sulphur oil of 3 per cent sulphur was a Smackover oil, and showed very little increase in abrasion over straight mineral oil, and that wear occurred with lead-soap and copper-oleate oils.

ETCHING

Another disadvantage which might present itself in the manufacture of a compounded lubricant for high pressure is the possibility of the lubricant causing etching of highly polished metal parts.

Sulphur in its free state, particularly when in the presence of a small percentage of water, is very active in producing etching, and the effect of adding 0.5 per cent of water to these oils is shown in Fig. 15, after 50 hours' immersion. The oils used were: (1) straight mineral oil of 150 viscosity at 210 deg. fahr.; (2) Smackover oil of similar viscosity, which is a natural sulphur oil of 3 per cent sulphur; (3) straight mineral oil (oil 1, with the addition of 2 per cent of free sulphur).

When sulphur is in its free state, considerable discoloration is produced, which is obviously undesirable in anti-friction bearings. The effect of discoloration on natural sulphur oil is much less marked, and perhaps no trouble would be experienced with this oil.

It is important, therefore, that lubricants containing sulphur should not have this element in a free or active state, which would be detrimental to highly polished surfaces such as anti-friction bearings.

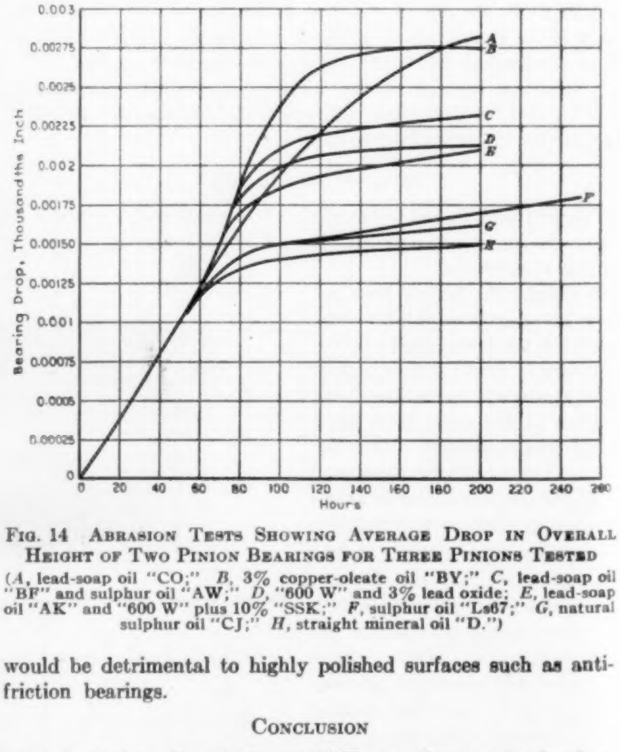

FIG. 14 ABRASION TESTS SHOWING AVERAGE DROP IN OVERALL HEIGHT OF TWO PINION BEARINGS FOR THREE PINIONS TESTED
(*A*, lead-soap oil "CO;" *B*, 3% copper-oleate oil "BY;" *C*, lead-soap oil "BF" and sulphur oil "AW;" *D*, "600 W" and 3% lead oxide; *E*, lead-soap oil "AK" and "600 W" plus 10% "SSK;" *F*, sulphur oil "Ls67;" *G*, natural sulphur oil "CJ;" *H*, straight mineral oil "D.")

CONCLUSION

In conclusion, the authors would like to advocate the development of standard apparatus for determining the carrying capacity of lubricants to be used for gearing in general and particularly for high unit loading.

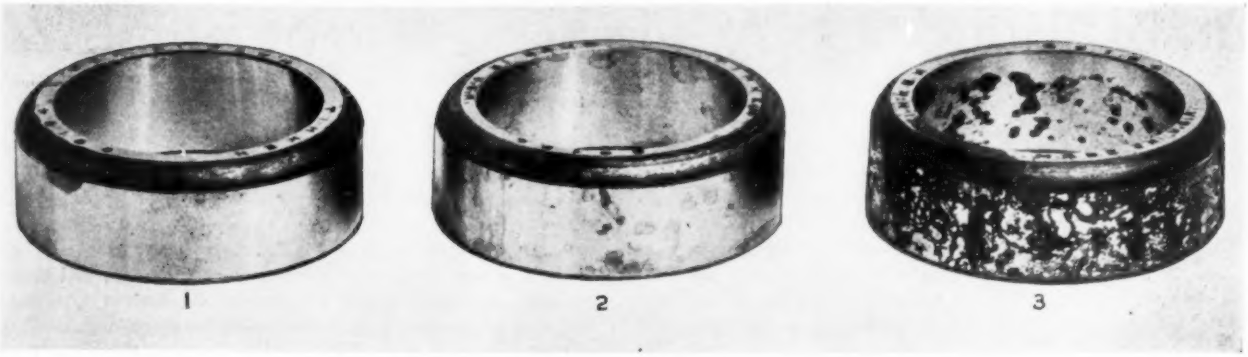

Fig. 15 Etching Produced by Sulphur, With Small Quantity of Water Added

The effect of rubbing speed and surface temperature should be taken into consideration, and also the quantity of oil flowing over the loaded members during the test.

From the results obtained on the abrasion machine the use of an abrasive filler should not be used where these lubricants must lubricate anti-friction bearings, and the etching effect of the lubricant must be held to a minimum.

A lubricant made for this type of service should have at least the following characteristics:

(a) Freedom from separation when standing and in service
(b) Minimum of abrasive action
(c) Ability to carry certain specific loads at definite rubbing speeds
(d) Freedom from channeling at low temperatures
(e) Be reasonably cheap and conveniently obtainable
(f) Shall not produce etching or discoloration of bearings and the like.

Considerable research work has been done within the last two years, and all the important oil companies are now busy developing lubricants which will be suitable for the higher speeds and heavier loads which are becoming more and more in evidence day by day.

Welding Progress at the A. O. Smith Plant

By T. McLean Jasper,[1] Milwaukee, Wis.

This paper covers the history of welding of pressure vessels in one plant covering a period of one-third of a century. The oil industry is credited with having provided the opportunity for the rapid development of welding, not being limited by code restrictions as to the size and shape of desired pressure equipment. Testing equipment is described, and tests on steel for pressure vessels are detailed.

The history of welding by the A. O. Smith Corporation dates back to the year 1897, or about one-third of a century. The first product to be welded consisted of bicycle hangers and clips. This welding was performed with acetylene gas obtained from France. In 1899 the first electric-arc welding was performed, which soon replaced the acetylene torch for this type of work. Electric butt or resistance welding was first used in 1903 for solid spindles. Then, in 1911, welding by oxygen and hydrogen gas came in use for automobile parts. Rear-axle housings first had minor parts welded with the oxyacetylene gas, and in 1913 reinforcing rings were spot-welded into these housings.

The electric arc replaced oxyacetylene for quantity production in 1917, and from that time on, this new method of welding has held the premier position in the company's progress in welding.

Since this period over 1,000,000 tons of steel have been put into electric-arc-welded products, of which the chief details are given in Table 1.

TABLE 1 WELDED PRODUCTS OF A. O. SMITH CORPORATION SINCE 1918

Type of product	Quantity of units	Total weight in tons	Years shipped
Aerial drop bombs	287,895	4,318	1918–1919
Artillery poles	52,857	3,964	1918–1919
Automobile rear-axle housings	2,797,152	48,950	1918–date
Casing couplings	1,218,626	21,326	1923–date
Large pressure vessels	1,675	52,165	1925–date
Oil and gas line pipe, miles	7,838	1,054,120	1927–date
Total		1,184,843	

The first and second items of the list in Table 1 were war materials, necessitating a rapid expansion in production. The service conditions demanded a weld as strong as the plates that were joined, without an increase in thickness of the welded section. It was at this time that the foundation was laid for the type of welding and the principles of quality which made possible the present broad application of the welding art.

From the time that welding was first employed a third of a century ago up to 1917, welds were applied only to secondary members, in which a possible failure meant little to safety of life and property. However, with the application of welding to axle housings, a failure might mean serious injury or loss of life.

The principles of quality welding established at this time demanded a weld of a material similar to the plate in strength and energy-absorbing qualities. This meant high ductility and impact values in the deposited weld. It also meant that the strength and energy-absorbing qualities of the metal adjacent to the weld be not impaired by the act of welding. These requirements necessitated great improvements in the quality of the plate steel and in what at that time were considered very stringent materials specifications for its production.

From the beginning, welding had to face opposition, chiefly from zealous code committees and from interests equipped for the older forms of fabrication, and obviously also from users that had suffered unpleasant experiences with welded materials of inferior quality. This attitude is now rapidly changing, thanks to the production of welds of high quality and to the tireless efforts of the pioneers in welding. Thirteen years of diligent application and experimental work has shown results in the company's welded-steel products which in many instances embrace the most severe types of service to which steel can be put. Users of equipment know the advantages of welding and are learning to differentiate between good and bad work.

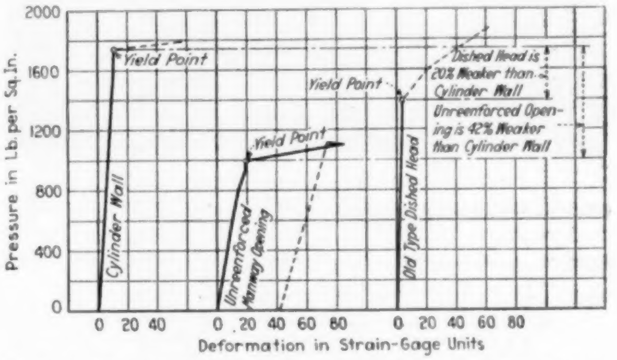

Fig. 1 Lack of Uniformity in Strength of Vessel With Dished Heads and Unreenforced Openings

(These curves were plotted from test results obtained simultaneously during destruction test on a vessel 6 ft. in diameter, 2 in. thick, and about 40 ft. long.)

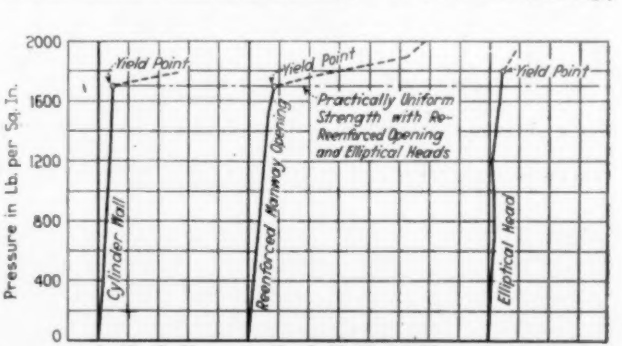

Fig. 2 Uniform Strength in Vessel With Elliptical Heads and Reenforced Openings

(These curves were obtained from tests to destruction on full-size production vessels 40 ft. long, 6 ft. in diameter, with 2-in. wall.)

It certainly was fortunate for the future of welding that, during this development, the oil industry was guided by progressive, wide-awake men. This allowed the development of welding to proceed in such a manner that it won out in a most difficult type of equipment for a hazardous service.

Presented at the National Petroleum Refining Meeting, Elizabeth, N. J., May 5 and 6, 1931, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

Looking back over these years of the company's welding development it is noteworthy how many full-sized vessels were tested to destruction as part of the program to perfect both design and process. It is curious that, until then, so very few tests on full-sized equipment were available on which sound engineering judgment could be based. Long-time experience was the measure of advancement practiced, and naturally very timid progress was made. This attitude produced a condition in which industries were being retarded because of their unwillingness to spend a relatively small amount of money to carry on logical testing.

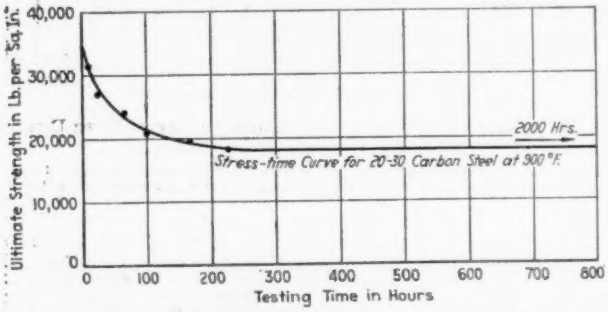

FIG. 4 METHOD IN ARRIVING AT LONG-TIME ULTIMATE STRENGTH OF STEELS

(The two last specimens were run for 2000 hours without failure at a stress of 17,000 and 18,000 lb. per sq. in. respectively.)

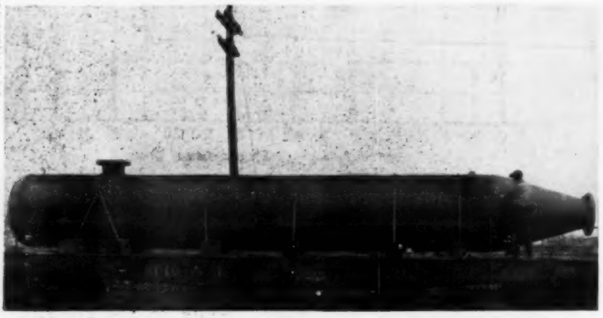

FIG. 5 ONE OF THE FIRST WELDED OIL-CRACKING STILLS

(This was 41 ft. long, 5 ft. in diameter, and $2^1/_2$ in. thick, and was shipped July 25, 1925.)

Testing is an important adjunct to proper engineering application in that it points out weaknesses in methods of construction and design, which can be taken care of only when known and actually understood. Through this means the designers of the future will and can pay more attention to safety than has been done in the past. Safety, of course, is a term which is both relative and arbitrary. Testing is the most important means for clearing up this matter.

The elements which enter into the question of safety in a vessel are as follows:

1 Design
2 Materials
3 Fabrication
4 Testing

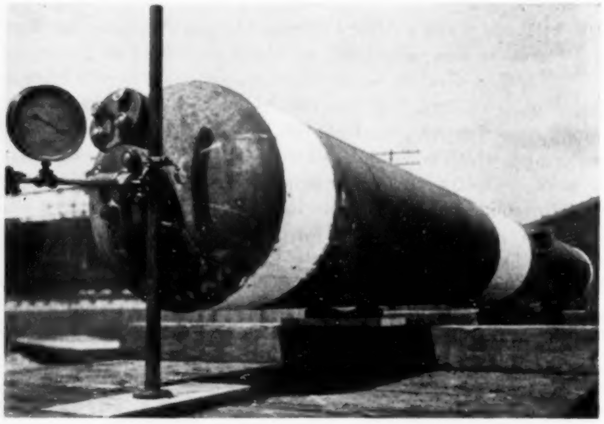

FIG. 6 WELDED REACTION CHAMBER OF CHROME-VANADIUM STEEL

(Operating pressure is 5000 lb. per sq. in. Vessel is shown under hydrostatic test pressure of 10,000 lb. per sq. in.)

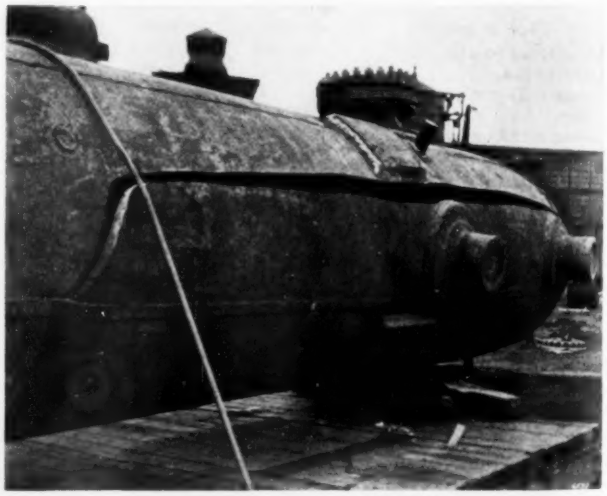

FIG. 7 RESULT OF DESTRUCTION TEST ON WELDED VESSEL AFTER $3^1/_2$ YEARS' SERVICE

(Full strength of the steel was developed, and the fracture occurred through the plate proper, away from the welds.)

Pressure-vessel design is a matter over which there has been almost as much controversy as over the acceptance of welding. This company early practiced methods of design which were based on the outcome of destruction tests on large vessels and numerous researches on the materials used for their construction. It is gratifying that today these principles of design are quite generally recognized and accepted.

Figs. 1 and 2 show how a design can be checked by means of testing. However, the design of a vessel cannot be tested in miniature. The thin walls of such a miniature test vessel will invariably give results which cannot be directly interpreted for a thick-wall vessel. Of course, it is costly to work with full-sized vessels, but nevertheless it is the least expensive method of safe development.

After all, knowing what a vessel will carry in service is much more important to the user than what the calculations of a theorist show it should be able to carry.

On the matter of materials it is interesting to observe how welding has shown up defects in steel not previously known or understood. This has resulted in improved quality of present-day steel used in welded products and in longer life of vessels made from such steel because of its greater resistance to corrosion.

Figs. 3 and 4 show testing equipment and typical long-time test results for a 0.20 to 0.30 carbon steel when used at 900 deg. fahr. A clear understanding of the strength of steel under long-time tests at elevated temperatures is essential, particularly to the refiner, and this, in conjunction with the quality of steel, is all that need be said about materials at this time.

Correct fabrication methods for large-size, heavy-wall vessels is much more important than for thin-wall vessels, and the proof of successful operation is needed to establish adequate precautions in fabrication. Fig. 5 shows such a large vessel, which has been in successful service for nearly six years.

Today it is possible to successfully weld vessels from almost any kind of appropriate steel. A considerable number of stainless steels and of alloy steels of other compositions find application in welded vessels. Even vessels made of common carbon steels lined with stainless steels were introduced by this company. Fig. 6 shows an example.

While testing cannot be carried to destruction with each vessel, there is no reason why every vessel cannot be tested to a relatively high value of stress in conjunction with lime wash, which will show up possible weak points. That this is not detrimental to large vessels is well proved by subsequent tests made on some vessels that this company built nearly six years ago for the oil industry. After three and one-half years of successful operation, these vessels were withdrawn from service and tested to destruction. They developed the full strength of the steel from which they were made, fracturing through the plate proper, as shown in Fig. 7.

From the foregoing it is evident that the oil industry is to be credited with having provided the opportunity for the rapid development of welding and in turn has greatly profited thereby. This industry was not code-restricted, and being free to buy and use equipment best suited for the requirements, naturally made use of the fabrication process which did not limit the desired pressure equipment as to size and shape.

Discussion

Walter Samans.[2] This paper rightly calls attention to the commendable leadership which the A. O. Smith Corporation has exerted in the development of rational designs for pressure vessels of welded construction.

The author's statement that the user is more interested in what a vessel will carry than in what the calculations of a theorist show it is good for, is not believed to be a reflection on the proper use of theory in design, but rather on the limited spread of theory that has been corroborated by practical tests.

In this connection, his last paragraph, pointing out that the oil industry, as regards pressure vessels, was not code-restricted and was able to profit thereby in taking advantage of modern progress in fabrication, is of particular interest. The A.S.M.E. Unfired Pressure Vessel Code has since recognized fusion-welded vessels by a new section, which, while for the present applied to service temperatures not exceeding 300 deg. fahr., will eventually, with the expected cooperation of the oil industry, have no limiting service temperatures, as far as materials permit.

There still remains much to be done on full-sized tests to determine the practical limitations of such theoretical knowledge as can be mathematically developed when taking into account the variables in the metallurgy of steel and its alloys and the tolerances that must be permissible in fabrication.

On the whole, the paper presents the high points showing need for uniform strength in all parts of the pressure vessel, to obtain maximum service life and safety.

PME-54-3

New Development of Chromium-Tungsten Steel for Oil-Refining Service

By V. T. MALCOLM,[1] INDIAN ORCHARD, MASS.

Apparatus used in oil-refining service has been designed mostly from practical experience instead of experimental research, and the experience gained from operation over long periods gives notable results, among them being that certain alloys are resistant to corrosive conditions, and that if these alloys are used the so-called limiting creep stresses can be more than doubled over carbon steel. Other factors besides the strength of metals and corrosion resistance that must be considered are thermal expansion, thermal conductivity, resistance to abrasion, scaling, and oxidation. The search for an alloy steel that would resist the severe service in oil refining resulted in the development of chromium-tungsten steel. A series of tests are described in the development of properties required of a steel for high-temperature construction and service.

DURING recent years engineering interest in the design of equipment for operation at greater pressures and higher temperatures has steadily been increasing. This is true of structures of the most varied sorts, but actually has been most marked in the field of oil refining. The oil-refining industry, not perhaps as much hampered by tradition and precedent, and under greater pressure and increased efficiency, has not hesitated to construct and operate equipment, including valves and fittings, at temperatures as high as 1100 deg. fahr., as these progressive engineers and constructors have not feared to go to this temperature after experience and careful practical experiment.

However, the conservative attitude of engineers has been reasonable in view of the limited amount of information available upon the behavior of metals and alloys at high temperatures, and particularly on account of the manner in which it has been presented and regarded.

It is felt, however, that the rational interpretation of what is now known of the behavior of metals under stress and temperature justifies a less conservative attitude.

There is very little doubt that guessing and unsupported assumptions have liberally been indulged in, but it is certain that no solution of the problem is likely to command acceptance unless backed by specific established facts.

That the study of corrosion resistance and of the properties of metals at elevated temperature is receiving much attention is shown by the numerous articles on these subjects in the technical press, and from these articles valuable data have been accumulated, but it is certain that the entire investigation will be made far more simple when agreement is reached by various investigators.

Much of the apparatus now in operation in refinery service was designed from practical experience rather than from experimental research; and the experience gained from operation of certain equipment over periods of long duration gives results that are well worth considering, among which is the fact that certain alloys are resistant to peculiar corrosive conditions of refinery service and that, if these alloys are used, the so-called limiting creep stresses can be more than doubled over carbon steel when equipment is being designed for safe operation.

However, there are other factors besides the strength of metals and the corrosion resistance at elevated temperatures that must be taken into consideration, these factors being thermal expansion, thermal conductivity, resistance to abrasion, scaling, and oxidation.

The oil refinery, with its processes involving complex reactions mostly of a highly corrosive nature, presents special problems in the supply of a suitable alloy for tanks, evaporators, tubes, valves, fittings, etc., to restrain these corrosive activities from being exerted on the plant itself, either by direct contact or through other vapors.

Until recently the materials used in refinery service were cast iron, cast steel, and some limited use of bronze and brass. However, with the use of higher pressures and temperatures, many of the metals that formerly served the purpose are now no longer used except for unimportant service, and the refineries are now found to be in a state of transition toward the use of special metals and alloys, as had been experienced in other industries some years ago.

Special metals and alloys cannot fail to be of importance in affecting the destinies of refinery engineering progress; and developments in this direction should be of great interest, especially if noteworthy advances are to be made; for it has not been a difficult matter to increase the pressure of operation, because increased pressure can be taken care of by simply increasing the thickness of the metal used, but higher temperatures and greater corrosion resistance will have to be arrived at much more slowly and with greater caution.

What the refinery engineer needs is a comparatively cheap metal that will have high physical properties not impaired by high-temperature service. He needs a metal that is resistant to corrosion, a metal that will hold its surface under heavy sliding pressures, and one that will not suffer from abrasion due to the great velocity of the pressure and gases used; and in order that a metal or alloy may have this resistance to corrosion and oxidation, it must be stable at the temperatures employed and be capable of resisting for the economic life of the piece of equipment of which it forms a part the stresses to which it will be subjected.

All should like to see this ideal alloy, possessing, as it would

---

Previously he was associated with the Bartlett Hayward Company of Baltimore as engineer of tests. He is a member of the Joint Research Committee on the Effect of Temperature on Properties of Metals, the Heat Treatment Committee of the Iron and Steel Division of the A.I.M.E., the Foundry Committee of the A.I.M.E., the Committee on Steel Castings for High Temperature Service of the A.S.T.M., and the Committee on Pipe Flanges and Fittings of the A.S.A.

Presented at the National Petroleum Refining Meeting, Elizabeth, N. J., May 5 and 6, 1931, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society

have to, innumerable contradictory qualities, but it is not wise to sit down and wait for it. It is much more to the point to make the best of such metals as are now at hand and to believe until definite proof to the contrary, that progress is still possible with the use of existing alloy steels.

In these circumstances, the knowledge of the wonderful fertility of the field of alloys has stimulated the search for new alloys. Because of the developments of refinery processes now being pursued so vigorously and successfully in the direction of reactions carried out under high temperature and pressure, superior-strength alloys become still more desirable—in fact, a necessity.

To those engaged in the study of metallurgy, who are aware of the many directions in which alloying has been found to transform the physical properties of metals, the conferment of chemical stability by such means is entirely possible.

There was a time when manufacturers, as a general rule, did not care to bother with special steels or alloys, and particularly is this applicable to plants making specialized products, for the production of these in the regular conduct of business presented peculiar problems which could not be solved without much experimental work.

Because of demands made by the modern refinery for alloys to take the place of ordinary carbon steels (which have been used to a great extent in the past because of their relative cheapness and ease of fabrication) and on account of their recognized limitations, it has become necessary for the manufacturer of specialized products to develop particular alloys that are resistant to corrosion, abrasion, and oxidation and that at the same time maintain their strength at elevated temperature.

It is almost impossible to exaggerate the importance of the place that alloy steels are taking in the industrial world. The day of special alloy steels has certainly arrived, and the engineer who would keep in line with the march of progress should give more than momentary consideration to the spectacular advance of certain of these alloy steels.

Alloy Steel for Refinery Service

Years of laborious and costly scientific and practical research were required in the search for an alloy steel that would withstand the severe service encountered in oil refineries, and this work resulted in the development of chromium-tungsten steel. Its discovery and application have been made possible only through the coordinate help of the metallurgist and refinery engineer.

Metallurgists, as a general rule, have accepted the belief that metal consists of two states, a crystalline and an amorphous state. The crystalline phase or state is "thermally stable but mechanically unstable," and an amorphous phase is "thermally unstable but mechanically stable." This implies that the two phases are not fixed, but may vary according to given conditions.

According to White and Clark,[2] if it is desired to increase the strength of a metal consisting of two phases of unequal strength the following ways are open:

(1) The addition or formation of some substance which by its presence increases the strength of the weaker phase.

(2) The addition or formation of some substance which tends to remove the weaker of the two phases.

And from this it is first necessary to determine which of the phases is the weaker and then to take steps to strengthen or remove this weaker phase.

It is a well-known fact that at ordinary temperature the fracture of steel proceeds through the grains and not around them, this being caused by the greater strength of the amorphous boundaries. As the temperature is increased, however, the amorphous phase weakens at a more rapid rate than the crystal proper and a temperature is reached where it proceeds around the grains and not through them. This temperature, which Jeffries[3] calls the equicohesive temperature, corresponds closely to the recrystallization temperature. Therefore it is important to know over what temperature range and for what duration stability is desired before the effect of alloying elements can be properly determined.

White and Clark[2] advance the following hypothesis: If stability is desired below the equicohesive temperature, they find that—

(1) The addition or formation of any element, compound, or constituent which does not enter into solid solution with the matrix, but which by the very nature of its presence interferes with crystal slippage, will tend to increase the stability of the materials of which it forms a part.

(2) The addition or formation of any element, compound, or constituent which strengthens the grain boundaries by interfering with plastic flow will increase the stability of the material of which it forms a part.

Considering these foregoing principles and the effect of certain alloys upon the structure of metals to which they are added, it should be possible to predict and explain the influence of various alloy additions upon the stability of the resulting alloy.

Many alloying elements influence stability throughout the temperature range of the steels to which they are added, but the effect may vary depending upon the temperature under consideration.

The carbide formers, such as chromium and tungsten, increase the stability of metals below the equicohesive temperature because of carbide particles interfering with crystalline slippage, and they increase stability above the equicohesive range due to carbide formers at the grain boundaries interfering with plastic flow.

It is now generally recognized that, when a metal is alloyed with one or more elements, the properties of the metal are changed to a marked degree. Therefore, by suitably alloying a metal, for instance with chromium and tungsten, the properties of the resulting alloy possess profound qualities. One of the most important objects in the manufacture of chromium-tungsten steel is that the alloying elements enable one to decrease the injurious or undesirable properties and to intensify others that are preferred in the final product.

The effect of carbon as a constituent of steel is well understood, and the presence of chromium and tungsten intensifies the effect of carbon in all the best qualities that it is capable of producing alone. These increases take form not only in the physical results such as tensile strength, elastic limit, dynamic strength, resistance to wear and fatigue, increased hardening power, lack of brittleness, etc., but also in the purity, solidness, and homogeneity of the metal, because the alloying elements induce a freedom from occluded gases.

A quality often described as "tough hardness" is especially desired and is one of the outstanding features of chromium-tungsten steel. This so-called quality is in all probability due to the somewhat finer and denser structure of the microscopic constituents and their uniform distribution. This fine dense structure so paramount in quality steels is obtained only through the actual influence of the combination of alloying elements in producing in the steel a condition of purity and freedom from gases, and subsequently forms a metal which, at the time structural changes occur, is in the best possible condition for these changes to take place.

This dense structure is one of the major reasons for high physical properties and greatly increased resistance to fatigue, shock, erosion, and corrosion.

---

[2] "Stability of Metals at Elevated Temperature," University of Michigan Engineering Research Bulletin no. 11, Nov., 1928, pp. 92–94.

[3] "Effect of Temperature, Deformation, and Grain Size on the Mechanical Properties of Metals," Trans. A.I.M.E., vol. 60 (1919), pp. 474–577.

The addition of chromium and tungsten to improve the physical properties and corrosion resistance is particularly valuable because they possess, when added to steel, all the advantages of ordinary steels as regards casting and forging. This type of steel can be cast, forged, rolled, and stamped; it machines well, and the chemical and physical properties are readily under control and enable the manufacturer to consistently comply within reasonable limits of the specifications.

As the production of clean, sound steel is the first requisite, the second of great importance is the thorough and proper heat treatment, so that the alloy steel may possess the best properties of which it is capable.

ALLOYING ELEMENTS

The use of chromium as an alloying element to retard corrosion was first mentioned about 100 years ago when Faraday, in England, in 1820, made experiments with alloys to retard oxidation and when Berthier, in France, in 1822, reported that when a small amount of chromium was added to iron he found an alloy not readily attacked by acids.

Chromium has been called the "master metal" even in these days of spectacular advances in metallurgy, because it is almost indispensable and through its characteristic properties it probably affects a more diversified range of industrial activities than any other metal in common use except iron.

Chromium, either alone or in combination with iron, forms a very stable carbide, diffusing itself throughout the metal and inducing a fine grain and correspondingly great toughness because of its reluctance to accumulate into sizable masses.

Furthermore, the chromium remaining after all the carbon is satisfied enters in solution in the iron and confers considerable resistance against corrosion to the base metal. The addition of chromium does not increase the brittleness of steel, as would be the case were additional hardness obtained by the use of a higher carbon content. Chromium steels harden much deeper than the same steels without chromium, and as chromium refines the grain of the steel and is partially dissolved in the iron, both characteristics add to the toughness and hardness of steel—a truly remarkable combination.

Chromium produces certain characteristic effects on the properties of steel, as follows:

(1) It lowers the carbon content of the eutectoid ratio.

(2) It raises the temperature of transformation Ac_1–Ar_1.

(3) It forms with carbon a series of carbides which go into solution slowly. High temperature is necessary as the speed of diffusion of carbon is diminished.

Chromium dissolves in iron in all percentages, forming solid solutions with the ferrite. In the presence of carbon, however, it forms a double carbide with the iron. These carbides that are deposited within the crystals will interfere with the process of crystalline slippage, and for that reason materially increase the stability of the alloy at all temperatures below the equicohesive temperature.

The carbides which are precipitated at the grain boundaries will interfere with plastic flow in the material, and so increase the stability of the steel above the equicohesive temperature. However, the relation to the ductility above the equicohesive temperature must constantly be borne in mind.

It is generally agreed by metallurgists that the effect of chromium in steel is progressive and that there are no areas of composition the boundaries of which indicate abrupt changes in physical properties owing to transition of structurally free solid solutions to free carbides of different composition.

With chromium between 4 and 6 per cent there is no porosity in the form of pinholes when used in high-temperature service.

Likewise, compositions which produce the free carbides show greater strength in the alloys in which they are found than compositions which throw the carbides into solid solution as evidenced by the superior results obtained by the use of tungsten over and above nickel.

Tungsten, therefore, alloyed with chromium in steel, produces the best results as to stability either above or below the equicohesive temperature of any of the series of alloy steels tested.

Tungsten combines with carbon rather than with iron and exerts a very strong effect. It is essentially a carbide former.

Tungsten lowers the eutectoid percentage of carbon; but from the work accomplished, indications are that tungsten may not necessarily raise the Ac point to a great extent, but decidedly increases the rate of sluggishness at which this change takes place.

This same sluggishness is also encountered in the cooling cycle when coming out of solution, and a much greater hardness is developed.

The presence of tungsten increases the strength even in the cast or rolled condition, but like most alloy steels, the tungsten alloyed steels require heat-treatment to develop their best properties.

Tungsten has that ability to inhibit grain growth and gives a very high elastic ratio, and for the same strength has a much higher ductility than other types of alloy steels.

Perhaps the most important property of tungsten alloyed steels is their resistance to tempering, for in the softening after normalizing treatment it requires a very much higher drawing temperature and a longer time, which of course means that the steel may be used more safely at higher operating temperatures, and also due to the high draw, internal stresses are released to a much greater extent than with other types of alloy steels.

Inasmuch as tungsten alloyed steels do not require drastic quenching and have a slower rate for deep hardening the internal stresses may be kept very low.

Tungsten alloyed steels, particularly with the addition of chromium, show marked resistance to both the single blow and repeated impact, have excellent mechanical properties, and can be machined as readily as other types of alloy steels having much lower hardness.

Tungsten alloyed steels, with chromium, are characterized by the exceptional fineness of the grain, and this fine grain is undoubtedly a reason for high elastic ratio. Temperatures of treatment that would ruin most ordinary alloy steels can safely be used in the chromium-tungsten steels.

Tungsten is a distinctly modern metal, and the industrial applications are necessarily somewhat limited, but there is little doubt that if tungsten ores were more abundant and the metal more easily manipulated, it would displace other alloying elements for many purposes. Tungsten itself is harder than quartz, it never rusts, and it is insoluble in acids. Its expansion by heat is one-third that of iron, and it has a melting point of 6600 deg., which is greater than the heat of the electric arc. It is almost three times as heavy as iron, and its strength is greater than the strongest steel. It has been worked into wire 0.0002 in. in diameter—almost too thin to be seen, yet stronger than copper wire ten times its size.

Tungsten has that ability of sustaining high temperature without a breakdown, and any one familiar with shop practice knows that a tungsten alloyed tool is at its best when working at red heat.

CHEMICAL PROPERTIES

The chemical properties of chromium-tungsten steel meet the following specifications:

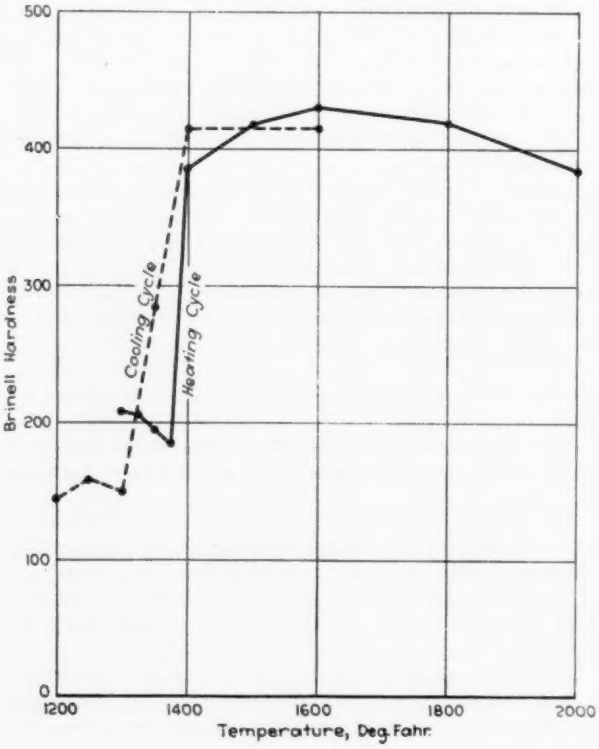

FIG. 1 HEATING AND COOLING CYCLES

Carbon	0.15–0.25
Manganese	0.55 max.
Silicon	0 50 max.
Chromium	4.50–6.50
Tungsten	0.75–1.00
Sulphur	0.05 max.
Phosphorus	0.05 max.

The chemical analysis of steels on which the following tests were made is as follows:

Rolled		Cast	
Carbon	0.153	Carbon	0.25
Manganes	0.43	Manganese	0.53
Silicon	0.12	Silicon	0.42
Chromium	5.89	Chromium	5.87
Tungsten	0.69	Tungsten	0.80
Sulphur	0.015	Sulphur	0.017
Phosphorus	0.019	Phosphorus	0.021

Test Results, Thermal Analysis, Rolled Steel. Disks were cut from the "as rolled" bars and held at the following temperatures for $^1/_2$ hour before quenching in water:

Temperature, deg. fahr.	Brinell hardness
1300	207
1325	202
1350	196
1375	187
1400	387
1500	418
1600	430
1800	418
2000	387

From this cycle the Ac transformation point appears to be between 1375 and 1400 deg., while the maximum hardness is obtained at 1600 deg., with 430 Brinell.

Quenching from higher temperature appears to retain the austenite.

COOLING CYCLE

Temperature, deg. fahr.	Brinell hardness
1600	418
1400	418
1350	286
1300	149
1250	156
1200	149

This cycle indicates the sluggishness of this type of steel in coming out of solution. A decided drop in hardness is noticed at 1350 deg. fahr., and a second is obtained at 1300 deg. fahr. where the maximum softness is developed.

From this it may be noted that in the heating cycle, employing a temperature range of 1300 to 2000 deg. fahr., there is a decidedly increased rate of sluggishness at which transformation takes place. This sluggishness is also encountered in the cooling cycle when coming out of solution, and this phase is common to tungsten alloyed steels. Maximum hardness is obtained at 1600 deg. fahr. From the hardness values as shown, it appears that austenite is retained at 1800 deg. fahr. and above. Heating and cooling cycles are shown in Fig. 1.

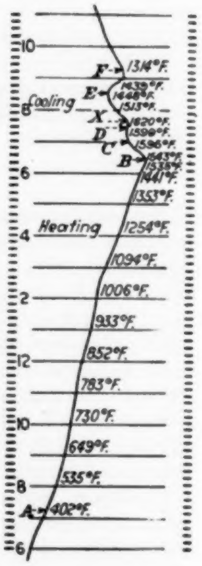

FIG. 2 TIME-DILATION CURVE

DILATOMETRIC ANALYSIS

Cast chromium-tungsten steel was studied to determine the critical points.

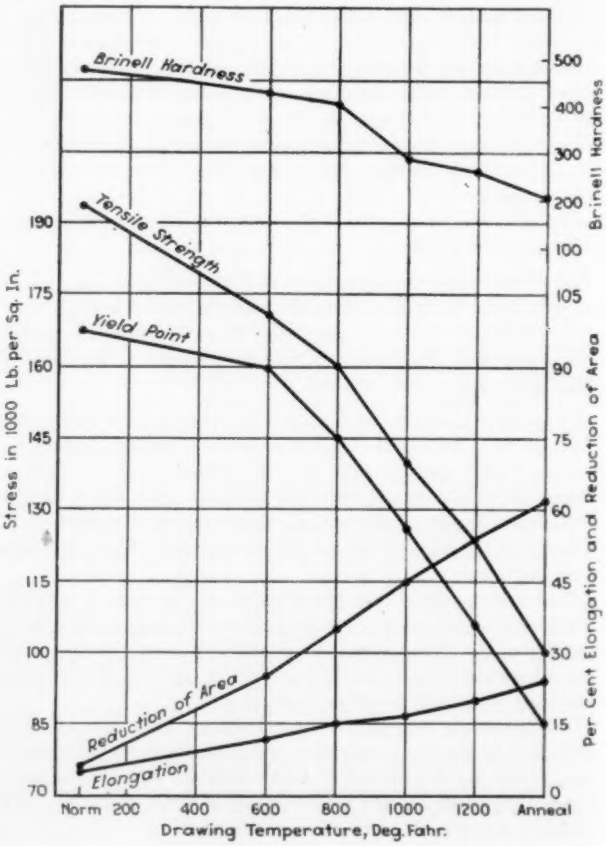

FIG 3 (RIGHT) EXPERIMENTAL HEAT-TREATMENT RESULTS

Fig. 2 shows a typical time-dilation curve as determined on chromium tungsten with the Rockwell dilatometer.

From curve *A* to *B* there is normal expansion of alpha iron. At *B* expansion stops and contraction begins, denoting the beginning of the Ac transformation.

From *B* to *C* the loss in volume due to the alpha-gamma transformation continues, as shown by the contraction, while from *C* to *D* nearly constant volume obtains, until solution of carbides is complete.

This "hold time" or period of nearly constant volume is quite characteristic of this type of steel. At *D* there is the beginning of reexpansion, denoting the completion of the Ac transformation. From *D* to *X*, at which point the furnace current was shut off, expansion of austenite takes place. Cooling at the normal furnace rate immediately starts, and there is a period of austenite contraction from *X* to *E*, where expansion marks the beginning of the Ar transformation. The increase in volume accompanying the gamma to alpha transformation continues from *E* to *F*.

Experimental Heat Treatment

Cast chromium-tungsten test bars were normalized at 1750 deg. fahr. and drawn at temperatures noted, after which three bars were tested in tension from each treatment with the following average results:

Fig. 3 shows test results, and Fig. 4 shows photomicrographs obtained from experimental bars.

Heat Treatment. The fact that steel is improved by heat treatment has been known for many centuries, but it has been only in fairly recent times that heat treatment of steel has been studied and to a great extent perfected.

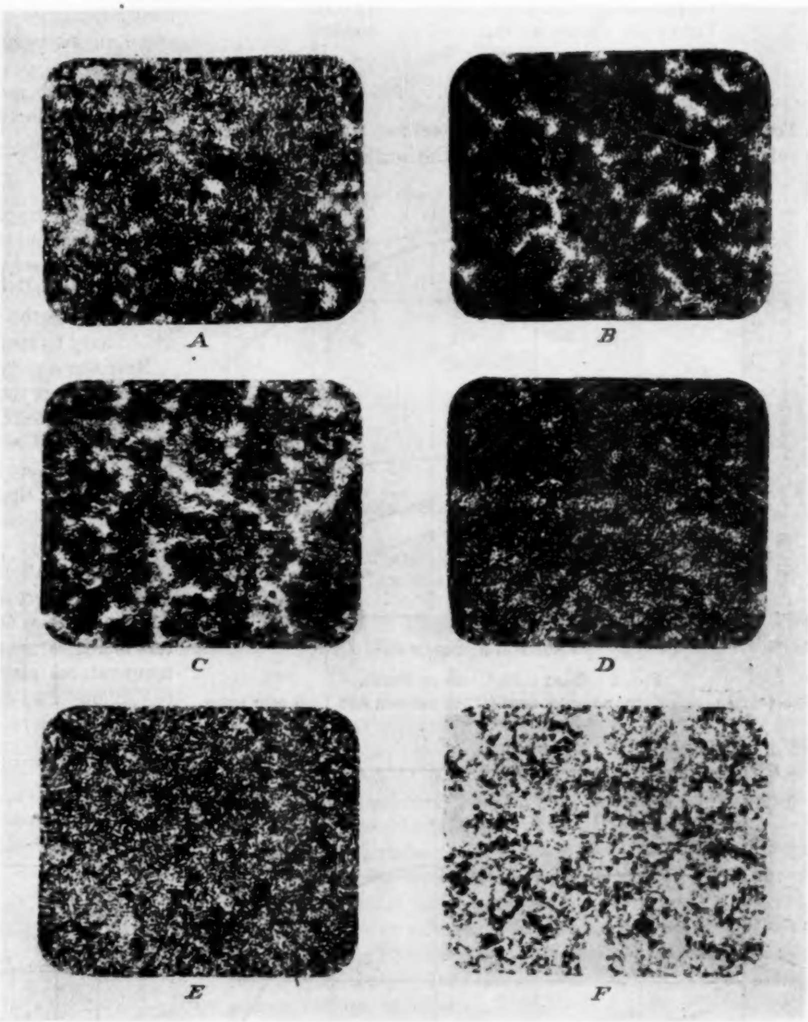

Fig. 4 Photomicrographs, Etched Nital × 100

(*A*, as normalized; *B*, drawn at 600°F.; *C*, drawn at 800°F.; *D*, drawn at 1000°F.; *E*, drawn at 1200°F.; *F*, annealed at 1600 to 1650°F.)

	Normalized	Drawn, 600 deg.	Drawn, 800 deg.	Drawn, 1000 deg.	Drawn, 1200 deg.	Annealed, 1600 to 1650 deg.
Tensile strength (psi)	193,860	171,000	160,570	140,000	124,000	100,000
Yield point (psi)	167,270	159,930	145,000	126,000	105,900	85,000
Elongation in 2 in., per cent	5	12	15	17	20	24
Reduction of area, per cent	6.7	25	35	45	54	62
Brinell hardness	490	425	401	285	260	210

Heat treatment, of course, will not give to steel the properties which it does not contain, but it does bring out and make available the properties that are inherent to the steel.

Without going into detail, the purpose of heat treatment may be summed up as follows:

(1) To increase softness and ductility.

(2) To secure a desirable combination of strength and elastic limit with fair ductility and resistance to shock.

(3) To eliminate any existing coarseness of grain and to impart to the steel a fine dense structure insuring toughness.

(4) To relieve any internal stress that may have been previously set up.

The first point to be considered is the temperature to heat steel past the critical transformation so that any existing coarse structure is broken down.

The second point is the time element or length of time that the steel should be kept at required temperature. Complete saturation of the steel is one of the most essential requisites to good heat treatment, and prolonged soaking is preferable to incomplete saturation.

The third point is the cooling, which should be as rapid as possible in order to retain the fine grain structure, after which it is necessary to draw, to such a temperature as to obtain the physical properties required.

From previous test results it was determined that a normalizing treatment at 1750 deg. fahr., followed by drawing at 1200 to 1250 deg. fahr., obtained the best physical properties and structure in order for the steel to retain its stability at temperatures of service operation.

The steel is held at the maximum temperature, so that the rate of heat penetration is $^1/_2$ in. per hour, after which it is withdrawn and cooled in still air.

After the steel has reached a black heat, it is reheated or drawn at 1200 to 1250 deg. fahr., and it is held at this temperature so that the rate of heat penetration is $^1/_2$ in. per hour, and then allowed to cool with the furnace. By this treatment, the following physical properties are obtained:

Tensile strength, lb. per sq. in...	125,000
Yield point, lb. per sq. in.......	100,000
Elongation in 2 in., per cent.....	18
Reduction of area, per cent.....	45
Brinell hardness................	240 to 260

Test Results. Just as ordinary cast steel met the requirements of refineries several years ago, so did the ordinary tensile test suffice for acceptance of steel. With the advent of high-temperature metals, however, a closer study had to be made of such properties of metals as resistance to shock, endurance limit, resistance to scaling and oxidation, resistance to corrosion, thermal expansion, short-time tests at elevated temperature, and finally the creep values when tested over long-time periods, because engineers are today demanding material that will "stay put."

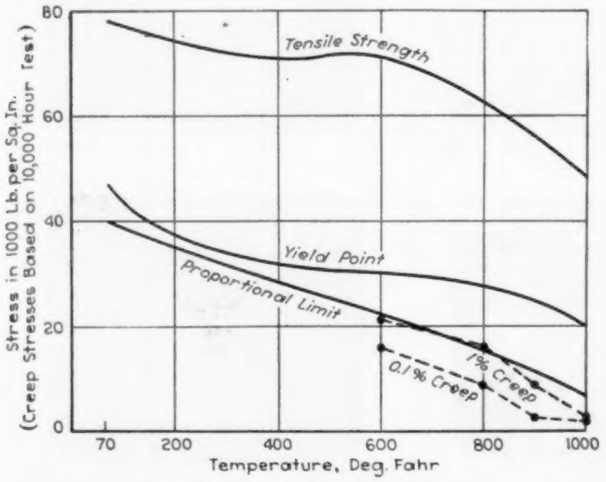

FIG. 5 CAST 0.35 CARBON STEEL

(Short-time tensile tests and creep tests for 0.1 per cent and 1 per cent creep in 10,000 hours.)

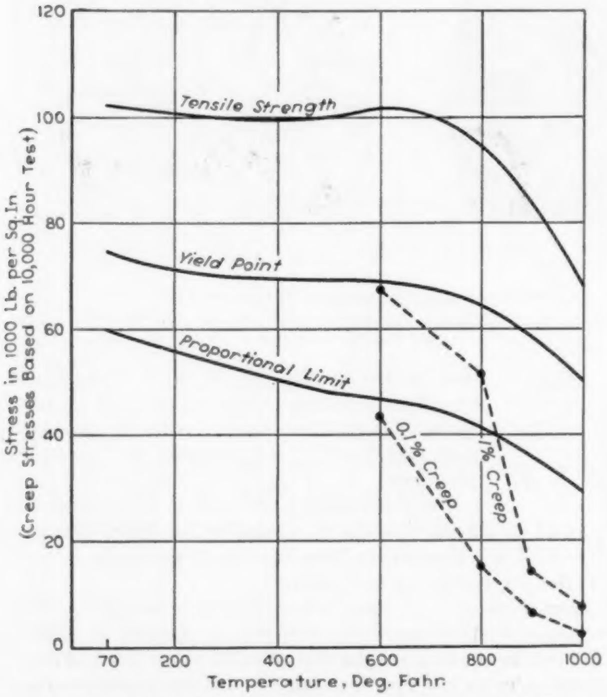

FIG. 6 CAST CHROME-NICKEL STEEL (0.35 CARBON, 2.00 NICKEL, 0.80 CHROMIUM)

(Short-time tensile tests and creep tests for 0.1 per cent and 1 per cent creep in 10,000 hours.)

The methods used for making these tests have been described in a number of previous papers[4] by the author and will not be repeated in detail.

HIGH-TEMPERATURE TESTING

What are the properties required of a steel for high-temperature construction and service? It is at once obvious that the primary characteristic acquired is the ability to carry loads continuously without appreciable deformation or at least harmful permanent deformation—the same characteristic as required in steel for use at ordinary temperature.

Now the ability of a steel to withstand stress, be it tensile, compression, or shear, at ordinary temperatures and continuously, is fairly indicated by the conventional short-time test. The standard steels will not usually fail under continued application of loads and stresses at ordinary temperatures which do not exceed one-quarter of their strength or one-half the elastic limit. Thus engineers have been able to utilize test data of this sort with adequate safety.

But the relation between the results of the conventional tests of steels of short duration and the capacity of the same steels to withstand stress changes markedly as the temperature of use and test increases; so much so that results of short-duration tests at temperatures above 700 deg. fahr. are inadequate criteria of continuous load-carrying capacity at those temperatures. At ordinary temperature steel flows or yields quickly if at all under

[4] "Investigation of Bolt Steels," by V. T. Malcolm and J. W. Juppenlatz, Trans. A.S.S.T., vol. 11, pp. 177–216. "Metallurgical Developments in the Valve and Fitting Industry," by V. T. Malcolm, *Mechanical Engineering*, Dec., 1925, pp. 1141–1143.

applied load—so quickly that its yielding may be easily observde and measured in the usual tensile test. But at higher temperatures steel may flow continuously under load, but so slowly that days, months, or even years are required to detect and measure it. At loads considerably below those at which in short-duration tests at high temperatures it will yield perceptibly, steel will yield slowly but continuously, and finally fail by rupture.

It is this fact, experienced from time to time, in attempts to push operating temperature limits higher, which undoubtedly has induced conservatism among engineers with respect to design of high-temperature equipment. The factor of ignorance was too great 15 years ago.

It is, however, in the author's opinion, no longer too great; in fact, our exact knowledge of the behavior of steels under continued applied load at high temperatures is in some respects better than that concerning steels at ordinary temperatures. Actual tests of flow or creep have been made on our steels, and it is confidently felt that it is known with a reasonable degree of accuracy the temperature and stress limits of their satisfactory and defined performance.

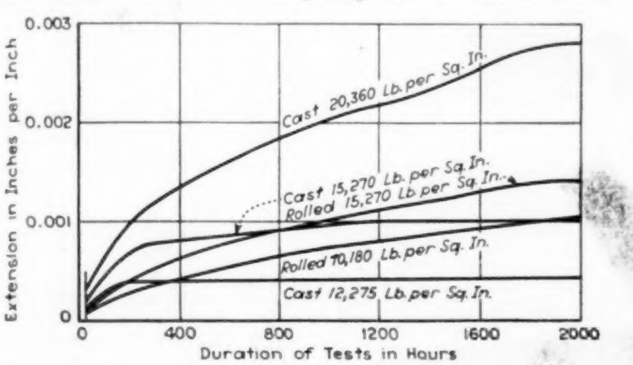

Fig. 8 Creep or Flow Tests on Chromium-Tungsten Steel at 1000 Deg. Fahr. With Various Loadings

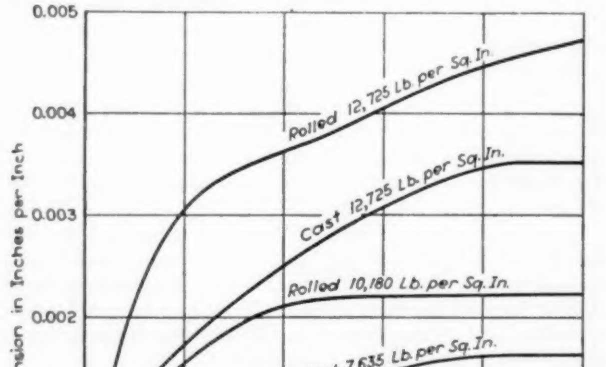

Fig. 9 Creep or Flow Tests on Chromium-Tungsten Steel at 1100 Deg. Fahr. With Various Loadings

Extensive investigation into the creep or flow of metal has demonstrated that for each composition of steel there is a range of stresses upward of zero, the continuous application of which does not produce rupture at least within reasonable periods of time, and for each of which there is, speaking approximately, a limit of deformation which also is not exceeded within reasonable periods of time.

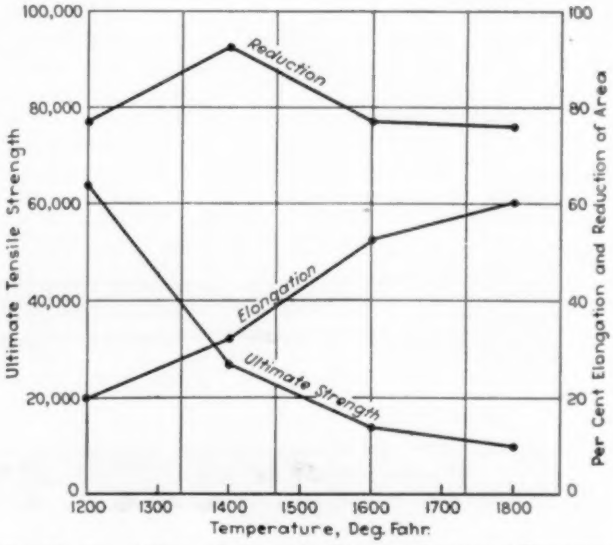

Fig. 10 Short-Time Tests on Rolled Chromium-Tungsten Steel at Temperatures From 1200 to 1800 Deg. Fahr.

One may call these ranges of stress creep-limit stresses; that is, he stresses at which certain limiting values of creep are not exceeded (within reasonable periods of time). Thus a 1-deg. creep-limit stress at 1000 deg. fahr. is that stress which may be safely applied, probably indefinitely, without rupture and without more than 1 per cent deformation.

Creep-limit stresses as determined by tests of the sort described may serve quite satisfactorily as safe design limits for high-temperature valve and fitting construction, and in fact are the only determinable stress limits which may so serve, and this fact has been amply confirmed by the experience of the author and his company in the practical design, construction, and operation of valves, fittings, and bolts. It is obvious that different types of construction will allow of different limiting values of deformation, for which different creep limit stresses would be required as safe design limits.

Figs. 5, 6, and 7 give short-time and limiting creep stresses of several steels at various temperatures with 1 per cent and 0.1 per cent deformation based on actual 10,000-hour tests and not calculated from short-duration tests.

Figs. 8 and 9 show results of creep tests carried out on chromium tungsten steel at 1000 and 1100 deg. fahr. with different loads.

Fig. 10 shows results of short-time tests on rolled steel from 1200 to 1800 deg. fahr.

Other Tests

Under this heading is included impact, both single blow and repeated bending, endurance, torsion, bend, scaling, thermal expansion, and resistance to corrosion.

Impact Tests. This method of testing steels is considered to be one of the most important of the mechanical tests, as it affords a reliable indication of the resistance to deformation (of hardness and tensile strength) and also when cohesion is small in relation to internal frictional resistance to distortion of the cohesive strength. In our work an Amsler Charpy type machine was used with capacity of 125 ft-lb.

With heat-treated chromium-tungsten steel, the rolled sustained 110 ft-lb. average and the cast 18 ft-lb. average. The cast heat-treated material was aged at 950 deg. fahr. for 20 hours and then tested, by impact, to 19 ft-lb. When aged at 850 deg. fahr. for 20 hours and tested, by impact, it sustained 19.6 ft-lb.

Repeated Bending Impact Tests. In this test on heat-treated chromium-tungsten steel an Eden Foster machine was used to reproduce stress conditions which are met with where the effect of alternating blows is produced on the material at positions where there is a reduction of the cross-section.

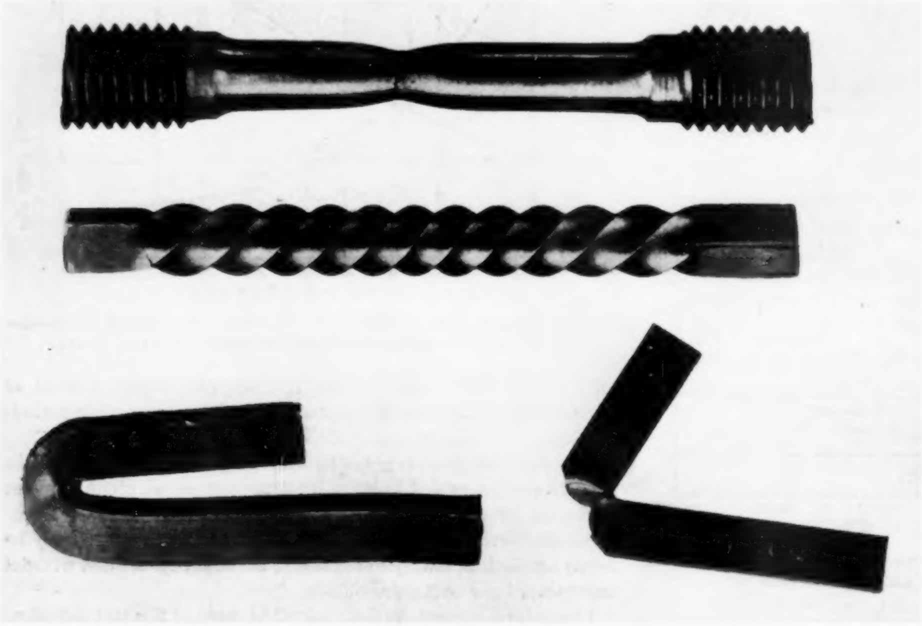

Fig. 11 Chromium-Tungsten Steel Bars After Various Tests
(Upper, tensile test, cast metal; middle, torsion test, cast metal; lower left, bend test, cast metal; lower right, impact test, rolled metal.)

The test bar is fixed in the machine where it receives the blow on a reduced section at the rate of 90 blows per minute with a hammer whose weight is 5 lb. and which falls from a height of 4 in. Between each blow the bar is turned through 180 deg., and test is continued until failure occurs. The rolled sustained 1400 blows and the cast 850 blows. The cast heat-treated material was aged at 950 deg. fahr. for 20 hours and tested to 870 blows. When aged at 850 deg. fahr for 20 hours and tested, it sustained 860 blows.

Endurance Testing. The ratio of the bend endurance limit to the tensile strength of a metal may be called the endurance ratio or, more specifically, the "bend tension static endurance ratio."

Endurance or fatigue machines are of two forms, the beam type or cantilever type. In our work we used the Farmer beam type, as modified by Prof. H. F. Moore.

Endurance or fatigue tests are made on these machines by taking a number of test pieces, beginning with a stress about one-half the tensile strength of the metal, and testing to destruction. The stress is somewhat reduced in successive tests until a load to withstand 20×10^6 is obtained without fracture. This test is very desirable for determining the endurance properties of the steel used for bolts and spindles for high-pressure and temperature service.

With heat-treated chromium-tungsten steel, tested to an endurance of 20×10^6 cycles, the rolled showed 46 per cent of tensile strength and the cast 43 per cent of tensile strength.

Torsion Tests. The ultimate strength in torsion of the heat-treated cast chromium-tungsten steel was found to be 92,000 lb. per sq. in. and the angle of twist 1050 deg.

Bend Tests. In both the heat-treated cast and rolled chromium-tungsten steel it was found that test bars would bend through an angle of 180 deg. Fig. 11 shows chromium-tungsten steel bars after various tests.

Thermal Expansion. Thermal expansion is one of the most important points that has a direct bearing on design of equipment for safe operation at high temperature, and it can reasonably be assumed that many failures taking place at high temperature are caused by the use of a combination of metals entirely unsuited for the work or from lack of knowledge on the part of the designer of certain stresses, not readily calculated, due to the non-uniformity of temperature distribution.

A test of the mean coefficient of expansion of heat-treated chromium-tungsten steel was as follows:

	Rolled, per °F.	Cast, per °F.
70°F.	....	....
300°F.	0.00000623	0.00000648
550°F.	0.00000673	0.00000692
800°F.	0.00000695	0.00000710
1000°F.	0.00000703	0.00000715

Wear and Abrasion. Hardness appreciably improves service performance, but hardness itself is no certain criterion of erosion resistance, as this depends to a great extent upon the structural composition. Hardened and drawn steels are superior for severe service conditions on account of their toughness, and this toughness is certainly a factor that tends to resist erosion and wear.

Resistance to erosion and wear does not, in general, increase directly with strength and hardness. Both hardness and toughness are important factors in determining the wearing qualities of a steel, because hardness increases resistance to penetration, scratching, and displacement of metal, while toughness makes it difficult to tear off small particles of metal.

Therefore, chromium-tungsten steel which has a considerably higher hardness and toughness for the same treatment than other alloy steels is better suited to resist erosion and wear.

It should be remembered at this time that any hardness or toughness produced in any steel by quenching and tempering will be lost in service if the tempering operation necessary to produce the required hardness and toughness has been carried out at a temperature below the operating temperature.

Chemical Stability. Excellent physical properties at elevated temperatures, however, are not the only criteria to be used in selecting metal for this service, as scaling and oxidation are decided factors. The real difficulty in connection with high-temperature work is the combining of necessary physical properties with some particular chemical stability so as to have correct design for the complete unit.

Problems of corrosion at high temperature, while not so formidable, are far more difficult to solve because of greater chemical affinity at elevated temperature.

Corrosion Testing. The ultimate aim of all corrosion tests should be to derive a comprehensive series of tests to which standard specimens of materials may be subjected and by which the rate of corrosion of these metals may be predicted for certain service conditions.

One of the most important though somewhat neglected studies of the corrosion problem is the action of various gases at high temperature.

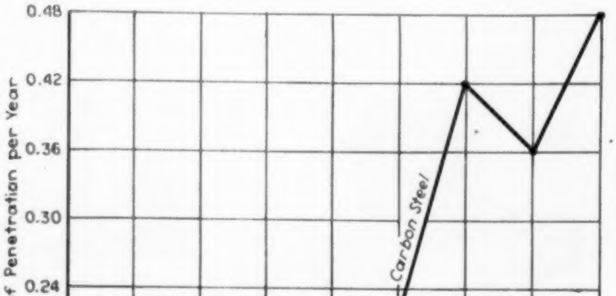

FIG. 12 TESTS ON SEVERAL STEELS IN REFINERY SERVICE AT 850 TO 930 DEG. FAHR.

(Tests 1 to 5, regular crude; 6 to 8, west Texas crude. Each test was of 10 days' duration.)

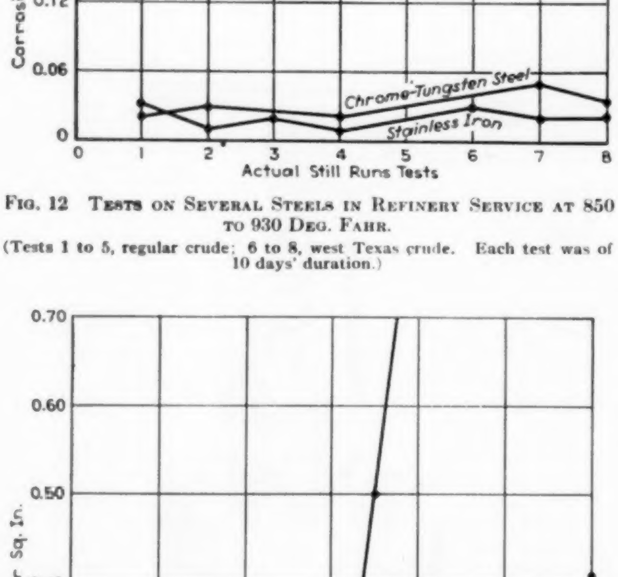

FIG. 13 SCALING TESTS ON SEVERAL STEELS

(Twenty cycles of test; each test of 12 hours' duration.)

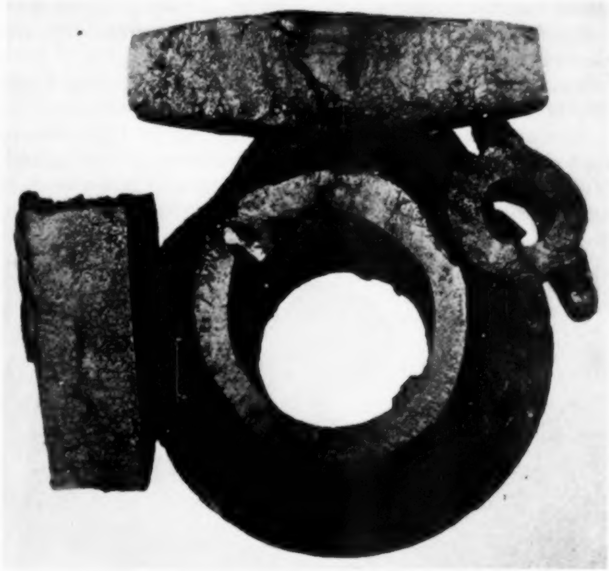

FIG. 14 BROKEN 1350-LB. STEEL VALVE BODY

(In the "as-cast" condition. Note soundness of metal.)

Therefore, in the study of corrosion there are two conditions to consider; namely, "erosion," which is the disintegration or destructive action by physical causes, and "corrosion," which is the disintegration or destructive action by chemical causes.

Little is really known about the mechanism and true nature of corrosion, and so much depends upon the kind of reaction produced that it is hard to make a prediction, based on laboratory tests, as to what will happen after a piece of equipment has been in service a month.

In our work, efforts have been made to overcome this difficulty in determining true corrosion by using apparatus designed as nearly as possible to duplicate service conditions, and by noting the film) pitting, etc., and reducing the work to inches of penetration per year or month, so that a relative figure may be obtained for different classes of metals. Only service tests, however, tell the true story. Fig. 12 shows tests of several steels in actual refinery service. Fig. 13 shows results of scaling tests on several steels.

UNUSUAL TESTS

A number of unusual tests were made to determine the fitness and solidness of chromium-tungsten-steel valves, and a résumé of certain of these tests is given.

Destruction Tests. A number of valves were broken in the "as cast" condition to determine the soundness and homogeneity of steel. Examination revealed that the castings were solid throughout, showing no porosity, cracking, or interior shrinkage due to poor molding or steel-making practice.

Fig. 14 shows a broken 1350-lb. valve body, as cast.

Valve bodies were heat-treated by normalizing at 1750 deg. and drawing at 1250 deg., and then tested in order to determine their resistance to shock and the ductility of the steel. The procedure in this test was as follows:

Valve bodies were placed on a steel bed, and a 3000-lb. ball was allowed to drop through 40 ft., hitting the casting directly in the center, each blow having an energy of 120,000 ft-lb. As many as six blows, making direct hits on the casting, were required to break it. This test shows the remarkable resistance to shock and the splendid toughness of the chromium-tungsten steel.

Part of a flange was taken from a casting and placed under a power hammer having a striking energy of 1200 ft-lb. per blow, and 200 blows were required before failure occurred. The section was reduced 33 per cent before fracture.

Fig. 15 shows a chromium-tungsten fitting after impact test. Fig. 16 shows a chromium-tungsten valve after impact test.

In connection with testing of steel castings for high-pressure, high-temperature service, the author believes that test bars are indicative only of the quality of the metal and heat treatment and do not give an idea as to the strength or solidness of the casting itself. Neither does he believe in taking test bars cut from castings, for the reason that they do not show the true conditions.

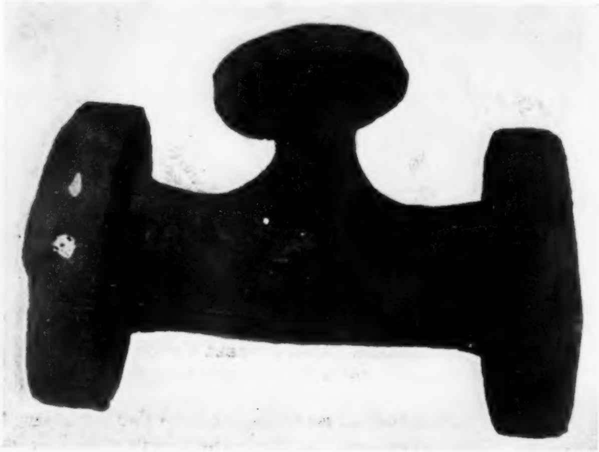

Fig. 15 Heat-Treated Chrome-Tungsten-Steel Fitting Unbroken After Test

(This was after having been struck six times by a 3000-lb. ball dropping 40 ft.)

However, with molding practice standardized in such a manner that "shrink heads" and gates are the same for each group of castings poured, it may be better practice to test a certain casting or number of castings from each group made from the same pattern.

By this method, strength, ductility, and toughness may be readily noted, as well as any other defects such as shrink, blowholes, piping, cracks, etc.

This method of test is in use by the author's company and has proved of great value.

From the results of our tests, it will be noted that the usual factors of safety as employed are sufficient, and should stresses be reached which would produce creep, there is only a remote probability of rupture until at least 20 to 25 per cent of the total creep or distortion has taken place.

This means, with the use of chromium-tungsten steel, that should factors of safety for some reason or other be neglected and a valve be subjected continuously to high temperature and great pressure, so as to build up circumferential creep of 0.03 in. per year, it would simply result in slight expansion of the valve and would do no harm as regards safe operation of the plant.

Fig. 17 shows a 1350-lb. oil-refinery valve for 1200 deg. of temperature.

Cost

That chromium-tungsten steel, on account of the costly alloys used, is necessarily more expensive than ordinary steels, is met by the fact that the length of service life has been increased and, most important, great savings are effected by much less frequent renewals, and while there is no doubt it will require time to convince some refinery engineers of the advantages gained, its use must eventually be found to be highly economical.

Conclusions

In summing up the various factors that enter the design of apparatus for high-temperature service, the most outstanding is the fact that the relation of stress to strain can no longer be represented by Hooke's Law.

In the study of steel specifications much is found on heat treatment, tests, and chemical analyses, but nothing is stated about manufacturing methods, except to specify the steel-making

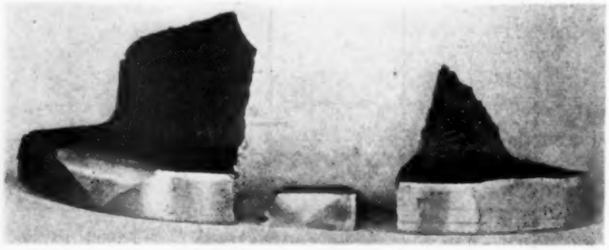

Fig. 16 Result of Power Hammer Striking Broken Flange of Chrome-Tungsten-Steel Valve

(Small piece in center was struck 200 blows with a 600-lb. hammer dropping 2 ft., before fracture occurred. Compare reduction with other flanges.)

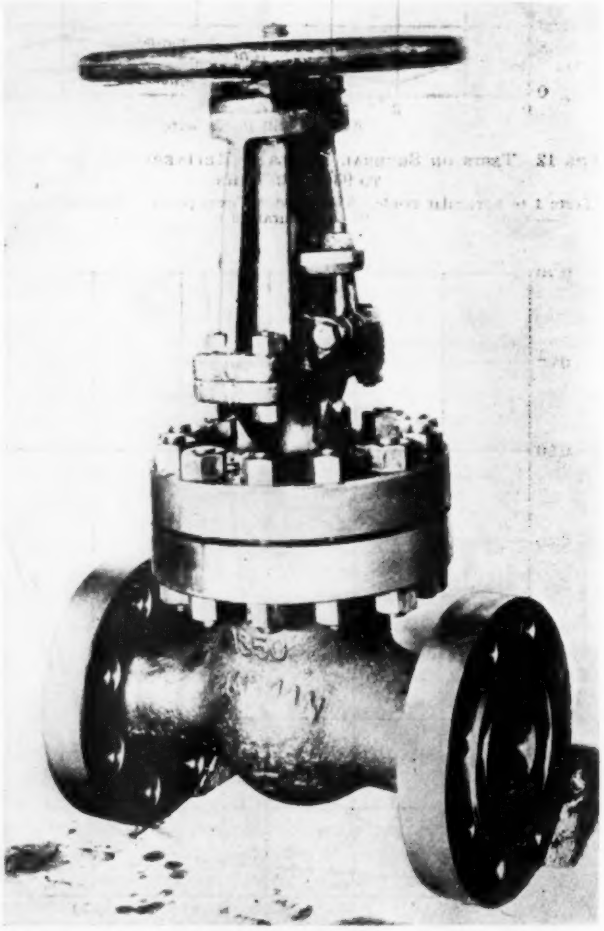

Fig. 17 A 1350-Lb. Refinery Valve for 1200 Deg. Fahr. Operation

process and that the steel must be free from injurious defects. From this one may infer that, as long as the steel meets the clauses specified, the quality of the material and method of manufacture are not questioned, and any failure in service must be from some other source than material. This inference is incorrect, for while certain steels meet specifications, manufacturing methods, if not correct, may cause a lot of trouble to the ultimate consumer.

With such conditions in mind, it is of the utmost importance to place rigid inspection and safeguards other than specifications on steel being made for high-temperature service, to insure it being correct for the purpose intended.

As previously stated, our company recognized that something better than ordinary steel was required in the oil-refining industry owing to the highly corrosive and high-temperature conditions, and it is our firm belief that chromium-tungsten steel will materially increase the life of valves and of fittings in the oil refinery.

While in other practical applications chromium-tungsten steel may be regarded as past the experimental stage, there is a strong reason to believe that with increased production and various advances now being made in manufacture, the market for this steel will become much broader.

PME-54-4

Evolution of Pressure Vessels to Meet Present-Day Refining Pressures and Temperatures

By H. LeROY WHITNEY,[1] NEW YORK, N. Y.

In the growth of the oil-refining process to meet the demand for fuels for internal-combustion engines, the pressure vessel has played a foremost part. The paper covers the progress of riveting and welding in perfecting a tight and dependable container. Failures attributed to defective plate and to defective welding led to greater experience and operating knowledge. Recognizing the future tendency to still higher temperatures and pressures, research was devoted to developing a new method of electric welding and the rolling of smooth seamless cylinders of large diameter with which to fabricate vessels of any commercial requirement.

TWO factors are responsible for the strides made in refining processes: the advent of the motor car and competition within the refining industry itself. Two decades ago the refining process consisted primarily of topping straight-run gasoline and kerosene in shell stills. Such vessels as were required were of light wall, and riveted construction was adequate. Pressures were low, temperatures were negligible, and high rate of production was not a factor. The motor car changed all of this. As internal-combustion motors became more perfect, fuel requirements not only grew tremendously, but became more exacting. The chemical engineer of the refining industry was called in to knock off a few hydrogen atoms here, add a few carbon atoms there, and generally change nature's idea of things.

To accomplish this interchange of structural atoms, both heat and pressure were necessary and the refining plant began to lose its general appearance of a disjointed steam plant and assume the appearance of the modern refinery as known today.

In the pressure-vessel industry, during the birth of "cracking," riveting was the generally accepted method of joining steel plates. Oils, and especially hot oils and vapors, have a peculiar method of rapidly and with general abandon finding their way through a riveted joint, and it required only a brief investigation to convince the operating man that something must be done.

Almost paralleling the change in refining methods was the development of forge-and-hammer lap welding. This process was not new in America 30 years ago, but as practiced was crude, uncertain, and not always satisfactory. M. W. Kellogg believed that the development of a welding process that resulted in a product bottle-tight and entirely dependable would be an essential contribution to the refining industry.

Both oxyacetylene and electric-arc welding as practiced at that time were fully investigated, considerable experimenting was done, and several vessels were built, but neither process gave such results as was believed necessary. Attention was then turned to the forge-welding process, and development was conducted until the product was dependable and satisfactory.

There were certain limitations to this process evident from the start: (1) The quality of the product depended on the human element, (2) entirely uniform steel plate was not available, (3) plate in excess of 2 in. could not be economically welded, and (4) only low-carbon plate, and consequently low-tensile-strength plate, could be welded.

For general purposes, however, the process was eminently successful, as is evidenced by the many hundreds of vessels that were produced, some of which have seen many years of service and are still in operation.

As is the history of any epoch-making development, in the development of the refining of petroleum there were pressure-vessel failures. Some could be attributed to defective plate and some to defective welds, but the greater proportion was due to lack of operating knowledge and experience. Little was known of the difference between sweet and sour crudes, and when the latter were used, vessels were operated in many instances long after they had corroded away, above the liquor line, to a thickness where failure was inevitable. The vessels which are particularly referred to were partially full of oil under pressure and direct-fired. Every operating man was endeavoring to increase his output of gasoline, and as a consequence many vessels were kept on stream until the layer of deposited coke was so thick that it acted as an insulator, causing overheating of the wall of the vessel which often caused failure. Improper design also contributed to failures.

The lessons learned from these failures resulted in a great advancement of the art of welding and in the design of the vessels. The results of the knowledge obtained were as follows:

1 More stringent material specifications.

2 Increase of the knuckle radii of dished heads until the ellipsoidal-shaped head was produced.

3 Proper reinforcement of openings.

4 The necessity for stress-relieving of the completed vessel.

5 Marked improvement in pressure-still operations.

6 Direct firing of pressure stills was an unnecessary hazard.

The art of refining was also moving forward, increasing the temperatures and the pressures, which, combined with large-diameter vessels, exceeded the welding capacity of the forge-welding process. Seamless forged vessels were being used with entire satisfaction when properly constructed, but their use was limited both for economic and physical reasons. Heavy riveted vessels also were being used, in some cases with calked seams and in many cases with seal-welded seams and rivets. Neither type of riveted vessel filled the requirements of the service.

---

[1] Chief Engineer, Piping and Pressure Vessel Division, M. W. Kellogg Company, Inc. Mem. A.S.M.E. Mr. Whitney was born in New York City in 1884. He was educated at St. Paul's School, Concord, N. H., and at Sheffield Scientific School, Yale University, graduating in 1905. After a brief experience in mining, he joined the Kellogg organization in August, 1906, and has been with it ever since, except for service with the First New York Field Artillery on the Mexican border in the summer of 1916 and during the World War from June, 1917, until May, 1919; served with 302nd Field Artillery of the A.E.F. He is a director of the Kellogg company. Mr. Whitney is a member of the Boiler Code Committee of the A.S.M.E.

Presented at the National Petroleum Refining Meeting, Elizabeth, N. J., May 5 and 6, 1931, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

Recognizing the future tendency of the industry toward still higher temperatures and pressures, two research programs were authorized involving the development of a new method of electric welding and the rolling of smooth seamless cylinders of large diameter with which to fabricate vessels of any commercial requirement. The reason for the development of seamless cylinders rolled from pierced ingots was that this seemed the best method by which clean, tough steel of uniform structure and analysis could be manufactured. The benefit by the elimination of the longitudinal joint is obvious.

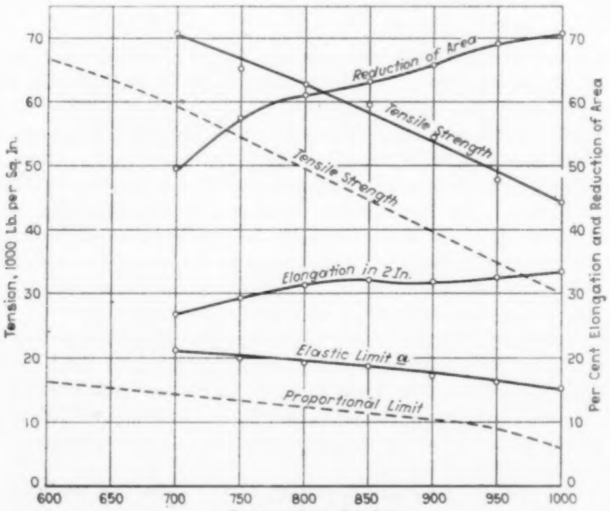

FIG. 1 SHORT-TIME TENSION TESTS AT HIGH TEMPERATURES

[Solid line, Kellogg seamless steel, 0.18 per cent carbon: broken line, 0.24 per cent carbon boiler plate, as reported by H. J. French in Bureau of Standards Technical Paper No. 296. Each plotted point represents the average of four test bars (standard 0.505-in. bars) taken from a seamless cylinder 78 in. inside diameter by 1$^3/_4$ in. thick. a (On Elastic Limit line) Comparable to the proportional limit as determined by H. J. French. Elastic limit determined with extensometer dial; one division equals 0.0001 in.]

Coincident with the use of higher operating pressures and temperatures has come the study of the properties of steels of various analyses under these conditions. A great amount of commendable work has been done, both on short-time high-temperature tests and long-time tests, to determine the proportional limit and creep values. There is a wide divergence of opinion on the subject of creep, but the important thing is to analyze the data available and to apply it correctly, taking into consideration the service for which the steel is destined. A very small amount of creep would destroy the efficiency of a turbine, whereas in a pressure vessel a considerable amount of creep is not harmful; and, further, the desired life of any particular pressure vessel must also be taken into consideration, not forgetting that where excess thickness is provided to take care of corrosion, the approach of the creep point is materially postponed.

There are two kinds of steel that ordinarily are used in the manufacture of plate, seamless cylinders, seamless forgings, and tubing—namely, rimmed and killed carbon steels. In both short-time and long-time high-temperature tests made on these kinds of steel, the manganese content has been given very little consideration, for the reason that most commercial steels are fairly low in this element. It is quite definite, however, that at high temperatures between 800 and 1000 deg. an increase in the manganese content from nominal manganese of 0.30–0.50 to 0.60–0.80 is much more beneficial than an increase in the carbon content from 0.20 to 0.30. Most authorities will concur with this statement.

Another point on which most authorities seem to agree is that the elastic limit or proportional limit of steel at high temperatures, as determined by short-time high-temperature tests, is a very fair indication of what creep value may be expected if long-time tests were run.

Fig. 1 is a chart of short-time high-tension tests at high temperatures. Kellogg seamless-cylinder material, shown by the solid lines, is compared with 0.24 per cent carbon boiler plate, shown by broken lines, as reported by H. J. French in Bureau of Standards Technical Paper No. 296.

Fig. 2 shows a transverse fracture of a rimmed steel ingot where the line of non-oxidized blowholes is very clear. Attention is called to the uniform distance of these blowholes from the ingot wall, and also to the depth, which indicates the very best rimming practice.

In addition to these non-oxidized blowholes, which theoretically are welded up when the ingot hits the blooming mill, segregation takes place in the steel while it is cooling, and not only is the dirt driven to the center and top of the ingot, but the carbon and other impurities also follow the same path to a considerable extent. The larger the ingot the more evident is this segregation, and chemical and physical analyses of any quantity of plates will show higher carbon content and higher tensile strength in the test bar taken from the end of the plate that represents the top of the cropped ingot than in the test bar taken from the end of the plate that represents the bottom of the ingot. In fact, A.S.T.M. Specification for Firebox-Quality Plate permits a 15,000-lb. variation in strength in the two test specimens from the same plate, and no limit as to the variation in chemical analysis is specified.

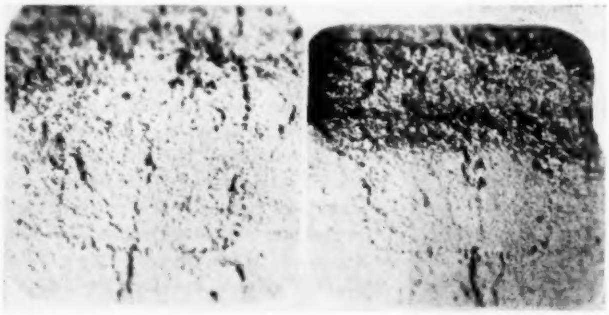

FIG. 2 RIMMED STEEL INGOT SECTION, SHOWING NON-OXIDIZED BLOWHOLES

FIG. 3 PIERCED INGOT BEFORE MACHINING

Unquestionably a certain amount of segregation goes on even in an ingot of killed steel while it is cooling, but as proof of the fact that this segregation is less than in rimmed steel, chemical analyses were made from samples taken from both ends and from the outer and inner walls of a great number of cylinders. These chemical analyses were so uniform that it is a fair statement to make that seamless cylinders rolled from pierced killed steel ingots are of uniform chemical analysis throughout. Table 1 shows the results of these analyses and gives the maximum, minimum, and average variation in carbon, manganese, etc.

TABLE 1 RESULTS OF ANALYSES

Element	Maximum	Minimum	Average
C	0.04	0.01	0.02
Mn	0.03	0.00	0.02
P	0.012	0.003	0.006
S	0.013	0.003	0.007

The cleanness and a certain amount of the uniformity of the steel is unquestionably due to the method of piercing, wherein the major portion of the center of the ingot, after it has been cropped, is punched out in the form of a slug.

Fig. 3 shows a pierced ingot at the plant of the Midvale Steel Company before being machined. The uniform wall thickness is to be noted. The reason for machining the outside of pierced ingots is to remove all possible laminations, slips, or surface cracks that always are present in the surface of rough forgings.

Fig. 4 shows a finished rolled cylinder 9 ft. inside diameter by 2 in. thick. Attention is called to the smoothness and true cylindrical shape. The only machining required on the finished cylinders is squaring up of the ends or the machining of welding grooves preparatory to welding.

The maxium dimensions of these seamless rolled cylinders are length 10 ft. and inside diameter 12 ft. The maximum weight of billet which can be handled at the present time is 25 tons. A 25-ton billet will give a cylinder 10 ft. long, approximately 3 in. thick at the maximum inside diameter of 12 ft., or 6 in. thick with an inside diameter of 6 ft. Shorter billets with a greater wall thickness can of course be handled, which would result in shorter finished cylinders of greater wall thickness. The minimum diameter to which cylinders can be rolled is approximately 36 in., but the rolling of small-diameter cylinders is not economical unless the walls are reasonably heavy.

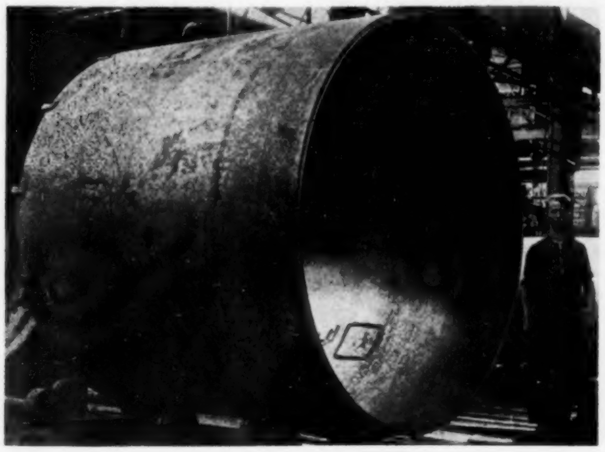

FIG. 4 ROLLED SEAMLESS STEEL CYLINDER, 9 FT. INSIDE DIAMETER BY 2 IN. THICK

Kellogg cylinders are rolled from hot-topped ingots of killed acid open-hearth steel of firebox quality, in two grades: grade 1 with a carbon content not exceeding 0.30 and grade 2 with a carbon content not exceeding 0.50. The minimum physicals guaranteed for these two classes are exactly the same as the minimum physical requirements for grades 1 and 2 seamless steel drum forgings, Specification S-4 of the A.S.M.E. Boiler Construction Code. The minimum tensile strength and elongation in 2 in. of the two grades are: grade 1, 60,000 lb. and 26 per cent; grade 2, 75,000 lb. and 24 per cent.

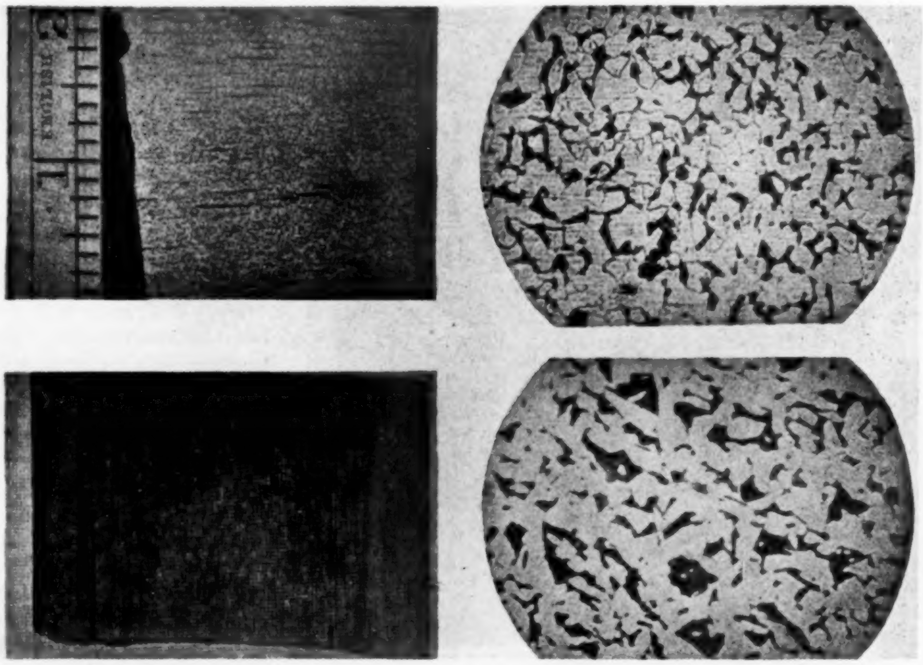

FIG. 5 MACROGRAPH OF SEAMLESS CYLINDER MATERIAL (ABOVE) AND OF A SPECIAL WELDING QUALITY PLATE (BELOW)

(The seamless cylinder material was etched 40 min. and the plate 20 min. in hot 1-to-1 hydrochloric acid. The respective micrographs at the right of each specimen show the grain structure.)

To illustrate the uniform physical characteristics, test specimens were taken from one lot consisting of 10 finished cylinders 9 ft. in diameter by 2 in. thick, having an average carbon content of 0.17 per cent. The maximum and minimum tensile strength, yield point, elongation, and reduction of area are given in Table 2.

TABLE 2 PHYSICAL CHARACTERISTICS OF TEST SPECIMENS

Tensile strength, lb.	Yield point, lb.	Elongation in 2 in., per cent	Reduction of area, per cent
69,750 (maximum)	48,350	33	61.3
65,250 (minimum)	40,450	29	48.4

The excellent physical qualities of this steel of comparatively low carbon content are due, first, to the steel from which the cylinders are made; second, to the working of the steel longitudinally in the piercing operation; third and most important, to the rolling of the cylinders which works the steel in the direction opposite to piercing and lays the fibers circumferentially and parallel to the line of greatest stress in a cylinder subjected to internal pressure.

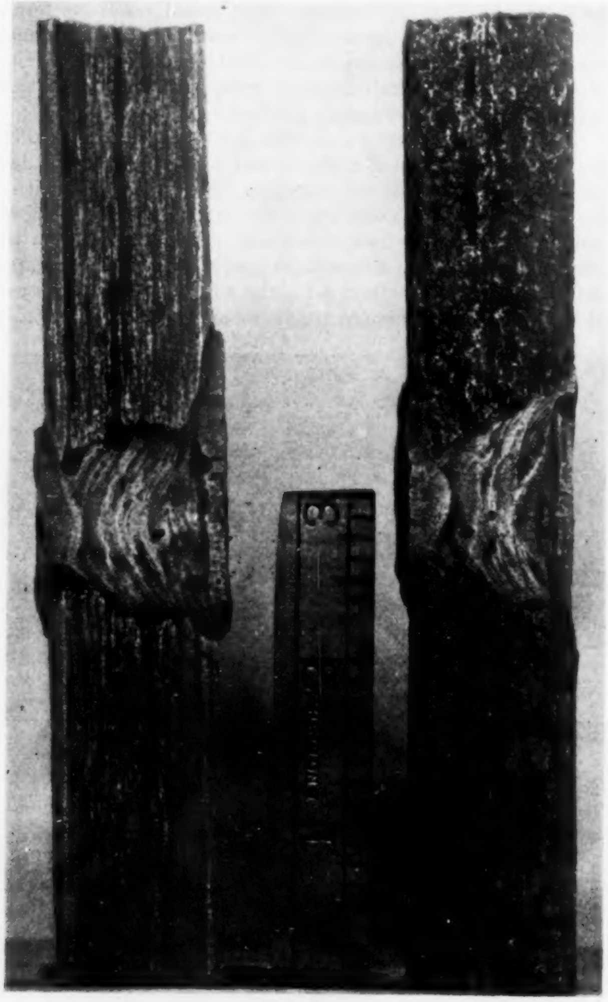

Fig. 6 Special Welding Quality Plate (Left) and Rolled Seamless Cylinder Material (Right)

(These 6-hour corrosion tests show how much more rapidly in relation to the respective welds the plate corroded than the seamless cylinder material.)

Fig. 5 shows macrographs of deeply etched sections—one (at the top) cut from welding quality seamless rolled cylinder stock 2 in. thick and one (at the bottom) a special discard welding quality plate $2^3/_8$ in. thick. The etching time on the plate sample was only 20 min., and reveals the porosity in the two surfaces of the plate and marked segregation lines between the two surfaces and the core of the plate, also the openness of the core in comparison with the two surfaces. It required 40 minutes of etching to bring out any lines whatever in the seamless cylinder materials, and the uniformly clean and dense structure throughout may be noted. Fig. 5 also shows micrographs of polished samples of the same seamless cylinder and plate material from which the macrographs (opposite to each) were taken. Both samples are of approximately the same analysis. The micrograph of the seamless material shows much better distribution of both pearlite and ferrite structure than in the plate sample.

In order to determine the relative resistance to corrosion of seamless rolled cylinder stock and special discard welding quality plate, samples of both materials welded by the Kellogg process were made, and bars were machined from these samples and immersed in a hot 1-to-1 solution of hydrochloric acid for six hours.

Fig. 7 Reaction Chamber, 60 In. Inside Diameter, $4^5/_8$ In. Thick, and 40 Ft. Long

Fig. 6 depicts the usual result from such corrosion tests. The rolled surfaces of both samples were very much more resistant to corrosion than the machined surfaces. The rolled surfaces of the plate material, however, corroded much more rapidly than the deposited metal, whereas the rolled surfaces of the seamless cylinder corroded at about the same speed as the deposited metal.

In the plate sample, segregation lines (or whatever one wishes to call these lines) are most evident, and wherever one of these lines joins the deposited metal, rapid pitting takes place. In the seamless sample corrosion is uniform over the entire machined surface, and there is no more pitting at the junction line than at any other point in this sample. The small pits in the deposited metal of both samples are but natural, as in hot etching there are always certain parts of a section that are more rapidly affected than others. In all steel practice it is known that the markings on a cross-section of an ingot will be carried down as the ingot is reduced, even if rolled to fine wire.

Fig. 7 shows a reaction chamber for use in the petroleum industry. This vessel is 60 in. inside diameter, $4^5/_8$ in. wall thickness, and 40 ft. long, made from seamless rolled-steel cylinders with ellipsoidal-shaped spun heads, joined with Kellogg circumferential seams. The weight of this vessel was approximately 150,000 lb.

PME-54-5

Suggested Specifications for Testing Tubular Heat-Transfer Equipment for Oil Refineries

By WALTER SAMANS,[1] PHILADELPHIA, PA.

This is a draft of specifications for testing tubular heat-transfer equipment after it has been installed in the refinery, this draft to serve as the basis for a more complete and general specification to apply to any equipment of this character which may be used by the refiner in oil processing. Points are enumerated that must be considered by the designer, and some mechanical details are listed which the purchaser's inspection must assure as being right, to avoid difficulties due to leakage of equipment, cleaning, and replacements in service.

THE purpose of this paper is to present a draft of specifications for testing tubular-heat transfer equipment after it has been installed in the refinery, which draft may serve as the basis for a more complete and general specification to apply to any equipment of this character which may be used by the refiner in oil processing. This draft is presented herewith as Appendix 1. It is not the purpose to make these specifications, as written, a finished product, but with the hope that a committee of the A.S.M.E. will be appointed, on which manufacturers of such equipment would be represented, and that such a committee would review the situation on this subject, so that by the next Annual Meeting of the Society something might be presented for adoption which would serve as a guide for users as well as manufacturers.

The related matter pertaining to shop inspection and actual operation, with data on field cleaning methods of such apparatus which is given herein, is contributed only as our share of experience, with the hope that it will draw out in the formal committee's deliberations such additional data from other refiners and manufacturers as will help to make the whole understandable. No one refiner can claim to have sufficient experience or be acquainted with a sufficiently varied practice in this regard to set himself up as an infallible guide. What follows, therefore, should not be taken as a complete exposition of the subject, no more than that the suggested draft of specifications is complete, and it is hoped that any discussion will be submitted to the committee aforementioned, and that the manufacturers will indicate their cooperation.

Approximately four years ago, when these specifications were first used in connection with the test of a particular group of apparatus, very few manufacturers had any means for duty-testing such units in their shops; and in fact, considering the varied nature of charging stocks, products handled, and the expensive apparatus needed for obtaining the various products in their unrefined state, together with all the attendant operating conditions, it is doubted whether even now any manufacturer can test large units in their entirety in a conclusive manner. The importance to the purchaser of having equipment meet specified duty, and considering that the manufacturer should not be bound by field conditions which cannot be expressed with certainty, particularly as to the corrosive nature of the products handled and the fouling of heat-transfer surfaces encountered, must be recognized by both parties. The few curves illustrated will indicate what the manufacturer of this equipment must face in order to guarantee satisfaction on the part of the refiner; and it would be unfair to the manufacturer to let him assume only heat-transfer values that have been obtained by tests on equipment operated with selected stocks or products, in having to fulfil a guarantee drawn up by the purchaser, without having that purchaser make all allowances for severe conditions that may be entirely unforeseen by the manufacturers' engineers unless they are expressed as completely as possible, with a frank statement on various troubles experienced in other similar apparatus previously used. Unless the refiner when purchasing such equipment is absolutely frank in giving these points proper consideration, he will not only do the manufacturer an injustice, but he will himself be disappointed in not being able to obtain the duty from the equipment when actually installed and in service, involving endless delays, trials to improve unsatisfactory apparatus, and further delays and expense incidental to obtaining additional equipment and its proper arrangement with apparatus already purchased, and which is affected by more than just the consideration of required additional heat-transfer surface as calculated.

In the following paragraphs are briefly enumerated the points the designer must consider and some mechanical details which the purchaser's inspection must assure as being right, to avoid difficulties due to leakage of equipment, cleaning, and replacements in service. Attention must be given to proper piping design in connection with these units, and it would not be out of the way for the purchaser to submit for the manufacturer's approval the piping hook-up selected, to assure the manufacturer that no improper strains will be brought upon his equipment which might contribute to leaky joints and even breaks.

In the design, the relative arrangement, mechanical construction, and fabrication methods, as well as the selection of materials, there are some markedly different problems than those encountered in the design of similar equipment in steam practice. These briefly may be summarized as follows:

1 The higher temperatures encountered.

2 Generally higher pressures.

3 The fouling of the surfaces in contact with oil in a crude state or in unrefined condition.

4 Corrosiveness of the oil and vapors.

5 Tendency on the water side to accelerate corrosion and

---

[1] Chief Engineer, Atlantic Refining Company. Mem. A.S.M.E. Mr. Samans joined the staff of the Atlantic Refining Company in 1905 and has been engaged in the construction and maintenance of buildings, bulk-loading stations, docks and wharves, and miscellaneous structures for refineries. From 1906 to 1916, he was engaeed with the Bessemer & Lake Erie Railroad (U. S. Steel Corporation) as designer and assistant engineer on bridges and buildings and miscellaneous structures, including terminal docks. He is a member and past-chairman of the Executive Committee of the A.S.M.E. Petroleum Division.

Presented at the National Petroleum Refining Meeting, Elizabeth, N. J., May 5 and 6, 1931, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

deposit of salts from cooling water on account of higher temperatures than encountered on steam condensers.

The fundamental factors which determine the design of a steam condenser must be largely discarded when these conditions have to be met.

Corrosion determines selection of materials, and this is made more complex by reactions obtained with neutralizers that may be used in oil processing. For instance, the use of soda ash, lime, or caustic, which must be used in excess to obtain the proper neutralizing effect on the sulphur compounds at the higher temperatures encountered with oil, may result in the need for steel tubes rather than non-ferrous tubes such as Admiralty. For high sulphur crudes, however, the effect of sulphur in light distillates makes Admiralty metal preferable. It is found that Muntz metal is seldom satisfactory under these conditions. However, while Admiralty metal is also subject to corrosion by alkalis, such metal in tubes and tube sheets in low-temperature service does not involve sufficiently rapid corrosion to prohibit them altogether, but the use of heavier gage tubes is advisable to give them longer life.

With steel tubes in the same low-temperature service, with the use of ammonia as a neutralizer, ammonium chloride will be deposited on the tubes, but at the same time the sulphur compounds rapidly attack steel tubes, forming a shell-like coating of iron sulphide which greatly interferes with heat transfer and which is more difficult to clean off, except by laborious hand methods.

Where cooling water is brackish, which cannot be avoided in certain localities, the tube sheets should be of the same material as the tubes, or recirculated cooling water must be provided, with cooling towers to cool it.

In general, the subject treated by this paper concerns mainly low-pressure apparatus used in connection with pipe stills, and the suggested specifications given in Appendix 1 should be taken as applying to such equipment, although they can readily be modified to suit condensers and similar units in connection with pressure equipment—that is, cracking still condensers, coolers, etc.

The fouling of tube surfaces, which on low-temperature units is more noticeable on steel tubes than on Admiralty tubes and to that extent interferes more with heat transfer, makes it unnecessary and undesirable to plan on the full benefits in heat transfer obtainable on clean surfaces with higher velocities of vapors or liquids. This condition, usually obtained by close spacing of tubes, coupled with careful baffling, increasing the effectiveness of the surfaces wiped except in isolated cases, encounters in oil-handling equipment surfaces that are so dirty that there really is a soaking heat condition, rather than a wiping action of the fluids passing over the surfaces. This is to some extent also true in water-cooled units, on the inside of tubes where dirty river water is encountered, and no economical method can be devised for overcoming that objection.

One can readily see the advantage of a wider spacing of tubes to enable surfaces to be cleaned more readily and to avoid absolute bridging of the spacing between the tubes by the salts and solids.

In the curves of heat transfer illustrated, the units consisted of 1-in.-diameter tubes in rectangular arrangement with $^3/_{16}$-in. clearance between tubes, and it was found that by omitting some of the rows of tubes, greater over-all heat transfer might be obtained by reason of having cleaner surfaces. The present standard for a number of oil refiners is to have this space between individual tubes $^3/_8$ in., but not less than $^1/_4$ in. between rows.

In connection with shop inspection of tubular equipment, which is the first phase of this subject, it is desirable to definitely limit the inspector's duties to following out construction details in accordance with plans, and to limit the type of repairs that can be made with his approval, so that if any special cases come up in which more extended alterations, repairs, or deviations from the plans appear desirable to the manufacturer's shop superintendent, either for facility in fabrication, future repair, or replacement in the field, or to avoid delay in completion, the inspector is protected from the too urgent argument by the manufacturer's shop superintendent, by having to refer such special problems to his home office. However, this is not an indictment of the manufacturer's methods, as generally they have been found whole-heartedly in favor of the purchaser's requirements.

The requirements for shop inspection by the purchaser's inspector are briefly as follows:

(1) *Prints.* Inspector to be provided with prints of apparatus sufficiently in detail to check sizes, material, nozzle tolerances, etc.

(2) *Hydrostatic Tests.* Inspector to witness these tests in manufacturer's shops. The pressure tests inside of tubes and around tubes shall be made separately and for a duration of three hours, during which time there are to be no leaks whatsoever. This length of time was confirmed in actual experience with cast shells that were thus found to have porous spots, and leaks at bolt holes and gaskets. The test around tubes is to be accomplished with ring-type closure piece between floating-head tube sheet and shell flange. This procedure indicates just which tube leaks from the outside and only leaky tubes need be rerolled. Test pressures to be applied are to be $1^1/_2$ to 2 times the designed working pressure. (Note that for naphtha units the design may be for 100 lb., although operated at lower pressures.)

(3) *Tube Bundle Removal.* All tube bundles are to be removed in the presence of the inspector, to determine definitely that correct clearance is available for readily withdrawing tube bundles from shells in a manner practicable by field methods. Where tube bundles are reversible, they must be removed and turned through 180 deg. and inserted and removed again, and there must be no indication of binding whatsoever. If slight grinding of baffles is necessary to produce freedom of withdrawal, they must again be inserted and withdrawn to the satisfaction of the inspector. Care must be taken that clearance between baffles and shells does not exceed the tolerance allowed.

(4) *Casting Inspection.* Imperfections in castings, due to core shifts, sand holes, etc., are cause for casting rejection, especially where minimum thickness specified is not met. In such cases, each instance must be referred to the purchaser's engineers. No welding of flaws will be permitted unless approved by the inspector. All porous metal and impurities must be cut out. Forged-steel pipe plugs are permitted, if the outside of the thread diameter required does not exceed three times the thickness of the metal at point of insertion.

(5) *Tube Sheet Warping.* All contact surfaces on tube sheets are to be refaced true and square if they become buckled or warped during the tube rolling operation.

(6) *Nozzle Locations.* Where nozzles and end flanges are welded to steel shells, the flanges on these nozzles should be faced and drilled true and square after the nozzle is securely welded to shell. This avoids any distortion to flanges, and hence provides for piping connections without the use of beveled fillers.

Nozzle locations are to be checked after assembly and must conform to plan within a tolerance of plus or minus $^1/_{16}$ in. for each 6 in. diameter of flange. The flanged faces must also be held within the plane specified on print with a tolerance of plus or minus $^1/_{32}$ in. per 6 in. diameter of flange. This is usually accomplished by setting up the units in a special frame.

Assuming that the foregoing methods have been followed and that the equipment has been installed in the plant, one must now be sure that it will be tested under properly controlled conditions which are well understood by both parties. It would be unfair to the purchaser to make a test for duty immediately after the equipment is installed, provided the understanding at the time of purchase contemplated a proper fouling factor. On the contrary, the purchaser should not expect, if the normal run on the equipment extends for a long period, as measured in weeks, that at the time of normal shutdown for overhauling, cleaning, and adjustment the heat-transfer equipment should have its full designed capacity. In other words, there must be some intermediate time, let it be assumed halfway through the normal period of running, at which the equipment will meet the designed duty, and that before this time arrives the equipment will have an excess duty, and that during the latter half of the run the equipment will have less than this duty. It would, further, be unfair to the manufacturer to consider that at the end of the normal run the equipment should have a definite percentage of capacity, for in some types of apparatus and with certain products that may be handled through such equipment, the variation in degree of fouling is not by any means a straight line, but may accumulate very rapidly within short periods, as will be described farther on. In the same way, both parties must expect a rather rapid drop in the heat-transfer rate in the first part of the normal running period after the equipment has been cleaned by the usual methods, and that after this, almost up to the time the equipment is shut down, the decrease in the transfer rate will be gradual but steady, with very few exceptions.

It should be agreed to by both parties, therefore, that the equipment shall have gone through at least one normal run, followed by a normal cleaning witnessed by both parties, before a formal acceptance test is made, and in this respect any specifications must be sufficiently flexible to permit this point to be properly covered for each purpose where a guaranteed duty is to be met on performance test.

With respect to corrosiveness of the materials that pass through the equipment and their effects on different materials, both parties should agree to what may happen on the basis of their joint past experience, and either approval must be given by both parties or a plain statement must be made at the time the equipment is purchased on the material selected. The author has in mind here only its effect on heat transfer and not on wear and tear or excessive corrosion due to the methods of running or the nature of the stocks run. No manufacturer should be asked to guarantee the life of equipment against corrosion, and it is not believed that this is now the generally accepted practice, but on the contrary, that it is specifically guarded against in the manufacturers' contract.

The methods of cleaning that may be followed are only outlined in the draft herewith, and it may be quite possible that certain refiners have other methods which are feasible to maintain the efficiency of heat transfer without interrupting the operation. For instance, in connection with the particular equipment for which a former draft of such specifications was made, it was found that by blowing the water side of gasoline condensers and coolers, where dirty river water was passed through the tubes, with compressed air every eight hours, a marked improvement in the reduction of temperature on the outlet of the naphtha stream was noted. Similarly, water streams injected on the vapor side help to wash off the accumulated ammonium salts where ammonia was used as a neutralizer, but care must be taken, on account of such additional water and colder reflux, that there is obtained proper separation at the point of drawing reflux and that the heat balance of the tower is not upset.

There is no doubt that much interference with heat-transfer rates is occasioned on water-cooled units by reason of muddy river water, and the refiner at the time of selecting and purchasing equipment and agreeing upon the basis for design should not forget that when using such muddy water he may be paying a premium, not only on extra surface and equipment, but also extra operating cost. An attempt should be made by him to evaluate this figure against the construction of settling basins or recirculation systems of cooling water involving cooling towers. A manufacturer of heat-transfer equipment will generally stand ready to offer all possible advice on this subject, as in many cases additional equipment for assuring a cleaner water supply that he may furnish may no more than offset the savings in first cost on heat-transfer equipment. Any interruption of water supply due to clogging lines and water-cooled sections of heat-transfer equipment will result in unbalanced operating conditions and clogging of heavy oil coolers due to decreased velocity, and on the extremely heavy oil, commonly termed high viscosity oil, the entire shell around the tubes may be filled with a jelly which cannot be removed except by taking out the tube bundle and cleaning it, which entails loss of time to the refiner.

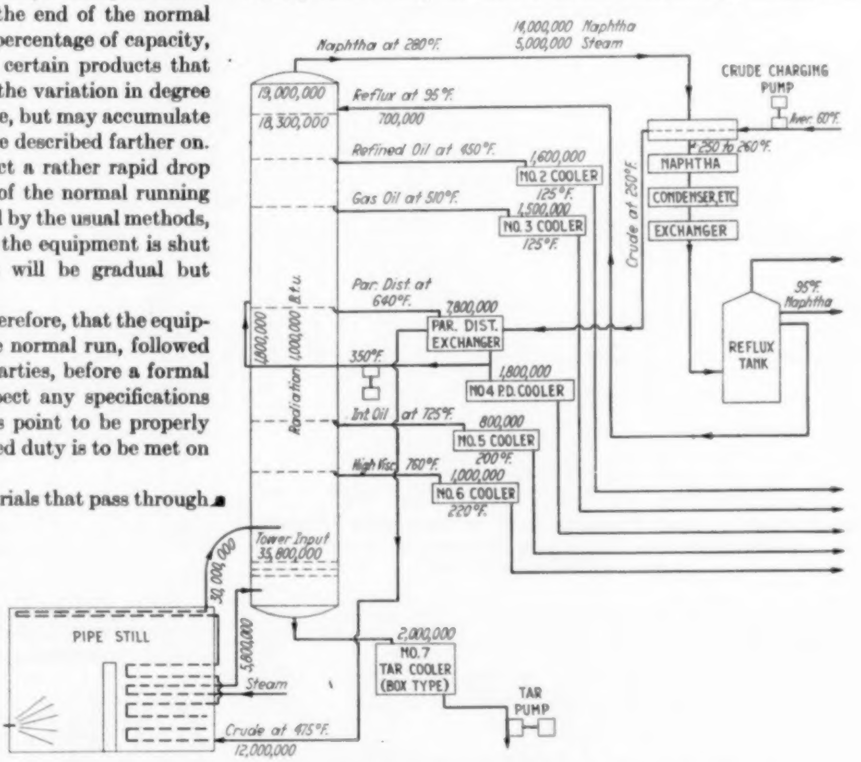

Fig. 1 Average Heat Balance of 3400-Bbl. Pipe Still, Nominal Capacity
(Heat values in B.t.u. per hour.)

It will be noted that these suggested specifications do not contain any reference to special cleaning compounds, although these may have been tried and found successful, as it is thought that the refiner will himself modify any specifications drawn up, based on his own experience.

Besides the method of cleaning tubes described in these specifications, at times the tubes have become plugged so solidly that some form of drill bit was needed to clean them out. Spare tube bundles are advisable for every group of similar units, so that the cleaning can be done at leisure, and clean bundles promptly installed to minimize shutdown time to conform to other work being done around the still battery of minor character. A special hydraulic pump may be maintained for blowing out tubes, using corks, but of course the limit of pressure possible for any diameter and gage of tube should not be exceeded. For cleaning and mechanical stability alone, the tendency has been toward larger tubes, and naturally of heavier gage to stand cleaning operations and to obtain longer life where corrosion is not entirely eliminated.

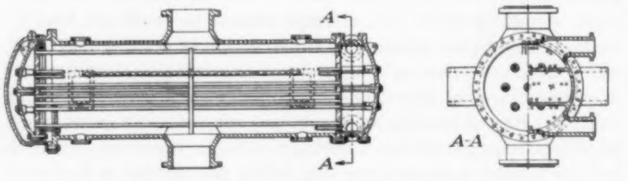

Fig. 2 Typical Vapor Condenser

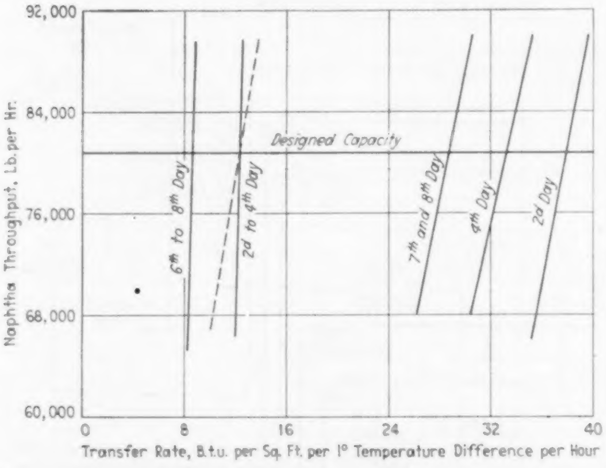

Fig. 3 Typical Heat-Transfer Rate of Exchanger (Naphtha to Crude) and of Condenser (Naphtha to Water)
(Calculated from the water side.)

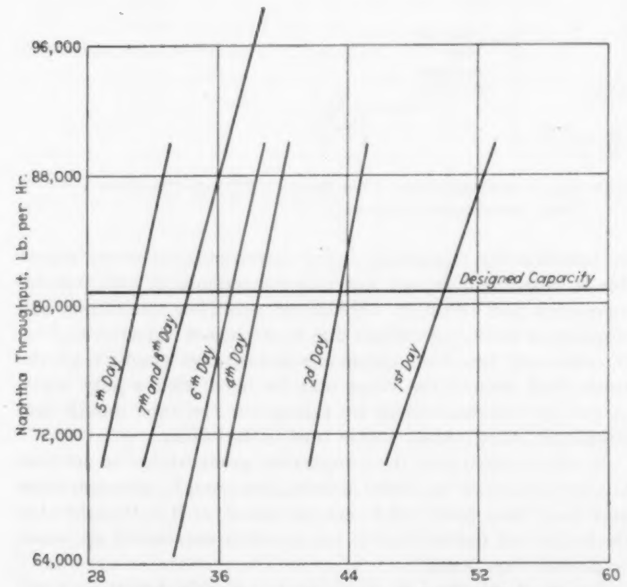

Fig. 4 Typical Heat-Transfer Rate of Condenser (Naphtha to Water)
(Calculated from oil side.)

Fig. 1 is the diagram of a crude fractionating still, indicating where the various side streams are taken off and the approximate temperatures and heat-transfer duty, on the basis of 3400 bbl. (50 gal. each) per 24-hour charge.

Fig. 2 illustrates a typical vapor condenser which is similar to the design for an exchanger, as in the latter case the crude charge is used as the cooling medium, and on account of higher pressures the floating heads and channel box may be of cast steel, whereas cast iron could be satisfactorily used for the water coolers.

Fig. 3 indicates the heat-transfer rate encountered on an installation similar to the typical shell design shown, in which steel tubes were used, and indicates the falling off in heat-transfer rate for readings taken every few days. The lines were drawn intermediate between a number of points obtained from a considerable number of observations, and in case of the condenser show a slope approximately proportional to the square root of the velocity of the vapors, the water rate being held constant. On the exchangers, however, the lines are steeper, the dotted line marked "2d to 4th day" being proportional to the square root of the vapor velocity. The solid line indicates the actual change in heat transfer with a difference in rate of vapor flow, the crude charging rate being approximately constant. The steep inclination of these curves is no doubt due to the heavy scale formation on the tubes, which consisted of iron sulphide and ammonium salts, indicating that the wiping action of the vapors did not have a material effect on what was practically a soaking heat effective through the scale on the tubes.

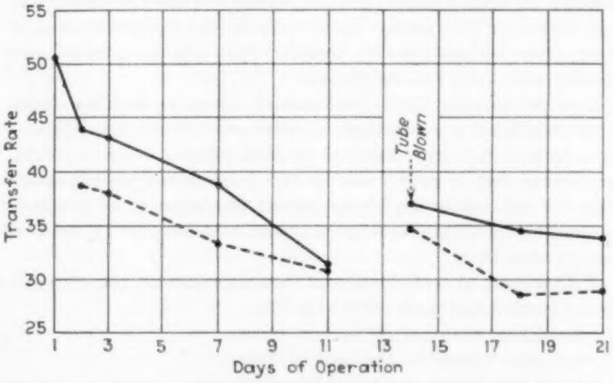

Fig. 5 Recovery of Heat-Transfer Rate After Blowing Out Inside of Tubes (Water Side) With Air and Water Mixture
(Solid line, oil side; broken line, water side.)

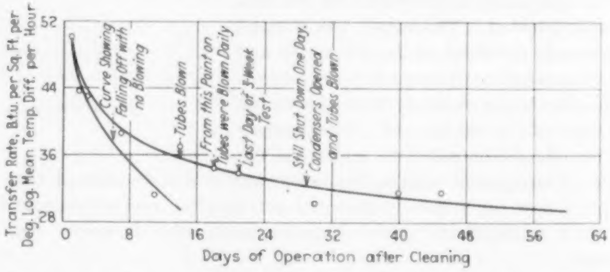

Fig. 6 Typical Heat-Transfer Rate of Naphtha Condenser (Water in Tubes)

Fig. 4 shows similar readings on the section of similar shells in which water is the condensing and cooling medium. A sudden drop on the 5th day and recovery on the 6th day is not clear, but may have been due to accumulation of mud on the water side which was automatically flushed out, when for some reason the pressure on water flow was temporarily increased.

Fig. 5, indicating the transfer rate, shows the falling off on the oil and the water sides, the difference depending upon the heat curves adopted for this test and plotted from actual points obtained by calculation. To some extent it shows the effect of blowing out the tubes by means of compressed air just before the readings taken on the 14th day, and temporary recovery, which is all that can be expected when the water is muddy.

Fig. 6 indicates similar points from another test in which a smooth curve is drawn, averaging the location of the points obtained by calculation. The actual location of the curve would vary slightly, depending upon the opinion of the one plotting it, but it shows a rapid falling off of heat transfer when the water side is not blown out and a more gradual falling off when tubes are blown. The right-hand half of this curve might be almost a horizontal line under the most favorable interpretation of the points in question.

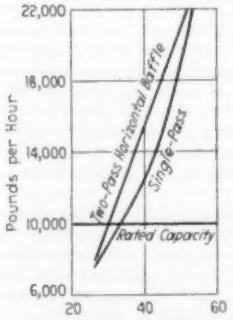
This curve is an illustration of where the manufacturer might go wrong by assuming a heat-transfer rate between 40 and 44, whereas the purchaser would expect to have the full duty when the heat-transfer rate was in the neighborhood of 32 to 34.

Fig. 7 shows the change in heat-transfer rate at various rates of flow of refined oil. In this particular instance the flow was in a zigzag direction across the tubes on the two-pass flow, and an average of an approximate ring and disk flow on the single-pass flow, and as this was a fairly clean oil, it appears that there was more short-circuiting on single-pass than on double-pass, or rather that there were more dead corners.

Fig. 8 shows a similar line for a high-viscosity oil cooler, indicating a very flat slope, and it is believed that a curve more accurately drawn would not be a straight line, but would be steeper at the upper capacity and flatter at lower rates. That is, for this particular kind of oil, the lower rate would result in overcooling of this oil and the formation of a jellylike substance blocking the spaces between the tubes.

Figs. 9 and 10 show, respectively, the paraffin distillate to crude exchanger and the paraffin distillate cooler where water was used as the cooling medium.

The points calculated from the readings are shown for these charts, and the lines are only approximate slopes, and in fact, on Fig. 10 either of two lines may be assumed as the proper one. There, again, the steeper line for the cooler indicates solidification, or at least high viscosities at lower rates of flow.



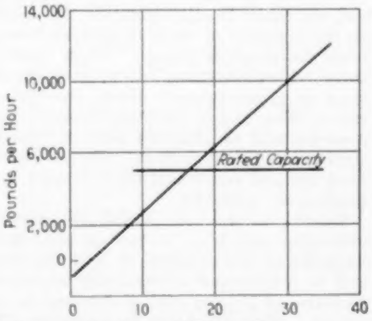


Fig. 7 Refined Oil Cooler

(Typical slope line. More points for plotting might indicate curves at upper and lower ranges.)

Fig. 8 High-Viscosity Oil Cooler

It is hoped that the various items of information given and the rather unscientific way in which the matter is presented will be considered merely as something in the way of a contribution toward what should be considered as real research work. In other words, the data that can be given by one company, based largely on tests made on one fairly large installation and being made for the purpose of obtaining approximate data for checking guaranteed duties, can only be incomplete for real research study.

As stated at the beginning, it is an effort to make a start on some form of uniform specification for performance tests to which both manufacturers and purchasers can agree, and with the hope that work can be carried to conclusion by others, cooperating toward what may be considered as a highly desirable end.

Appendix 1

PROPOSED SPECIFICATIONS FOR PERFORMANCE TEST ON PIPE STILLS, FOR EXCHANGERS, CONDENSERS, AND COOLERS, WHEN MADE IN PURCHASER'S REFINERY

(Based on original specification drawn up by E. H. Ten Broeck, The Atlantic Refining Company.)

I Cleaning

Operations, in sequence, are as follows:

(*a*) The outside of the tubes to be flushed with water injected under pressure available into the openings in the top of each unit, while the tube bundles are still in position.

(*b*) After withdrawing the tube bundles, the outside of the tubes to be scraped, if required, with thin steel strips, as thoroughly as their arrangement will allow.

(*c*) The outside of the tubes shall then be washed off with water, using preferably a fire hose and plant fire pressure.

(*d*) The inside of each tube to be brushed with wire brushes, and at the same time water shall be injected at the end of the tube opposite that which the brush enters, in order to keep the bristles effective—that is, clear from fouling.[2]

(*e*) The inside of each tube shall then be flushed with water, and air injected with the mixing nozzle, using fire pressure on the water and plant compressed air.

---

[2] For the removal of slime and mud, it has not been general experience that either a straight air blowing or a straight water washing will be effective. Good results have been secured in the removal of such deposits by introducing air and water together in the same nozzle under a pressure of 100 lb. per sq. in. Very effective washing is secured in this manner. Also, effective cleaning has been secured by the use of manufactured plugs, which may be secured for standard sizes of tubes. These plugs fit inside of the tube with a fairly close clearance and would be blown through either by water or air pressure. Use of such plugs would be much more effective than the use of ordinary corks. It is expected that such of these cleaning means shall be adopted as actual inspection of the deposit on tubes indicates may be necessary. As to the cleaning of the tubes on the outside, it is expected that such foreign deposits as can be removed shall be removed and that tube bundles will be removed so that the entire length of the tubes may be observed.

The work shall be under the direction of the manufacturer's representative.

II Instruments

(*A*) *Temperature Measurement.* To be taken with glass thermometers having graduations directly on the glass, at at least 2-deg. intervals and checked against a standard thermometer (Bureau of Standards) at two points and showing errors not exceeding 1 deg., plus or minus.

Thermometers to be installed in ordinary pipe wells of 1/4-in. or 3/8-in. pipe with lower end welded shut in the usual manner.

Wells to extend 3 in. into 4-in. pipe, 4 in. into 6-in. and 8-in. pipe, and at least 6 in. into larger pipes or nozzles on shells of units under test, all measured from the outer surface. All wells to be inserted so that oil or mercury can be held in the bottom to give good contact between the bulb and wall of the well. If any well is installed at an angle in a pipe, so that it is parallel to the direction of flow, it shall be at least 1/2 in. from the inner wall of the pipe and must extend to at least 2 in. past the inner side of the elbow or tee. Temperature measurements shall be made at the following points:

On vapor side: (*a*) In vapor inlet nozzle of naphtha exchanger unit or in vapor pipe leading thereto at a point not more than 24 in. above the face of the nozzle flange. (*b*) In one of the nozzles connecting the exchanger and naphtha condenser units. (*c*) In the outlet pipe from the lowest condenser unit, the well to be installed in the horizontal pipe.[3]

Temperature measurements between the sections of a condenser unit, if it is sectional, may be made by the manufacturer, if he desires and provides the thermowells.

On liquid side: (*a*) In water inlet line to lowest condenser at any convenient point between the unit and the supply main. (*b*) In water outlet from upper condenser unit at any convenient point not more than 4 ft. from the outlet flange on the condenser. (*c*) In cold-oil inlet line to exchanger unit at any convenient point between the charging pump and the unit. (*d*) In oil outlet line from exchanger unit at any convenient point not more than 4 ft. from the outlet flange on the unit.

(*B*) *Pressure Measurements.* On vapor side, to be taken with manometers using Hg or CCl_4 for the indicating medium. If CCl_4 is used, its gravity shall be determined by comparison with water in a U-tube and the result accepted by the representative of the manufacturer.

On liquid side, the water pressures and oil pressures shall be measured by means of industrial pressure gages of approved make, having a range equal to 1 1/2 to 2 items the maximum pressure to be encountered.

Pressure gages to be calibrated either directly on a deadweight calibrating machine or by comparison with a standard gage that has been so calibrated. Gages must not vary more than 1 per cent, plus or minus, throughout the expected working range.

Pressure measurements to be made at approximately the same points as the temperature measurements, and in addition, the differential pressures across the naphtha exchanger unit and the condenser unit to be measured on the vapor side.

(*C*) *Quantity Measurements.*

On vapor side: (*a*) Naphtha Forward Flow and Reflux. To be measured by a standard thin-plate, sharp-edge orifice and manometer installed in the run-down line between the outlet of the condenser and the water separating tank at a point below the gas vent connection, making necessary correction for water (steam) measured, as described below.

(*b*) Steam. The steam to be measured by a standard sharp-edge orifice placed in the supply line to the steam superheater, if one is used. If a calibrated round-edge orifice is used in connection with steam-flow control, the pressure against this orifice may be taken as a correct indication of the quantity of steam passing, in accordance with the customary formula (Grahsof's) for such round-edge orifices. The pressure gage used is to be an ordinary pressure gage (of approved make) as regularly supplied on the still. Before starting the test, the orifices are to be removed and examined to determine whether their condition and dimensions are satisfactory and new ones supplied if necessary. The pressure gage to be calibrated or checked against a standard instrument and must be correct to plus or minus 1 per cent. The quantity of steam to be maintained at substantially the specified quantity ( ) lb. per hr. (Blank to be filled in with proper figure for each case.) A variation in this rate of flow of plus or minus 5 per cent will be permitted.

(*c*) Gas. The gas to be measured by a thin-plate sharp-edge orifice and manometer (or draft gage), and the orifice plate will be removed, inspected, and renewed if necessary, before the start of the test. While it is desirable that the gas from the still under test be segregated, this is not always possible where the still is in a battery, and in some cases the quantity of gas from the still under test should be taken in proportion of the still throughput to the entire throughput of the battery, as determined by the quantity measurement on the charging oil.

On liquid side: (*a*) Crude Oil. The quantity of crude oil passing through the unit may be determined by the number of pump strokes, where reciprocating charging pumps are installed. The pump for the still on test to be calibrated by gaging the amount pumped out of one of the regular charging tanks in a measured period of time. The amount removed from the tank must be such as to lower the level in the tank by at least 2 ft. Three calibrating runs to be made on different days and the average taken to use in the calculations of the test results. These pump calibrations need not be simultaneous with test runs on the naphtha exchanger and condenser units, but are to be made at the convenience of the still operators and must be completed within 30 days after the tests on the manufacturer's units. These calibrating runs to be witnessed and the calibration accepted by the representative of the manufacturer. If a centrifugal charging pump is used, the quantity of oil charged to still on test should be measured by the usual orifice plate.

(*b*) Water. If necessary, the water used may be heated to the specified entrance temperature by recycling a portion thereof, maintaining it as near to this specified temperature as practicable, and it may be measured by a V-notch weir in a suitable measuring tank. It will usually be more convenient to measure the water quantity by means of orifice plates placed in the measuring section.

III Procedure

The test shall be made on the crude specified in the order, if possible, or another crude accepted by both parties may be substituted during such portions of the test as may suit the convenience of the refinery superintendent. After the units are cleaned, as described above, they are to be reassembled as promptly as possible and the stills started and operated in the normal way for a period of 14 days[4] on the acceptable crude. A "set" of test readings to be taken each day for a period of 7 days. (It may be agreed that several days will intervene between "sets" of readings.)

Each "set" of test readings shall consist of three "series" of runs, one "series" of runs to be at a rate above that specified and one below, and the other at approximately the specified rate (rate to be based on the quantity of crude oil passing through the unit, as determined from the speed of pump). Each "series" of runs shall consist of three "determinations," each determination requiring four observations at approximately 5-min. intervals, of each temperature and rate of flow, and at least one observation of each pressure, and one measurement of charging rate by counting the number of pump strokes in a 15-min. period. The above readings are not to be started until uniform conditions are indicated; that is, the system must be balanced in operation.

During all the test period, the vapor temperature entering the exchanger unit is to be held as near that specified as possible. A variation of plus or minus 20 deg. will be permitted. The water rate will be maintained substantially constant at the specified rate. A variation of 2 1/2 per cent in charging rate, plus or minus, will be permitted. The actual rate as measured will be used in calculations.

IV Calculations

The method of calculation shall be as follows:

For each "determination" the average of the readings of each instrument will be taken and the transfer rate calculated as follows:

Naphtha to Crude Exchanger Unit. The heat absorbed by the crude oil will be determined by use of the .... curve of heat content of oil and vapor. Curve prepared by ....[5] It will be assumed that no vaporization takes place in the crude while passing through this unit.

---

[3] It was noted in tests for which the original of these proposed specifications was formulated that the temperature in the vertical outlet pipe from the lowest condenser unit varied by 20 to 30 deg. from the temperature several feet farther on, in a horizontal run of this pipe where the pipe was full of liquid. This difference may be accounted for by the liquid falling from the tubes on to the upper thermometer being cooler than the mixture of vapor and liquid at the second location.

[4] The provision that the stills be operated for 14 days after a normal cleaning preceding the formal duty test is based on a normal run lasting during the 6 or 7 weeks following the normal cleaning time. It is important, on the basis of falling off of efficiency due to fouling and roughening of tube surface, that the manufacturer consider a proper fouling factor to take care of these features, as that is the actual working condition. The time of starting test should, however, in a general specification be left open—that is, with blank spaces to be filled in—depending upon the type of apparatus purchased and the service for which it is intended.

The logarithmic mean temperature difference between the two mediums will be calculated on the assumption that true counterflow exists.[5]

The transfer rate will be calculated by dividing the quantity of heat per hour, determined as above, by the log mean temperature difference multiplied by the effective surface of the exchanger unit.

For purposes of comparison, the transfer rate required to meet the specified conditions will be calculated from these conditions in the same manner. In this calculation, the temperature drop of the vapors through the exchanger unit will be assumed to be the same as that actually found as the average for the particular "set" of test readings under consideration.

Naphtha Condenser. The heat absorbed by the water will be determined by multiplying the quantity in pounds per hour by the temperature difference between the inlet and outlet.

The logarithmic mean temperature difference will be calculated on the assumption of true counterflow as for the exchanger unit.[5]

The transfer rate will be calculated by dividing the heat quantity, as determined above, by the logarithmic mean temperature difference multiplied by the effective surface of the condenser unit.

For purposes of comparison, the transfer rate required to meet the specified conditions will be calculated from these conditions in the same manner. In this calculation the temperature of the vapor entering the condenser unit will be assumed to be the same as the vapor outlet temperature from the exchanger unit as determined above.

V INTERPRETATION OF RESULTS

After making the calculations as described above, the transfer rates for each "determination" shall be plotted against the naphtha throughput in pounds per hour and a curve drawn in the usual manner through these points.

The point where this curve crosses the line representing the specified naphtha rate shall be taken as the transfer rate of the unit for that day. If any of these points are obviously not in agreement with the others found in that "set" of readings, these "off" points need not be considered in drawing the curve for that "set." They should be shown on the sheet, however.

If the points for any "series" are so widely distributed that there is doubt as to the position of the curve, it shall be determined by taking the average naphtha rate for the three readings of the series and the average of the three transfer rates as calculated. If the one point is obviously in error, it may be neglected and the other two used as above. If two points are obviously in error, the entire "series" may be neglected and the position of the curve determined by the remaining two "series" of the "set." If two "series" of a "set" are obviously in error, the entire "set" shall be omitted. This omission shall not be considered to affect in any way the validity of the test, provided that not more than two such omissions shall be made.

The average transfer rates for all the days of the test shall be the figures used in determining the capacity rating of the units.

If this figure is below the average of the specified transfer rates, determined as above for each set of readings, the shortage of surface shall be considered to be the difference between that now installed and that which would be required to meet the specifications calculated from the actual average transfer rates as determined from these tests by the method outlined above. This shortage shall be separately determined for each unit, that is, exchanger and condenser.

VI SIDE-STREAM COOLERS AND EXCHANGERS[6]

For the cooler to be tested, the tube bundles are to be withdrawn and cleaned in a satisfactory manner,[7] similar to that described above for the naphtha units, and inspected thereafter by the representatives of both parties, before replacing in shell.

The size of weighing tank should be as large as practical, but preferably not less than will accommodate a 10-min. flow period. This period should be taken at a time when indications of uniform conditions are evidenced.

The quantity of cooling water can be determined by connecting the outlet pipe through a hose to a section of pipe containing a standard thin-plate sharp-edge orifice, and the flow regulated at inlet valve to within plus or minus 5 per cent of the specified quantity. Where recycling of cooling water is impracticable to maintain the specified water-inlet temperature, both parties may agree to a modification in the flow rate of cooling water to compensate for any water temperature that may be available at the time of the test.

Inlet and outlet temperatures of oil to be taken by approved indicating pyrometer and/or glass thermometers, and by the latter on the water side. All such temperature-indicating devices to be located as nearby as possible to the unit being tested. Average indications taken during one "set" of test readings to be used in the calculations.

Although cooler shells are customarily not insulated, no account shall be taken of heat radiation from shell, where oil is outside of tubes.

VII GENERAL AGREEMENT

Before starting preparations for this test, the manufacturer and the purchaser must agree through their accredited representatives to the conditions as outlined above, after making such modifications as may be mutually agreed upon, and no deviations will be permitted without further written agreement between the companies.

Before starting the test, all equipment must be inspected by the accredited representative of the manufacturer and approved by him in writing. This inspection and approval must include the following items:

(1) Cleanliness of equipment.

(2) Thermometers: Type; calibration; location; wells and their installation.

(3) Pressure gages: Type; calibration; location and installation.

(4) Manometers: Type; location and installation including connections. (Note: For small rates of cooled oil a disk meter may be agreed upon.)

(5) Orifice plates: Condition; dimensions; location; position of taps; connections to manometers or pressure gages. (Note: Orifice plates to be in accordance with A.S.M.E. accepted practice.)

(6) Water-measuring equipment: Size and arrangement of tank; condition and dimensions of weir; type and position of hook gage. (Note: Pitot tube readings may be agreed upon by both parties as an alternative.)

(7) Any other instruments, equipment, or arrangements not mentioned above.

If any instruments or equipment are not approved by the representative of the manufacturer, the manufacturer should promptly furnish such substitutes as he considers suitable, subject of course to purchaser's approval.

If, through accident or oversight, any item is omitted from his inspection and approval, such omission will not vitiate any of the data or results of the test. Equipment broken or failing during the tests will be replaced with similar equipment calibrated or checked in the same manner as the original items, and approved by the manufacturer's representative.

The data sheets for each set of readings shall be initialed by the accredited representative of the manufacturer, immediately after the conclusion of the test work on that set. No erasures should be made on these data sheets at any time. If corrections or changes to the readings are necessary, the original figures shall be crossed out and initialed by the representatives of both companies, with a notation explaining the change or correction.

General note: The proposed specifications in Appendix 1 are submitted not so much for discussion at this particular meeting, but with the idea in mind that a committee might be formed in the Petroleum Division of the A.S.M.E. which could use this data as a basis for a more complete and general specification which would be acceptable to both users and manufacturers, so as to have the tests of this character on a uniform basis throughout.

---

[5] The paragraph covering this should be written to permit of the latest method of calculation for each particular type of equipment and service as this work is developed by various research projects. While these original specifications, made for a particular test some time ago, assumed that no vaporization takes place in the crude oil passing through the exchanger unit, is is believed that data are now available which make it possible to more closely estimate this vaporization. Likewise, it is not always best to consider that true counterflow exists, but an agreement should be reached between the parties to the test at the time the units are purchased as to what assumptions shall be made on this factor.

[6] It is desirable that the piping arrangement at the units to be tested provide a spare run-down line from which the oil issuing from any cooler or exchanger can be drawn to a weighing tank, for determining the rate of flow.

[7] It has been found advisable in some cases to place the tube bundles in a soaking tank for a period of 10 to 20 hours, in which the contained water is heated by the continuous admission of steam, and to which certain cleaning solutions may be added, depending upon the experience of each refiner. This clause for cleaning may therefore be modified or blank lines provided for insertion of this additional requirement.

Discussion

F. C. Fyke.[8] These comments briefly outline other practices and experiences in regard to a slightly different phase of the testing of heat exchangers. These deal chiefly with the inspection of exchanger units at the manufacturers' plants, preparatory to their acceptance by the purchaser.

When the type of exchanger to be used and its design have been determined, the engineer's next function is the inspection of the material entering into the assembly and the completed exchanger prior to its acceptance and shipment. Ordinarily the manufacturer of heat exchangers must purchase his raw materials from outside sources. By raw materials is meant the steel plate for shells or completed shells, rivets, bolts, tubes, and castings. It is our practice to inspect all so-called raw materials at the various plants of their manufacture so as to be familiar with the processes employed and to see that the specifications are complied with, thereby saving time in the ultimate assembly through the non-receipt of defective or improper materials. We make one exception to this general rule in the case of castings, which are only inspected at the plant where the machine work is executed. We find that little can be learned by inspecting any reasonably good casting before machining. A thorough examination is made after machining, and whenever possible before assembly the castings are pressure-tested; in the case of steel, to four times the working pressure, and of cast iron, to twice the working pressure.

Any defects found either before or after testing are explored by chipping or burning out with a torch or carbon arc. An acid etch is used to determine whether the defect has been removed. If the number, extent, and location of the defects are not serious enough to cause rejection, permission is then given by the inspector to weld up the cavity. No castings with previously welded defects are acceptable, as our inspectors must in all cases examine the extent of the defect and be able to certify to its complete removal. After welding, castings are reannealed, wholly wherever possible; otherwise, local annealing is resorted to.

Where the size of the casting is within reason and the cost will permit, another testing method is sometimes used. This is a test to destruction by means of a drop ball. This may appear to be an antiquated method of examining castings, in the face of such modern methods as the X-ray, but it offers a sound method of locating certain types of defects, inherent to the particular pattern or foundry practice, such as shrinkage cavities, sponginess, and gas pockets, which may not be revealed by the X-ray. Obviously, the drop ball locates weak spots with a certainty that could not be approached by the slower and more laborious method of sawing up a casting.

When the size of the order warrants, a full-time inspector is assigned to the fabricator's plant to follow the fabrication of the exchangers; otherwise a thorough final inspection is made when the first unit is ready for acceptance, at which time any other units in the course of assembly are examined. Some of the chief points which are checked during the final inspection are easy removal and adequate clearance of the tube bundle, proper rolling of tubes for the full depth of the tube sheets, and evidence of overrolling or cracking of the tube ends. Minimum clearance between tubes and baffle plates should be demanded, not only to limit short-circuiting, but to prevent wear on the tubes, which may be caused by vibration where too large a clearance is allowed. A hydrostatic pressure test is applied, preferably to the tube bundle and shell unassembled. If, however, the unit is assembled for this test, the tube bundle is removed on completion of the test, and both the tube bundle and shell are carefully examined, particular attention being given to joints that may be calk-welded, as the welding is sometimes cracked in the pressure test. The pressure is usually maintained for one hour, during which time the shell is hammer-tested, and all rivets are tapped and all parts are examined for leakage.

In testing heat exchangers, two common sources of error have been noted which lead to the determination of fictitious heat-transfer coefficients. These are leakage around the baffles between tube passes and the use of the logarithmic mean temperature difference applied to the terminal temperatures.

An approximate check is available to determine the existence of leakage between the tube passes by comparing the actual pressure drop with the loss as calculated by the Fanning equation. If the actual pressure drop is materially less than the calculated amount, it is safe to assume that an appreciable amount of by-passing is occurring.

The logarithmic mean temperature difference is often used, regardless of whether the flow is strictly counter-current or not. The greater the variance from true counter-current flow, the greater the possible error that may be introduced in determining the true value of the coefficient. However, the log-mean temperature may be used in testing, and if the exchange design does not give it, then the manufacturer is penalized in that his product will only pass test if the transfer rate is sufficiently high to overcome the disadvantage imposed by the lack of counter-current flow.

Tests on various exchangers have shown that the artificial turbulence produced in the shell side of liquid-to-liquid exchangers by baffle plates materially increases the film coefficient as long as the flow is in the viscous range, but this effect disappears as the critical point is approached. Within the range of turbulent flow the only value of baffles is to increase the length of the path of flow, with the consequent decrease in the shell diameter and increases in the mean velocity. Any great amount of leakage through the shell-side baffle plates will of course tend to neutralize the above advantages; hence the advisability of careful inspection of these plates for excess clearance.

PME-54-6

Effect of Vacuum on Lubricating-Oil Distillation

By R. S. DANFORTH,[1] SAN FRANCISCO, CALIF

Vacuum distillation of lubricating oils possesses many advantages, and the paper brings out some of its basic features. The benefits of the vacuum process are mainly in the reduction of cracking, in the improved separation of fractions, and the reduction of heat input and condensing requirements. The author mentions a possible fractionator design and suggests a condenser design.

FOR some years it has been known that the vacuum distillation of lubricating oils possesses many advantages, and the purpose of this paper is to bring out some of its basic features. The benefits of the vacuum process are mainly in the reduction of cracking, in the improved separation of fractions, and the reduction of heat input and condensing requirements.

In lubricating-oil distillation, cracked products are usually less desirable. The extent of cracking depends mainly on the temperature and the time of exposure, the heavier molecules cracking at a lower temperature. C. R. Burch reported[2] experiments on Pennsylvania and other distillates indicating a cracking activity starting at temperatures varying between 584 and 644 F.

In the distillation of a lubricating oil in a shell still, on account of long exposure gas evolution usually becomes quite objectionable around 640 F, while in the modern pipe still, the limit of operation from this point of view is above 700 F, dependent on the type of oil.

EFFECT OF TEMPERATURE UPON COMPOSITION OF VAPOR

An important feature in distillation is the effect of a low boiling temperature in greatly decreasing the percentage of heavy fractions in the vapor. By Raoult's law, the ratio by weight of the lighter vapor fraction to the heavier equals the ratio of their weights in the liquid multiplied by the ratio of their vapor pressures. With a lower temperature the vapor pressure ratio is greatly increased, so that the vapor has much less of the heavier fractions. In the following example, taking merely two fractions for simplicity, the percentage of heavier fraction in the vapor is reduced from 29.2 per cent when distilling at 800 F under 974 mm absolute pressure to 5.1 per cent when distilling at 550 F and 32 mm pressure, or to 1.9 per cent at 450 F and 5 mm pressure.

As this increased separation is repeated on each plate of a fractionating column, the amount of reflux in fractionation, the heat required to reevaporate the reflux, and the heat input to the condenser are all reduced with lower temperature operation. The time of exposure and extent of cracking are decreased with the lessened amount of reflux. In distilling, the heat required is reduced by the smaller amount of heavier fractions evaporated.

Fig. 1 shows the variation of vapor pressure with temperature for normal hydrocarbons of the paraffin series. Mixtures of oils of equivalent boiling points follow practically the same curves.

For example, suppose we are distilling a lubricating fraction of 296 molecular weight from a heavier fraction of 492 molecular weight, the vapor in equilibrium with a residuum containing 10 per cent by weight of the lighter fraction. At a distillation temperature of 800 F the vapor pressure of the lighter fraction is 5000 mm, the heavier fraction 230 mm, and their ratio 21.7. The ratio of the weight of the lighter fraction in the vapor to the heavier fraction equals $1/9 \times 21.7 = 2.42$. This is equivalent to 70.8 per cent lighter fraction and 29.2 per cent heavier fraction in the vapor. Distilling at 450 F, the heavier fraction in the vapor will be reduced to only 1.9 per cent instead of 29.2 per cent.

By Dalton's law, the total still pressure equals the sum of the partial pressures of the fractions. The partial pressure of a fraction is equal to its vapor pressure multiplied by its mol fraction in the liquid. (The number of mols equals the weight in pounds divided by the molecular weight.) The mol fractions in the foregoing liquid would be 0.16 and 0.84, respectively. The still pressure would be 974 mm at 800 F and 5 mm at 450 F.

The effect of reducing the boiling temperature is shown in Table 1.

TABLE 1 VAPOR COMPOSITION, RESIDUUM RETAINING 10% BY WEIGHT OF LIGHTER FRACTION

(Two fractions having molecular weights of 296 and 492)

Temp., F	Vapor pressure ratio	Ratio of weights in vapor	Heavier fraction in vapor by weight, %	Still pressure, mm mercury
800........	21.7	2.42	29.2	974
700........	43.2	4.80	17.2	281
600........	97.8	10.9	8.4	76
550........	167.0	18.5	5.1	32
500........	268.0	29.8	3.3	13
450........	470.0	52.3	1.9	5

At 450 F the ratio of the lighter fraction in the vapor to the heavier is over 20 times the ratio at 800 F.

As a further example of the benefit of low temperature upon relative volatilities, assume that it is desired to remove a light fraction of 128 molecular weight from a lubricating-oil fraction of 394 molecular weight. Assuming 0.1 per cent by weight of the light fraction retained in the residuum, the results are as follows:

Temp., F	Still pressure, mm	Heavier fraction in vapor by weight, %
750....................	808	93.5
700....................	424	90.4
600....................	115	77.0
500....................	30	48.8
400....................	9	17.4

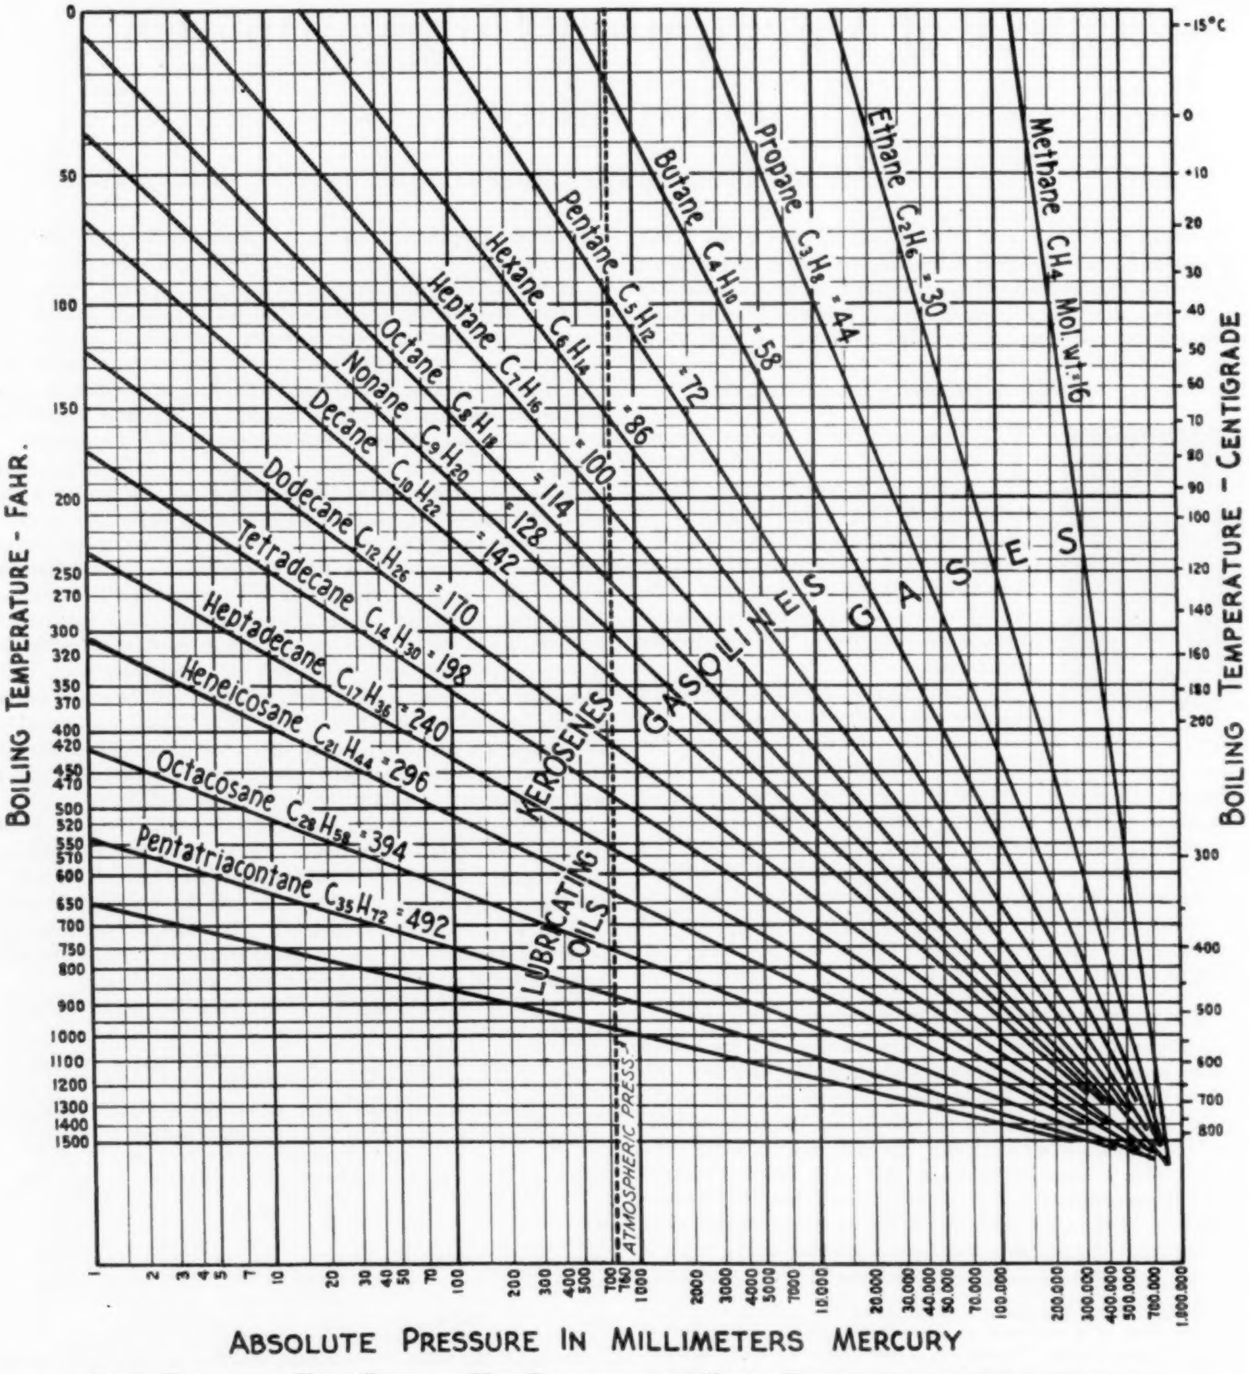

Fig. 1 Variation of Vapor Pressures With Temperature for Normal Hydrocarbons of the Paraffin Series
(Method of plotting according to E. R. Cox, *Industrial and Engineering Chemistry*, 1923, p. 592. Boiling points below 200 molecular weight from treatise on "Distillation," by C. V. Rechenberg. Above 200 molecular weight from Day, "Petroleum Industry," Vol. 1, p. 470.)

With high-vacuum distillation, sufficient separation might be secured in some cases to eliminate the use of fractionators entirely.

Distillation Temperature

The distillation temperature should therefore be as low as possible in order to improve the separation of fractions, reduce the quantity of gases formed by cracking, secure the highest quality product, and operate with the lowest heat input.

The distillation temperature can be lowered by reducing the pressure by operating under a vacuum or by indirectly reducing the partial pressure of the oil vapors by the presence of steam.

Vacuum and Steam Distillation

In dry vacuum distillation, the boiling point is lowered solely by the reduction of pressure. If the liquid is under a hydrostatic head, the low pressure will not be effective, so the main essential is to properly expose the liquid.

In steam distillation, the liquid is exposed at the surface, and

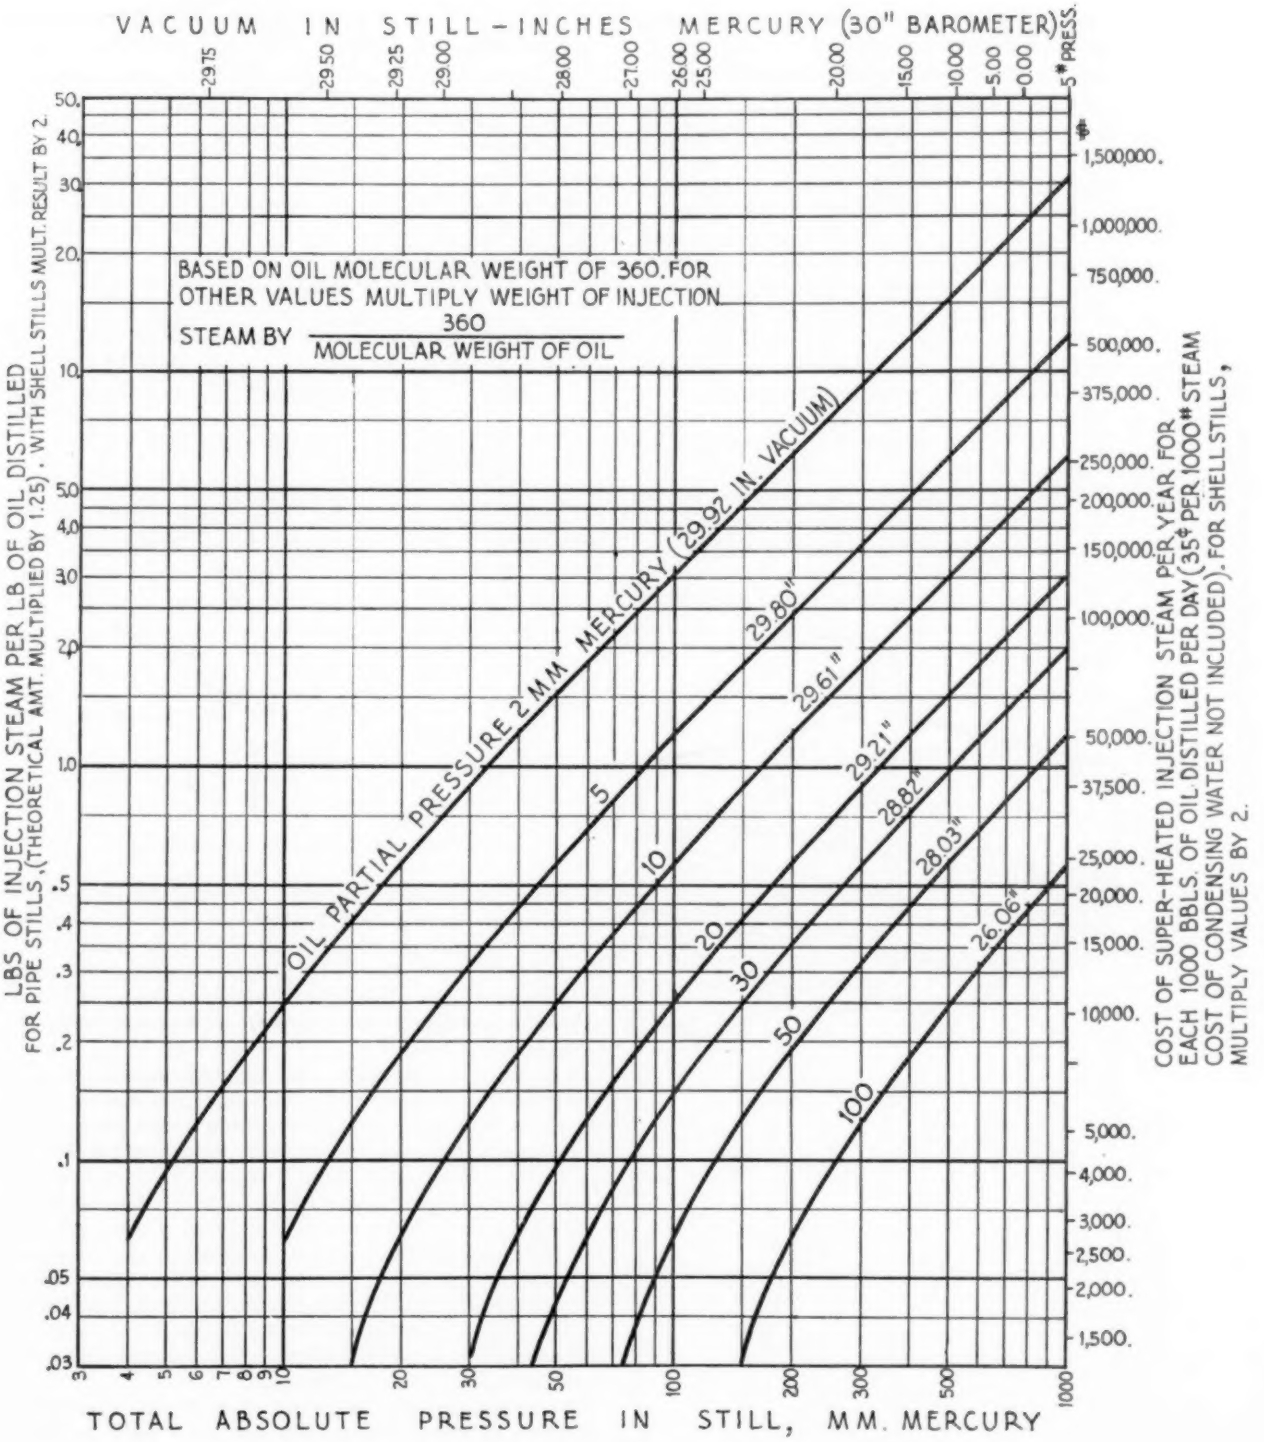

FIG. 2 INJECTION STEAM REQUIRED FOR STEAM DISTILLATION

in the steam bubbles, to a mixture of oil vapor and steam. The total pressure is divided between the partial pressures of the oil and the steam. The boiling point corresponds to the partial pressure of the oil, and is considerably lower than the boiling point corresponding to the total pressure.

AMOUNT OF STEAM REQUIRED

Assuming that the steam becomes saturated with oil vapors, the injection or distillation steam required per pound of oil distilled to secure a given boiling point is given by the following formula:

$$a = \frac{18\,(P - p)}{Mp}$$

where a = pounds of injection steam per pound of oil distilled over

P = total absolute pressure in the still

p = partial pressure of the oil corresponding to the desired boiling point (in same units as P)

M = average molecular weight of the vaporized oil.

With steam distillation in shell stills, owing to the high velocity, large volume, and slow diffusion, it is difficult to secure a uniform saturation of the steam with oil vapors, and between two and three times as much steam as theoretically necessary is often used. With pipe stills, where the steam is brought into more intimate contact, the theoretical amount is used and sometimes up to one and one-quarter times the theoretical amount. Fig. 2 shows the injection steam required for steam distillation in accordance with the foregoing, and also the yearly cost per 1000 bbl distilled over per day. The steam should be superheated above the distillation temperature, otherwise it will absorb heat from the oil being distilled. The cost of condensing water is not included.

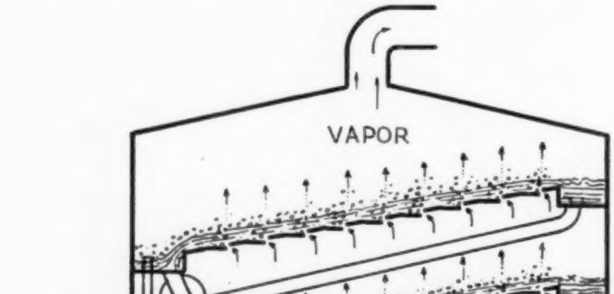

Fig. 3 Possible Fractionator Design

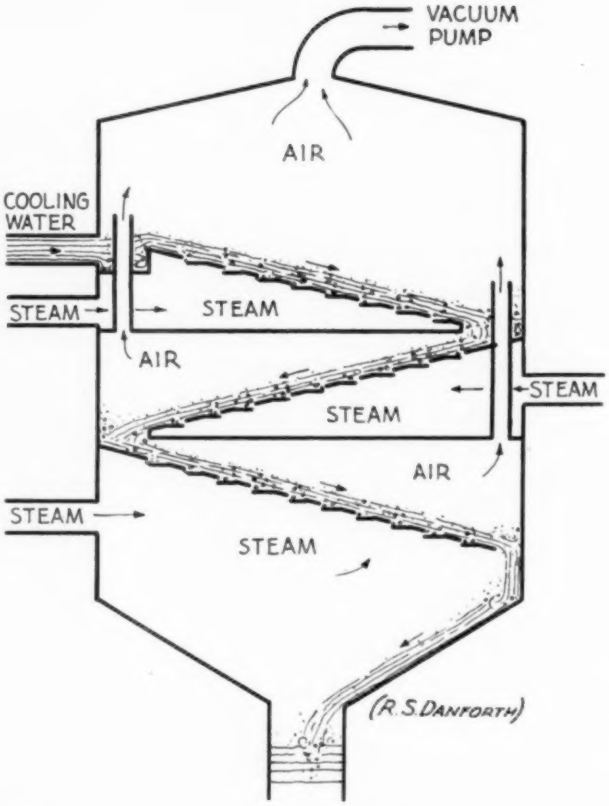

Fig. 4 Suggested Condenser Design

Considering simple distillation only, without reference to fractionating towers, in one dry vacuum plant the air leakage and non-condensable gases were less than 22 cu ft of free gas per minute for 3000 bbl per day oil distilled. To handle this volume of gas at 5 mm absolute pressure, it would require, with one type of vacuum pump, approximately 62 operating horsepower and, at $1\frac{1}{2}$ cents per kw-hr, about \$6075 per year. To secure the same boiling point by the use of live process steam in pipe stills at 50 mm pressure (28 in. vacuum), it would require a process-steam supply costing some \$60,000 or \$70,000 per year, with steam at 35 cents per 1000 lb, without considering the cost of cooling water required for its condensation or the operation of the vacuum apparatus. If low-cost steam is available, such as the exhaust from steam pumps, this cost will be greatly reduced or possibly nearly eliminated.

If no process steam is used, a high dry vacuum can be efficiently maintained, as only the non-condensable gases and air leakage have to be handled. If any process steam is used, the obtainable vacuum is limited by the cooling-water temperature in the steam condenser and is usually around 28 in. With cooling water around 60 F, $28\frac{1}{2}$ in. vacuum can be secured. With refrigerated cooling water, an absolute pressure of 20 mm could be secured.

A higher distillation vacuum can be secured with process steam by using a booster ejector[3] between the oil condenser and the steam condenser, but this booster has to handle the process steam as vapor under high vacuum besides the gases and air leakage. The steam consumption is therefore considerable, and cooling water is required for its condensation.

Where steam cost is important, it is therefore desirable to eliminate all process steam, and this could easily be done if fractionating towers were not usually required for clean separation of cuts.

Fractionating towers are usually used in commercial practice, and owing to the pressure drop through the bubble plates, it is impossible to secure the full advantages of dry high-vacuum distillation. Process steam is therefore customarily used, carrying as high a vacuum as is permitted by the condenser cooling-water temperature. Various types of fractionating towers, designed for a low vapor-pressure drop, have been used, but for various reasons they have not been extensively adopted.

---

[3] Kramer patent No. 1,619,348.

Injection steam in side-stream stripping sections was formerly supposed to have a mysterious action in removing the light cracked products. The effect of steam vapor at any point is to lower the partial pressure and boiling point of the oil, but it apparently does not affect otherwise the composition of the vapor. When the boiling temperature is lowered, the ratio of the vapor pressures is increased, increasing the percentage of light fractions in the vapor.

If process steam was not needed in the fractionating tower, the lowering of the boiling point required to vaporize in the strippers could be secured by the use of steam and a booster ejector to a separate condenser or by carrying a higher vacuum on the strippers. The volume of fixed gases to be handled would be small.

A Possible Fractionator Design

As an additional possibility as yet untested, the author mentions a fractionator in which the plates are inclined and fitted with vapor slots, as shown in Fig. 3. The liquid on each plate is circulated by pumps, so that it flows over the slots between guiding partitions. The hydrostatic head slightly assists the flow of vapor instead of opposing it, and the pressure losses caused by passing through the usual bubble caps should be greatly reduced.

The tendency to bypass should be reduced as each bubble of vapor is introduced into a fresh surface of the liquid. The liquid is thoroughly agitated, keeping its concentration uniform. The difficulty found in maintaining horizontal the plates of the usual bubble towers would not be present. Entrainment should be materially reduced, owing to the vapor leaving the liquid while traveling down the plates, and therefore having a considerable horizontal velocity. A serious objection is the installation of a pump for each plate operating under vacuum at a high temperature and the consequent mechanical difficulties.

Suggested Condenser Design

The foregoing principle might also be applied in the design of barometric condensers, securing a quick intermixture of cooling water and vapor, eliminating bypassing, and reducing the pressure drop through the apparatus. Fig. 4 indicates one arrangement, circulating pumps for each plate not being required.

PME-54-7

Analysis of Stresses in Sucker-Rod Joints

By EMORY KEMLER,[1] PITTSBURGH, PA.

A recent analysis of oil-field pumping production showed that 25 per cent of the lost production was caused by sucker-rod troubles. Much research has been attempted to determine the loads carried by the rods, but heretofore no attention has been given to the stress condition existing in the sucker-rod joint. These joint failures amount to 72 per cent of sucker-rod failures. As the sucker-rod joint is the largest individual trouble maker in pumping operations, the purpose of the paper is to determine the magnitude and distribution of load in the joint and to discuss methods of studying the problem.

IN a recent analysis of oil-field pumping troubles it was found that 25 per cent of the lost production was caused by sucker-rod troubles.[2] This fact has resulted in many investigations being undertaken to determine the loads carried by the rods. Much research has been done along this line, but no one seems to have given attention to the stress condition existing in the sucker-rod joint. These joint failures, if one includes failures at the fillet connecting the rod and pin or box, amount to 72 per cent of the sucker-rod failures. The sucker-rod joint is, then, the largest individual trouble maker encountered in pumping operations. It is the purpose of this paper to determine the magnitude and distribution of load in the joint and to discuss methods of studying this important problem.

Since the only variations in sucker rods made by the different manufacturers are in the method of manufacture and in the manner by which the pin and box are connected to the rod, the standard A.P.I. joint is taken as the basis for comparisons. As this is the most-used size, it has been taken as the standard in all calculations.

DISCUSSION OF PROBLEM

Types of Joint Failures

An analysis of field data on operating wells has shown that the sucker-rod failures are distributed according to the following percentages:

Unscrewed joints	10.8
Pin breaks	25.3
Box breaks	12.2
Body breaks	28.3
Heat-treatment failures	23.4

The unscrewed-joint failures need no explanation. They result from the action of the vibration of the rod in causing the joint to loosen and then gradually to become unscrewed. This type of failure can be solved either by increasing the make-up torque, which results in a higher initial load applied to the joint, or by using some patented thread form or locking device to prevent the joint from loosening.

The pin breaks take place at the root of the last vanishing thread. A typical example of a pin failure is shown in Fig. 1. The failure is due to fatigue, and it starts in the form of a crack at the root of the thread, which spreads until it results in complete fracture. This fatigue failure is the result of the high stress concentration at the root of the last vanishing thread. As will be shown later, this thread transmits a large part of the load, and the stress concentration is therefore high.

The size of the sucker-rod joint is limited by the size of tubing used, and any increase in the size of the joint is therefore impossible. The obvious remedy, then, for reducing pin breaks is to reduce the stress concentration. One possibility is to change the design of the pin threads in such a way as to reduce the stress concentration at their roots. Another possibility would be to modify the box in such a way as to improve the load distribution along the pin. Also, a reduction of the load carried by the joint could be accomplished by using no initial tightening, and this would result in a considerable strengthening of the pin. Such a method would require some special locking device to prevent the joint from coming unscrewed.

A typical box failure is shown in Fig. 2. The box failures usually take place after the box has become worn due to rubbing against the tubing. The reduction of area due to wear results in increased unit stress, which, with a high stress-concentration factor, results in failure. These box breaks, since they are caused by excessive wear, can be reduced only by some type of protector or guide. Some changes in proportions might result in a small decrease in failures.

The body breaks take place in the uniform section of the rod, as shown in Fig. 3. They are usually caused by fatigue and are accelerated by the presence of corrosion pits. The high stress concentration at the bottom of these pits results in a fatigue crack starting below the ordinary fatigue load. The body breaks are beyond control so far as design affecting them is concerned. These failures can be reduced only by decreasing the load or increasing the corrosion endurance resistance of the steel used in fabrication or by a protective coating.

The heat-treatment breaks are so designated because they were first supposed to be a result of the method of manufacture. The pins and boxes are formed by upsetting the ends of the rods.[3] After being upset, the ends are normalized in order to remove all upsetting strains and to cause a complete recrystallization of the metal into a fine-grained condition. If the ends are not properly normalized, the material will be weakened and there will be present some initial strains due to upsetting. There is also some stress concentration present at the fillets, because the rigidity of the joint causes any bending to be thrown into the fillet connecting the rod and joint and because of the change of

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

section. A typical example of this type of failure is shown in Fig. 4.

The problem of reducing heat-treatment breaks is one of metallurgy as well as mechanics. The methods of manufacture and of heat treating are properly metallurgical problems. The part belonging to the field of mechanics is the determination of the stress distribution and concentration in the fillet connecting the box or pin and rod.

A very complete study of sucker-rod failures has been made recently by Dr. Blaine B. Wescott and Mr. C. G. zurHorst.[3]

Variation in Actual Joints

In a recent investigation it was found that not one of a series of stock-joint studies conformed to the A.P.I. specifications.[4] It was shown, however, that with proper care and the use of better tools the manufacturers could meet these specifications without having undue hardships imposed on them. Since the variations in joints have a decided bearing on the value of any theoretical calculations, they will be discussed here.

In the aforementioned investigation it was shown that a lead error of 0.001 in. per length of thread consumes 0.0017 in. in the pitch-diameter tolerance or that a total error of 0.0017 in. on a sucker-rod box or pin consumes the entire pitch-diameter tolerance. This is equivalent to 0.00028 in. per thread, since there are six full threads on the standard A.P.I. pin. This is on the basis of all the tolerance on the pitch diameter being taken up by the error in pitch. Since a large part of the tolerance on the pitch diameter must be allowed for variation in machining, only a part can be taken up by error in pitch. It could safely be said that not more than one-third of the maximum possible error in pitch could be allowed. This would amount to 0.00009 in. per thread. Table 1 gives averages of measured pitches in actual sucker-rod pins and boxes.

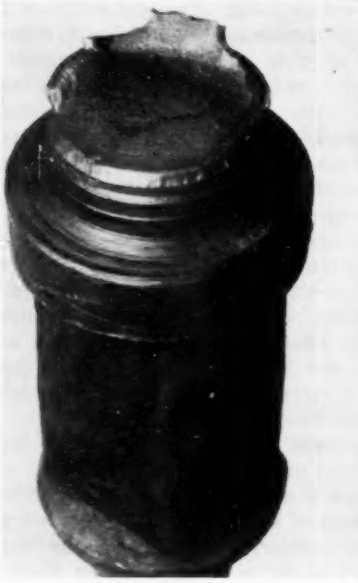

Fig. 1 Typical Pin Break

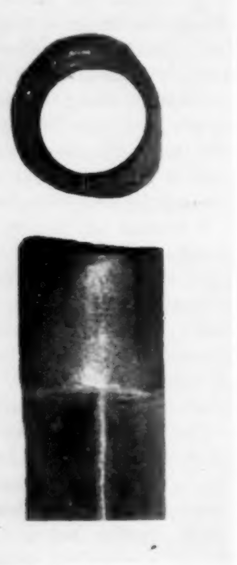

Fig. 2 Typical Box Failure

TABLE 1 AVERAGE LEADS IN $^3/_4$-IN. SUCKER-ROD BOXES AND PINS

Manufacturer	Lead per thread of pin	Error	Lead per thread of box	Error
A	0.10037	0.00037	0.10028	0.00028
B	0.09968	0.00032	0.10042	0.00042
C	0.10101	0.00101	0.10025	0.00025
D	0.10030	0.00030	0.09987	0.00013
E	0.10037	0.0037	0.09999	0.00001
F	0.10142	0.00142	0.10017	0.00017
G	0.10004	0.00004	....	....

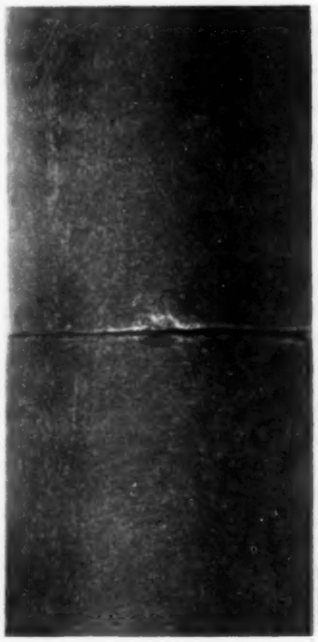

Fig. 3 Typical Body Failure

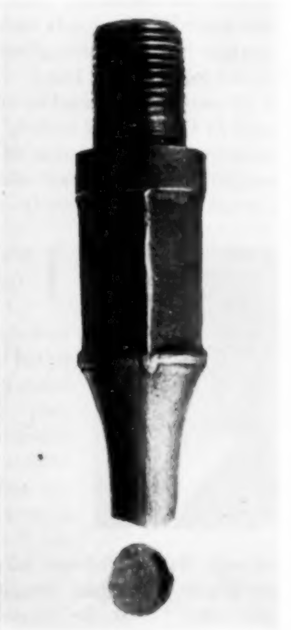

Fig. 4 Heat-Treatment Failure

From Table 1 it can be seen that the error in lead in all except a few cases is enough to consume all the tolerance in pitch diameter. The investigation carried out on these joints showed that not one of the pins or boxes approached the A.P.I. specifications. These results, therefore, cannot be used in comparing the variations in threads with the actual deflections to be obtained when the threads are loaded. Since it has been demonstrated that it is possible to make pins and boxes that will meet A.P.I. specifications without imposing undue hardships on the manufacturers, the comparison will be made on the basis of an allowable variation in pitch of 0.00009 in. per thread.

If the load were concentrated at the end of the thread, the deflection would be 0.0001 in. per 1000 lb load. It will be shown later that the first thread may carry as much as 40 per cent of the load. If the load were 20,000 lb, which would be an average value, as shown by the tensile tests on joints, the deflection of the thread would be 0.0008 in. The deflection of the first few threads is then many times greater than the maximum error in machining. Since the threads toward the end of the pin carry only a small amount of the load, the deflections caused by the load may be smaller than the errors in machining. We would therefore expect to find that the actual load distribution would vary but little from the theoretical where the maximum load occurs, but may vary considerably toward the end of the pin where there is little load transferred.

REVIEW OF WORK ON STRESS CONCENTRATION IN FILLETS, GROOVES, AND THREADS

Fillets

The stress concentration in fillets subjected to direct tension, compression, or bending has been investigated by Timoshenko and Dietz[5] for relatively small fillets. The results of this in-

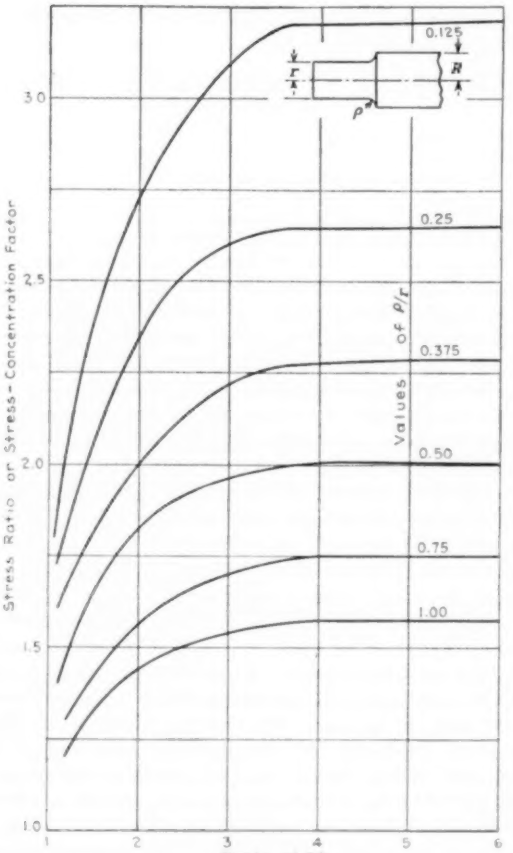

FIG. 5 STRESS CONCENTRATION IN FILLETS

vestigation are shown in Fig. 5. They show that the stress concentration may be very high in some cases. The stress concentration in cases where the radius is larger has been investigated by Moris.[6] The results of his test are given in Table 2. The proportions of the specimens are shown in Fig. 6. The catenaries were made with $BC/AB = 2$ and 4.

TABLE 2 MAXIMUM TENSION WHEN THE AVERAGE LOAD IN THE MINIMUM SECTION IS 1000 LB

Fillet radius	—Maximum tension for various values of W— 1.0	0.8	0.65	0.575	0.525
$^1/_2$ in.	1350	1210	1085	1028	1000
1 in.	1120	1120	1085	1015	1000
$1^1/_2$ in.	1060	1000	1000	1000	1000
2 in.	1000	1000	1000	1000	1000
2/1 catenary	1350	1350	1350	1350	1350
4/1 catenary	1060	1060	1060	1060	1060

There has been a great deal of work done on the stress concentration in holes and cracks.[7] This work has shown that the stress concentration in cracks or grooves may be very high. The amount depends, to a very great extent, on the shape of the crack. We would therefore expect that, if the sucker rods were corroded or pitted, the stress concentration in such pits would be high. If these corrosion pits happen to be at the fillet connecting the pin or box to the rod, the concentration would be much more severe than if they were in the body of the rod. Furthermore, the concentration due to a change of section occurs at a point only a little removed from the body of the rod, so the area of the section is very nearly the same as the body of the rod. We would therefore expect a larger number of the breaks to occur at this section. This is actually the case in sucker rods.

An increase of the fillet radius should result in a decrease in the failures at this connection between the pin or box and the body of the rod. For instance, the large diameter of the box at the connection is $1^1/_2$ in. and the diameter of the rod $^3/_4$ in., making $(R/r) = 2$. If the radius of the fillet is $^3/_8$ in., $(\rho/r) = 1$. From Fig. 5, it is seen that the ratio of the maximum stress to the actual stress is 1.45, or the stress at the section is 45 per cent greater than the average value or is 45 per cent greater than the stress in the rods. If a 1-in. radius had been used, the maximum stress would be 1.12 times the average stress, and if a 2-in. radius is used, there is no appreciable increase of stress caused by concentration. (See Table 2.)

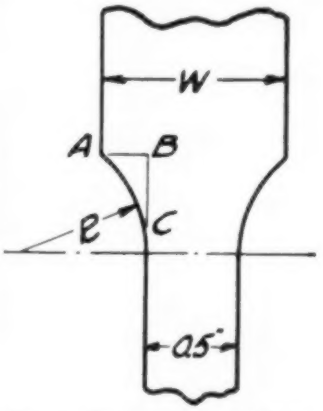

FIG. 6 PROPORTIONS OF PHOTO-ELASTIC SPECIMENS

The stress concentration in the case of torsion has been investigated by Jacobson.[8] The results of his investigation are shown in Fig. 7. This question of stress concentration in torsion caused by a change of section will be of use when the torsional stress caused by make-up is considered.

GROOVES AND THREADS

Moore[9] has investigated

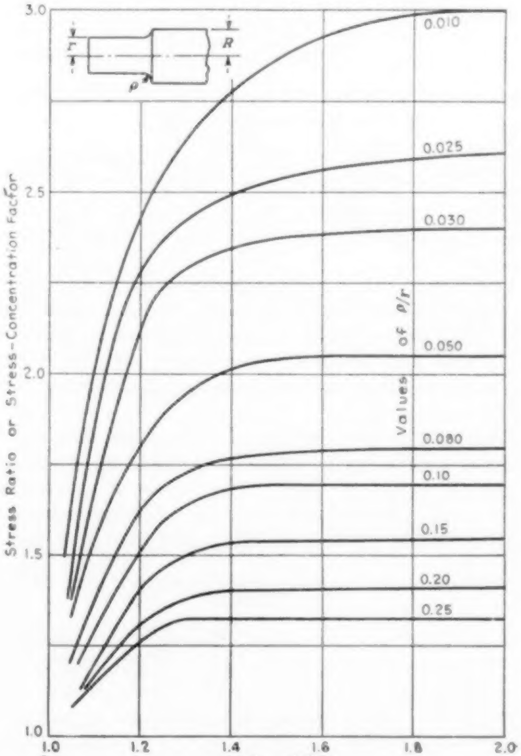

FIG. 7 TORSIONAL-STRESS CONCENTRATION

the relative effect of a radial groove and a continuous thread. His results on the endurance tests are shown in Fig. 8. The results of tests are given in Table 3.

The endurance limit of the grooved specimen shows a very large decrease in strength, while the threaded specimen of the same groove size shows a much higher endurance limit. The increased strength of the continuous threaded section under flexural stress might be due to the strengthening effect of the helical thread and partly for the reason that the minimum section is greater than the root diameter of the thread because of the helix.

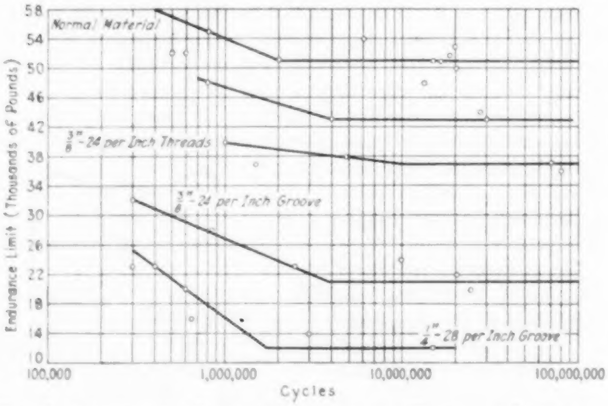

FIG. 8 ENDURANCE TESTS ON GROOVED AND THREADED SPECIMENS

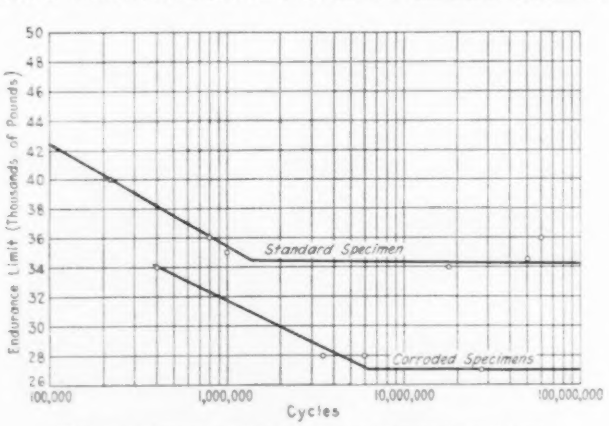

FIG. 9 EFFECT OF CORROSION ON ENDURANCE LIMIT

Mr. Moore also gives results of a specimen that had been subjected to a salt spray for 40 days. The average pitting was of the order of 0.0015 in. deep. The results of the endurance tests are given in Table 4 and Fig. 9, and show that such a small amount of pitting reduced the endurance limit 21.7 per cent. While his experiments were not extensive, they show that pitting seriously weakens the member.

Fig. 10 shows the results of Peterson[10] on stress-concentration factors due to U.S.S. threads by means of the plaster-of-paris specimens. These results show that the average stress concentration is nearly constant for all sizes of U.S.S. threads.

The results obtained by these investigators cannot be applied directly to our type of problem because they do not involve loading of the thread itself. When the joint is loaded, the threads transfer the load from the pin to the box, and they necessarily carry quite a load in bending, which greatly increases the stress at the root of the thread.

METHODS OF INVESTIGATION

USE OF THE EXTENSOMETER

The extensometer has been used to find the actual load that exists in a sucker-rod joint. When a string of sucker rods is placed in a well, each joint is tightened by a wrench, which may be from 18 to 60 in. long. With such wrenches, a considerable torque can be applied, and consequently quite a high initial tension will be put in the joint. In order to determine the amount of this load, it is necessary to measure the strain set up in the box, and from this calculate the value of the load. The small space available on the box for attaching an extensometer to determine this initial tension makes it necessary to use special attachments. On account of the small size of a joint, it is impossible to apply this method to finding the stress distribution in the threaded portion of the joint.

A Huggenberger tensometer with a magnification of 1010 to 1 was used in some tests made to determine the initial load in the joint caused by tightening. This instrument has a standard

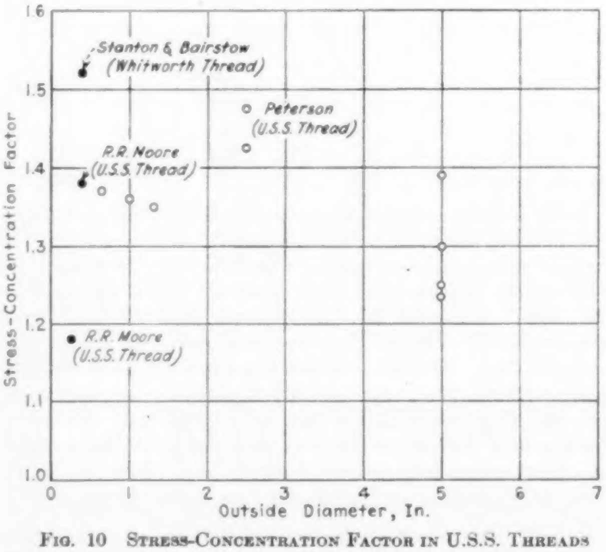

FIG. 10 STRESS-CONCENTRATION FACTOR IN U.S.S. THREADS

gage length of 1 in. In the tests on joints it was necessary to have a gage length of less than $^1/_2$ in., and so a special attachment was designed for this instrument, so that any gage length between $^3/_8$ in. and 1 in. could be obtained. The instrument with the special attachment is shown in Fig. 11 on a box that has been cut away to show the relative position of the extensometer and the threads.

[10] R. E. Peterson, "An Investigation of Stress Concentration by Means of Plaster-of-Paris Specimens," *Mechanical Engineer*, vol. 48, no. 12, December, 1926, pp. 1449–1452.

BRITTLE-MATERIAL METHOD

The brittle-material method is very simple in principle. Assume two specimens *a* and *b*, as shown in Fig. 12, to have the same net cross-sectional area. These two specimens are then tested to failure, and the breaking load of *a* is P_1 and of *b* is P_2. The ultimate strength of the material would be $S_a = (P_1/A)$, where A is the net area of the specimens. If there were no stress concentration, P_2 would equal P_1. The stress-concentration factor for a member having variation of cross-section is the ratio of the actual stress in the member with the irregularity to the stress as computed from a straight member. If we let k be the stress-concentration factor, then $k = (P_2/P_1)$.

It has been found upon comparing the results of photoelastic, plaster-of-paris specimen tests (brittle-material method), and actual fatigue tests on specimens with fillets that in all cases the photoelastic tests gave much higher stress concentration than the actual fatigue results and that the brittle-material method was much nearer the actual results, except in the case of chrome-nickel steels, which seem to be sensitive to stress concentration. A summary of this comparison was made by Peterson[10] and is shown in Fig. 13.

For a brittle material that has a very nearly straight-line stress-strain diagram, the same relation will hold between load and maximum stress as in a member of elastic material, provided the stress does not exceed the proportional limit of the material. In a brittle material, the stress concentrations, due to imperfections in the material, are greater than in ductile materials and play a large part in determining the strength of the specimen. It is therefore necessary to run duplicate tests and to use a statistical average.

This brittle-material method is based on the maximum-stress theory. This theory says that failure will occur when, and only when, one of the principal stresses reaches the value corresponding to the limiting stress in tension or compression, as the case may be. A discussion of this theory can be found in most advanced textbooks on strength of materials or applied elasticity. The theory has been shown to be true for such a brittle material as cast iron. In such a material the fracture always occurs at right angles to the axis of stress.

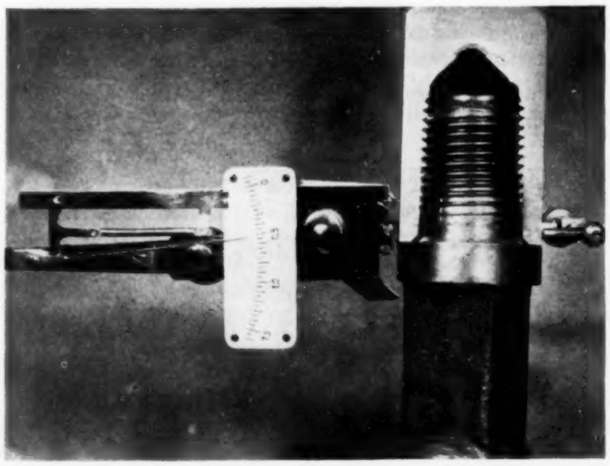

FIG. 11 HUGGENBERGER TENSOMETER, WITH SPECIAL ATTACHMENT

Because of the importance of stress concentration in connection with fatigue strength of a ductile material, such a method is very valuable. It has the further advantage of being a method that can be applied to three-dimensional stress problems.

PHOTOELASTIC METHOD

This method of stress analysis is limited to cases where the deformation is parallel to a plane. These are called two-dimensional stress problems. There are many three-dimensional problems that, because of radial symmetry, can be reduced to a two-dimensional problem for the study of certain features. An attempt is being made to use this method in the study of the sucker-rod problem. The problem of machining the sample is a very difficult one, and as soon as the machining methods are developed the analysis can be made.

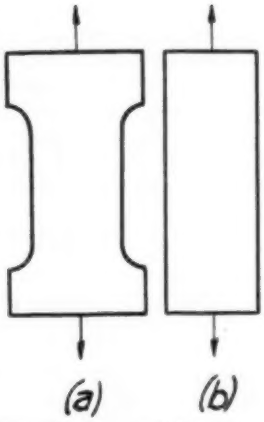

FIG. 12 BRITTLE-MATERIAL METHOD

THEORETICAL

This method permits a determination of the relation between the initial, applied, and total load in a joint and of the stress distribution in a joint. The method cannot be expected to give results that will represent every joint, because of the variation in the manufacture of joints. It will give results that should correspond to an average joint. Since this is all that we can expect to study, it seems that this should be of interest in a study of the general problem. In making such an analysis it is necessary to assume, as usually is the case in a solution of such problems, that the load is uniformly distributed across a section and that the material is not stressed beyond the proportionate limit.

LOADS CARRIED BY JOINT

TENSILE

In the following analysis it will be assumed that the loads will be applied by non-flexible members. This assumption causes little error in cases where the bolt or pin and compression members are relatively long, as is generally the case.

In a sucker-rod joint this is not the case. The part of the joint that takes the initial compression is short, and the elasticity of the threads will result in the actual loads as carried by the joint being less than the theoretical amount for a rigid case. It will be of interest to go through the theoretical case to determine the maximum load the joint may have to take and to determine the form of the equations.

In the derivation of these equations the following notation will be used:

A_p = area of pin
A_b = area of box
P_o = initial load in pin and box caused by make-up
F = applied load or load in rods
P = load in box when F has been applied
Q = load in pin after F is applied = $F + P$
Δ_p = unit stretch in pin
Δ_b = unit stretch in box
E = modulus of elasticity

When torque is applied to the joint in making it up, the box is compressed and the pin is put in tension. This initial tightening of the joint then causes the initial load P_o. The unit deformations caused by the load P_o are:

$$\Delta_p = \frac{P_o}{A_pE} \quad \text{and} \quad \Delta_b = \frac{P_o}{A_bE}$$

When the load F is applied, some of the compression in the box is relieved and the load in the box is reduced to some lower value P. If the compressive load in the box is relieved, the box will increase in unit length a small amount, which can be represented by $d\,\Delta_b$,

$$d\,\Delta_b = \frac{P_o}{A_bE} - \frac{P}{A_bE}$$

If the box increases in length, the pin also must increase in length. The load in the pin will be $(P + F)$, and if the change in unit length of the pin be represented by $d\,\Delta_p$,

$$d\,\Delta_p = \frac{P+F}{A_pE} - \frac{P_o}{A_pE}$$

Since these two deflections must be the same unless the joint actually opens, one can write that

$$d\,\Delta_p = d\,\Delta_b$$

or

$$\frac{F+P}{A_pE} - \frac{P_o}{A_pE} = \frac{P_o}{A_bE} - \frac{P}{A_bE}$$

$$P\left(\frac{1}{A_p} + \frac{1}{A_b}\right) = P_o\left(\frac{1}{A_b} + \frac{1}{A_p}\right) - \frac{F}{A_p}$$

$$P = P_o - \frac{F}{A_p\left(\frac{1}{A_p} + \frac{1}{A_b}\right)} = P_o - \frac{A_bF}{(A_b + A_b)}$$

$$P + F = P_o + F - \frac{FA_b}{A_b + A_p} = P_o + F\left(1 - \frac{A_b}{A_b + A_p}\right)$$

$$Q = F + P = P_o + F\left(1 - \frac{A_b}{A_p + A_b}\right)$$

For a $^3/_4$-in. standard A.P.I. joint the root area of the box and the area of the pin in the region considered are equal, so $Q = P_o + (F/2)$. The load in the joint at any time before the joint opens is then theoretically equal to the initial load plus one-half of the applied load. When the joint opens, $Q = F$, so the load to open the joint is given by $F = P_o + (F/2)$ or $(F/2) = P_o$ and $F = 2P_o$, or the load to open a joint is then twice the initial load.

RELATION BETWEEN TORQUE AND INITIAL LOAD

When a joint is made up by applying a torque to the wrench square, an initial tension is put in the pin and a compression in the box. They result in the load P_o being applied to the shoulder and the same load on the threads, as is shown in Fig. 14.

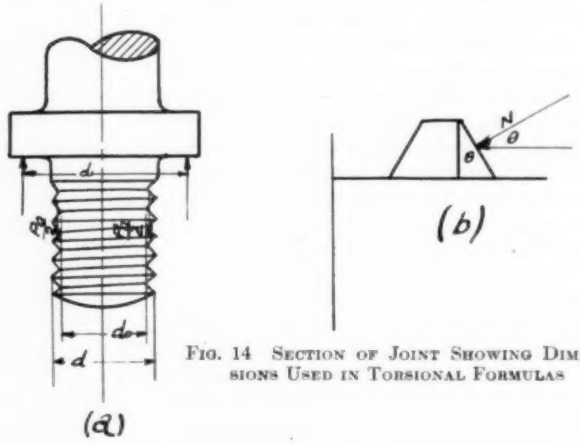

FIG. 14 SECTION OF JOINT SHOWING DIMENSIONS USED IN TORSIONAL FORMULAS

Let T = torque applied at wrench square
μ = coefficient of friction (assume the coefficient to be the same at the shoulder and thread).

The normal pressure N on the thread can be found from the relation

$$N = \frac{P_o}{\cos\theta}$$

For θ = 30 deg

$$N = 1.15\,P_o$$

$$T = \mu \times 1.15\,P_o \times \frac{d_o}{2} - \mu \times P_o \times \frac{d_1}{2}$$

$$= \mu P_o\left(\frac{1.15\,d_o}{2} - \frac{d_1}{2}\right)$$

For a standard $^3/_4$-in. rod d_o = 1 in.
d_1 = 1.28 in.

Then $T = 1.215\mu P_o$

$$P_o = \frac{T}{1.215\mu}$$

For a 3000 in-lb initial torque it was found that the average initial load was 19,500 lb. This would mean that the value of μ was 0.125 for the joints tested.

Magnitudes of Torsional Stress

When the joint is made up by applying a torque, part of the torque is taken up by friction at the shoulder and the rest by friction in the threads. The frictional torque of the threads must be transmitted by the pin, and this will then set up a torsional stress in the pin.

Let T_T = torque in the threads

Then $T_T = \mu \times 1.15\, P_o \times \frac{d_o}{2}$

If S_s = shearing stress due to torque in threads

$$S_s = \frac{T_T \times 16}{\pi d^3}$$

This is on the basis of no stress concentration. Because of the very sharp radius at the root of the threads, this stress concentration will be high. Fig. 7 shows the value of the stress concentration for different proportions. The upper curve has been extrapolated from other curves and is probably conservative.

In order to get an idea of the magnitude of this torsional stress, we can take the approximate dimensions of a threaded joint and find

$$(\rho/r) = 0.0105 \text{ approx.}$$
$$(R/r) = 1.13.$$

From Fig. 6, it can be seen that the stress-concentration factor is approximately 2.2.

As an example, take $T = 4500$ in-lb and $\mu = 0.15$.

$$P_o = \frac{4500}{1.215 \times 0.15} = 24{,}600 \text{ lb}$$

$$T_T = 0.15 \times 1.15 \times 24{,}600 \times {}^1/_2 = 2120 \text{ in-lb}$$

$$S_s = 12{,}800 \text{ lb per sq in.}$$

If the stress concentration factor is 2.2, the actual torsional stress at the root of the threads will be 28,200 lb per sq in.

The torsional stress in the joint would be of the order of magnitude of that calculated when the joint is first made up. It is probable that when some of the initial load in the box is relieved as the load is applied and the joint is subjected to vibration, a large part of this stress is relieved. The amount would depend upon the initial torque, initial tension, and the magnitude of the applied load.

Experimental

Experimental work is now in progress at the Gulf Research Laboratory on a study of the loads carried by joints under different make-up conditions. It has been found that the load carried by a joint can be represented by

$$Q = P_o + {}^1/_4 F$$

That is, the load in the joint is the initial load plus ¹/₄ of the load in the rods. The theoretical formula, on the basis of neglecting the flexibility of the threads, gave $Q = P_o + {}^1/_2 F$. This shows that the flexibility has quite an effect on such a short joint.

Some preliminary tests showed the initial load in a joint under ordinary make-up conditions to be in excess of 20,000 lb. This means that on wells 4000 ft or under and operating at ordinary speeds the initial load would be greater than the rod load and the load carried by the pin may be as much as 50 per cent greater than the load in the rods. It can be seen then that any type of joint that would eliminate the initial tightening would result in a big reduction in load carried by the joint.

LOAD DISTRIBUTION IN A THREADED JOINT

A Joint to Give Uniform Load Distribution

This example shows one method by which it is possible to get theoretical load distribution in an ordinary joint by using a special box.

Let a = effective length of nut
E = modulus of elasticity of material
P = load carried by joint
A_b = area of box
A_p = area of pin
L_b = load in box
L_p = load in pin
d_b = diameter of box
d_p = diameter of pin.

By definition of the problem the load in the pin at any section x is to be $L_p = P - \frac{Px}{a}$. The load in the box will then be $L_b = \frac{Px}{a}$. The unit elongation of the pin will be $\Delta_p = \frac{P}{EA_p}\frac{x}{(1 - a)}$ and the unit elongation of the box will be $\Delta_b = \frac{Px}{aA_bE}$.

Since they are the same, we can write:

$$\frac{P}{EA_p}\left(1 - \frac{x}{a}\right) = \frac{Px}{aA_pE} \ldots\ldots\ldots\ldots [1]$$

$$A_b = A_p \frac{x}{(a - x)} \ldots\ldots\ldots\ldots [2]$$

or

$$\frac{\pi(d_b^2 - d_p^2)}{4} = \frac{\pi d_p^2}{4}\frac{x}{(a - x)} \ldots\ldots\ldots [3]$$

$$d_b^2 = d_p^2 \frac{a}{(a - x)}$$

$$d_b = d_p \sqrt{\frac{a}{a - x}} \ldots\ldots\ldots\ldots [4]$$

The approximate shape of the box is shown in Fig. 15. A slight modification is necessary in this type of nut. When x approaches a in value, d_b approaches an infinite value, and when x approaches zero, $d_b \longrightarrow d_p$. In practice the box must have a small area at $x = 0$ and a finite area at $x = 1$.

In this arrangement no account need be taken of the elasticity of the threads, because the box deforms in such a manner as to cause each thread to take the same load, and since each thread will then have the same deflection, there will be no change in the distribution.

Theoretical Distribution in a Standard A.P.I. Joint

The theoretical distribution of the load in a standard A.P.I. pin will be given by the expression:

$$P = P_o \left(\frac{e^{Bx} - e^{B(2l - x)}}{l - e^{2Bl}}\right)\text{(footnote 11)}$$

where l is the working length of the thread, x the distance along the pin, and P_o the initial load. B is a constant involving the elasticity of the thread and is given by

$$B^2 = \frac{1}{\alpha E}\left(\frac{1}{A_b} + \frac{1}{A_p}\right)$$

α is the spring constant of the thread and is the displacement in inches between two originally coinciding sections of the pin and box caused by a unit force transmitted per unit length of the pin.

The foregoing equation is derived on the following basis:

If P is the load in the pin at any section x, the load in the box will be $P_o - P$. Let q be the load transmitted from the pin to the box per unit length along the pin, then $\frac{dP}{dx} = -q$.

If $d\Delta_p$ is the elongation of the pin in a length dx, then $d\Delta_p = \frac{Pdx}{A_pE}$ and $d\Delta_b = \frac{(P_o - P)dx}{A_bE}$.

If $d\Delta$ is the difference in elongation of the pin and box,

$$d\Delta = d\Delta_p - d\Delta_b = \frac{Pdx}{A_pE} - \frac{(P_o - P)dx}{A_bE} \ldots\ldots [5]$$

This difference must be taken up in the threads.

Then

$$\Delta = -\alpha q \ldots\ldots [6]$$

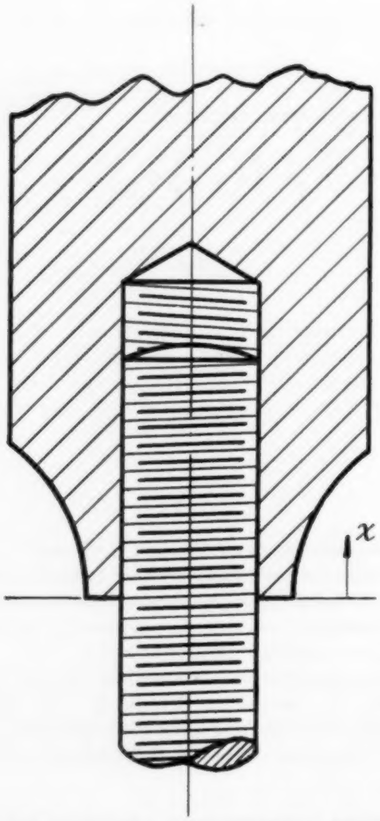

Fig. 15 Joint to Give Uniform-Load Distribution

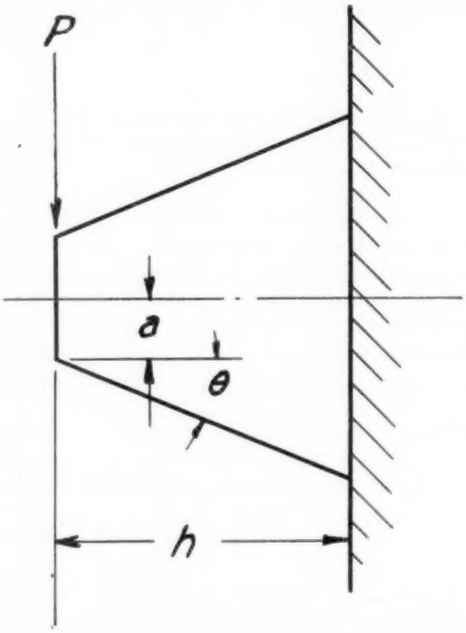

Fig. 16 Section Through Standard A.P.I. Thread

If this equation is differentiated with respect to x, we have

$$\frac{d\Delta}{dx} = -\alpha\frac{dq}{dx} = \alpha\frac{d^2P}{dx^2} \ldots\ldots [7]$$

since $q = -\frac{dP}{dx}$

From Equation [5]

$$\frac{d\Delta}{dx} = \frac{P}{A_pE} - \frac{(P_o - P)}{A_bE} \ldots\ldots [8]$$

Equating [7] and [8], we have

$$\frac{d^2P}{dx^2} = \frac{P}{\alpha E}\left(\frac{1}{A_p} + \frac{1}{A_b}\right) - \frac{P_o}{A_bE}$$

This equation when solved will give the load distribution quoted.

Deflection in Screw Threads

The section through a thread might be represented as in Fig. 16. A thread is then considered as a short cantilever beam. In such a short thread the deflection due to shear becomes of the same order of magnitude as that caused by bending, so it must be considered.

Let P = load per unit length along thread
h = height of thread
θ = $^1/_2$ angle of thread
a = $^1/_2$ width of thread at top
A = area of unit length of thread at any section x.

$$A = 2(a + x \tan\theta) \ldots\ldots [9]$$

$$S_s = \frac{P}{A} = \frac{P}{2(a + x\tan\theta)} \ldots\ldots [10]$$

If y_s represents the deflection caused by shear, we can write:

$$dy_s = \frac{S_s}{E_s}dx \ldots\ldots [11]$$

$$= \frac{P}{2E_s}\cdot\frac{dx}{(a + x\tan\theta)}$$

---

[11] J. P. Den Hartog, "The Mechanics of Plate Rotors for Turbo-Generators," Trans. A.S.M.E., vol. 51, 1929, paper APM-51-1.

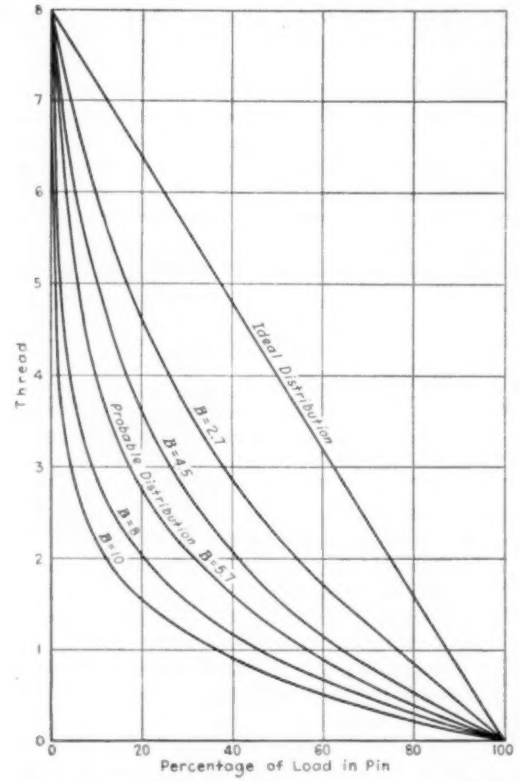

FIG. 17 LOAD DISTRIBUTION IN PIN AT ANY THREAD

$$y_s = \int \frac{P}{2E_s} \frac{dx}{(a + x \tan\theta)} = \frac{P}{2E_s \tan\theta} \log(a + x\tan\theta) + C. \quad [12]$$

For $x = h, y_s = 0$.

$$C = -\frac{P}{2E_s \tan\theta} \log_e (a + h \tan\theta) \ldots\ldots\ [13]$$

$$y_s = \frac{P}{2E_s \tan\theta} \log_e \frac{(a + x\tan\theta)}{(a + h\tan\theta)} \ldots\ldots\ldots\ [14]$$

If the deflection caused by bending is desired at several points, it would be best to determine the equation of the elastic curve from the relation

$$\frac{d^2y}{dx^2} = \frac{M}{EI}$$

where

$$I = \frac{1}{12} \cdot l \cdot (a + x \tan)^3 \times 8 = \frac{2}{3} (a + x\tan\theta)^3$$

so that

$$\frac{d^2y}{dx^2} = \frac{-px}{E \cdot {}^2/_3(a + x\tan\theta)^3} \ldots\ldots\ldots\ldots [15]$$

Since the maximum deflection at the end is all that is desired, it is simpler to use the strain-energy method, because there are no constants to be evaluated in accordance with boundary conditions.

If U = energy in system due to bending

$$U = \int_0^h \frac{M^2 dx}{2EI} = \int_0^h \frac{(Px)^2 dx}{2E \cdot {}^2/_3(a + x\tan\theta)^3} \ldots [16]$$

$$= \int_0^h \frac{P^2x^2dx}{{}^4/_3E\,(a + x\tan\theta)^3}$$

If Δ_p represents the deflection due to bending at the point where P is applied, and in the direction of P, we have

$$\Delta_p = \frac{\partial U}{\partial P} = \frac{\partial}{\partial P} \int_0^h \frac{P^2x^2dx}{{}^4/_3E(a + x\tan\theta)^3}$$

$$= {}^3/_2 \frac{P}{E} \int_0^h \frac{x^2dx}{(a + x\tan\theta)^3}$$

$$= {}^3/_2 \frac{P}{E \tan^3\theta} \left[\frac{a}{(a + h\tan\theta)^2} + \frac{1}{2} + \frac{2a}{(a + h\tan\theta)} - 2 + \log \frac{(a + h\tan\theta)}{a} \right]$$

$$= \frac{3P}{2\tan^3\theta} \left[\frac{a}{(a + h\tan\theta)} \left(2 - \frac{a}{2(a + h\tan\theta)} \right) - \frac{3}{2} + \log_e \left(\frac{a + h\tan\theta}{a} \right) \right]$$

If $\Delta = y_s + \Delta_p$ = total deflection due to P, then

$$\Delta = \frac{P}{2E_s} \log \left(\frac{a + h\tan\theta}{a} \right) + \frac{3P}{2\tan^3\theta} \left[\frac{a}{(a + h\tan\theta)} \left(2 - \frac{a}{2(a + h\tan\theta)} \right) - \frac{3}{2} + \log \frac{(a + h\tan\theta)}{a} \right]$$

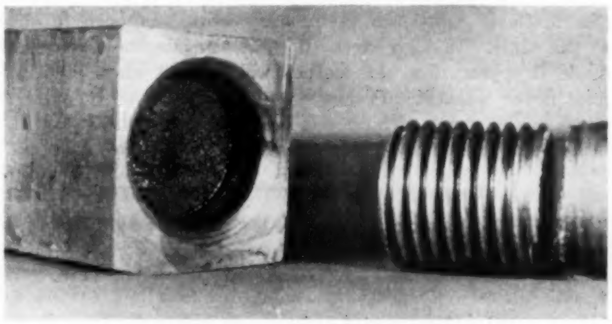

FIG. 18 FAILURE OF CAST-IRON JOINT

For a standard $^3/_4$-in. joint

$$a = 0.0057$$
$$E = 30 \times 10^6$$
$$E_s = 12 \times 10^6$$
$$\theta = 30 \text{ deg}$$
$$\tan\theta = 0.577$$
$$a + h\tan\theta = 0.0403$$

$$\Delta = 1.4 \times 10^{-7}P + 1.91 \times 10^{-7}P = 3.31 \times 10^{-7}P$$

The deflection caused by a load of 1000 lb is $\Delta_{1000} = 3.31 \times 10^{-7} \times 1000 = 3.31 \times 10^{-4} = 0.000331$ in.

The foregoing deflection is per inch of length. If we take the deflection for a complete thread, using the pitch diameter as the length,

$$\Delta_{1000} = \frac{0.000331}{\pi \times 1} = 0.0001055 \text{ in.}$$

DISCUSSION OF THE DISTRIBUTION EQUATION

Values for B have been calculated for various types of loading of the thread. For the load at the end of the thread $B = 2.70$, at $^1/_4$ the distance from the root $B = 4.5$, and at the center $B = 5.7$. In all these cases it is to be remembered that the deflection is the sum of the deflection of the pin thread and the deflection of the box thread. If, for instance, the box-thread deflection was not taken into account, the value of B for the load at the center would be $B = 8$. The most probable value for B would be for the case when the load comes at the middle of the thread. Fig. 17 shows the curves for the various values of B. These curves have been drawn to show the percentage of load in the pin at any point. It is seen that the increasing of the flexibility results in a very much better load distribution.

One other factor that affects the load distribution is the strength of the thread. If a load larger than the elastic limit of the material is to be applied to a thread, the thread will yield before this load has been reached and more load will be carried by succeeding threads. When ductile materials are used, this factor tends to cause a better distribution of load. In cases where the joint is subjected to fatigue loads, the joint is very weak if loads high enough to cause yielding are present, because fatigue failure will be rapid.

Distribution as Determined by Brittle-Material Method

The result of a test on a joint made of cast iron is shown in Fig. 18. It is seen that the joints in each case failed without any yielding and in the same identical place that fatigue breaks start. Only three tests were made, and all the joints broke in the same place. The difficulty with the use of this method was in obtaining good samples of cast iron and in getting a tensile-test specimen for comparison in which the stress-concentration factor would be known. Further work is being planned using this method. Only the preliminary work has been finished at this time. In view of the few experiments that have been made, it appears that this method will show at which point the joint is the weakest. It does not, however, show the state of stress in the region of failure as does the photoelastic test, and it may not give results as to the actual strength of the section.

Methods of Getting Better Distribution

Some of the methods that have been proposed previously in addition to the modified box to give uniform distribution are to make the threads with a variable pitch, to make the box with a parabolic surface on the inside,[11] and to increase the fillet at the root of the threads and thereby decrease the stress concentration.

The modified box has the disadvantage that it cannot be used where initial tightening must be used. The variable-pitch thread and box with a parabolic surface on the inside require such accurate machining that they are not practical. The increasing of the fillet at the root of the threads means shorter threads and consequently much higher load concentration at the first threads, as is shown in Fig. 16, because it will increase the value of B.

CONCLUSIONS

The results of this analysis show:

1 Any improvement in the endurance strength of the present joint can probably be brought about only by bettering the load distribution or by using a material with a much higher endurance limit.

2 A modification of the box by having a varying area would give a more uniform distribution of load along the pin.

3 An increase in the flexibility of the threads would give much better load distribution.

4 An increase in the radius at the root of the thread would greatly reduce the stress concentration at that point.

5 The initial load put in a joint in present practice results in the joint being under a much higher stress than if only the applied load was present.

6 The torsional stress set up in a joint by the initial tightening might be of importance in considering the strength of the joint.

7 The fillet connecting the rod and box or pin should be made with a radius of at least 2 in.

PME-54-8

Properties of Hydrocarbon Mixtures at High Pressures

By W. K. LEWIS[1] and C. D. LUKE,[2] CAMBRIDGE, MASS.

W. K. Lewis

The paper provides a comparatively simple method for the design of apparatus handling complex hydrocarbon mixtures at extraordinary pressures. The computation methods outlined enable one to calculate the density of any vapor, mixed or otherwise, at any temperature and pressure; the heat effect of any heating or cooling operation, whether conducted at constant pressure or changing pressure; the equilibrium between vapor and liquid at any temperature and pressure; the equilibria and changes in concentration throughout the tower in any operation of rectification or absorption, at whatever pressures they may be conducted; and the isothermal reversible work of compression of vapor mixtures, whatever the pressure range. These computation methods enable the refining engineer to design high-pressure equipment and operations with a high degree of precision.

C. D. Luke

A—PRESSURE-VOLUME-TEMPERATURE RELATION OF HYDROCARBONS

This laboratory[3] recently published an analysis of the data available on the behavior of the vapors of pure hydrocarbons at pressures up to and somewhat above the critical pressures.[4] This study indicated that one could treat all hydrocarbons containing more than 3 carbon atoms per molecule as conforming to the graphical equivalent of a single reduced equation of state. In other words, when the pressure on any given hydrocarbon is expressed as the reduced pressure, i.e., the absolute pressure on the system divided by the critical pressure of the material $P_R = P/P_c$, the temperature on the material as the reduced temperature $T_R = T/T_c$, and the volume as the actual volume occupied by the substance under these conditions of temperature and pressure divided by the volume of an equal amount of the substance in the critical state $V_R = V/V_c$, V_R is a unique function of P_r and T_r, the same for all higher hydrocarbons. It is perhaps more convenient to express the same result by saying that the behavior of any such hydrocarbon can be represented by the equation $PV = \mu RT$, where μ can be looked upon as a correction factor to the gas-law equation $PV = RT$, μ being a unique function of P_R and T_R. These relationships are shown in Figs. 1, 2, and 3, which may be considered as a graphical equation of state. In all figures μ is plotted against P_R for various values of T_R. The first plot, Fig. 1, is restricted to critical temperatures and below, while the second and third plots, Figs. 2 and 3, are for critical temperatures and above. The second goes up to a value of $P_R = 6$, while the third is continued to $P_R = 12$.[5] By the use of these plots one can calculate at any pressure and temperature, within the range represented, the vapor density of any pure hydrocarbon for which the critical conditions are known. For straight-chain paraffins, the data indicate that at the critical point the value of the ratio MP_c/T_c is equal to 5.0, where the pressure is given in atmospheres absolute, the temperature in degrees Centigrade absolute, and M represents the molecular weight of the hydrocarbon in question. For aromatic compounds without side chains, the corresponding value is apparently about 6.9. For saturated-ring compounds without side chains, a value of 6.0 should be employed. It is probably allowable to use for ordinary petroleum hydrocarbons a figure of from 5.5 to 6.0. Where the

[During the summers of 1930 and 1931 there were conducted at the Massachusetts Institute of Technology two conferences of five weeks each on the engineering phases of oil refining. The conferences were attended only by practicing engineers from the staffs of 24 companies in the industry, representing organizations not only in the United States, but in Canada, the Dutch West Indies, and the Argentine. In these conferences one of the major discussion groups dealt with those operations involving interaction of gases, vapors, and liquids, including evaporation, condensation, rectification, absorption, and the like. In the 1931 conference this particular discussion group was under the leadership of Dr. W. K. Lewis, Professor of Chemical Engineering at the Massachusetts Institute of Technology, formerly head of the Department of Chemical Engineering, and Mr. C. D. Luke, Research Assistant and Graduate Student in that institution. This paper is in no small degree an outgrowth of the conferences and work of that summer school.]

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[5] The article referred to[4] did not extend these curves to high values of P_R. The plots here given are constructed at higher values from Amagat's data on ethylene,[6] but experimental confirmation of the points is available from data on methane,[7,8] normal pentane,[9] isopentane,[10] and benzene.[11] Inasmuch as none of the data for the higher hydrocarbons covers the desired ranges of temperature and pressure, the extensive ethylene data were used in the construction of Figs. 1, 2, 3, and 4, which satisfactorily represent all available data on the *P-V-T* relations of hydrocarbons with the possible exception of methane.

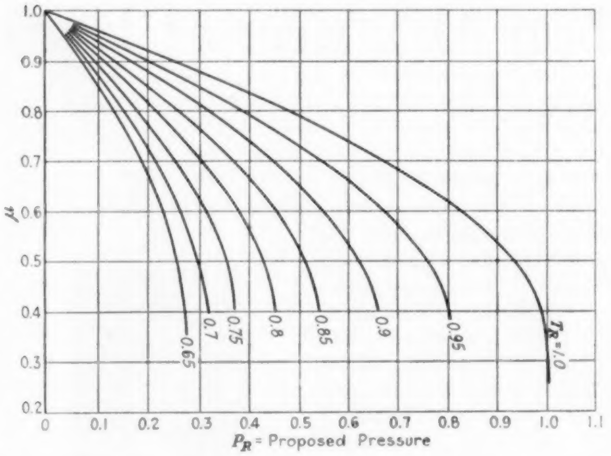

FIG. 1 RELATIONS OF HYDROCARBONS BELOW THE CRITICAL TEMPERATURE

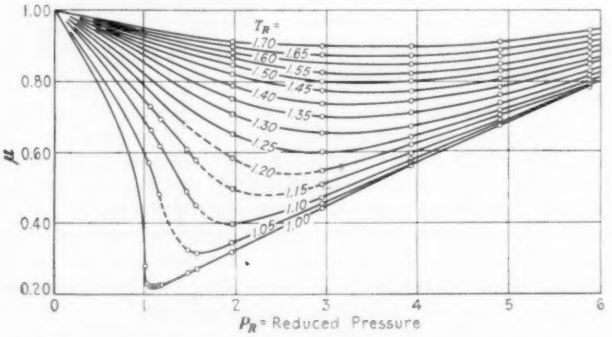

FIG. 2 *P-V-T* RELATIONS FOR HYDROCARBONS ABOVE THE CRITICAL TEMPERATURE (LOW-PRESSURE RANGE)

stock is of the type ordinarily referred to as highly paraffinic, one would use the lower value. For other stocks containing lower ratios of hydrogen to carbon, the higher figure is more probable. Granting that the value of this ratio to be employed for a given hydrocarbon can be estimated, if one knows a single point on its vapor-pressure curve, such as its boiling point, one can extrapolate its vapor-pressure curve by any of the well-accepted methods up to the point at which MP/T becomes equal to the value of this ratio. The corresponding pressure and temperature are the critical values for the compound in question. This places one in a position to estimate the vapor density of any hydrocarbon for which one knows the molecular weight together with a single point on its vapor-pressure curve.

To show the technique of employing these curves, assume that one wishes to know the density of benzene vapor at a temperature of 763 F and a pressure of 2335 lb per sq in. abs. The critical temperature of benzene is 551 F, and its critical pressure is 704.5 lb per sq in. abs. Therefore, the reduced temperature at the condition in question is $T_R = \dfrac{763 + 460}{551 + 460} = 1.209$, and the reduced pressure $P_R = 2335/704.5 = 3.315$. From Fig. 2 one reads the corresponding value of $\mu = 0.575$. If one wishes to express the result in lb per cu ft, one will use pressure expressed as lb per sq ft, volume as cu ft, temperatures as degrees Rankine (degrees Fahrenheit absolute), and quantities in pound-mols. In these units $R = 1543$. Since, however, one is interested in the volume of 1 lb, one is dealing with $1/M$ pound-mol; i.e., the volume in cu ft per lb is $\mu RT/MP = 0.04138$. In other words, the density of benzene vapor under these conditions is $1/0.04138 = 24.17$ lb per cu ft. One of the authors has measured the density of this material under these conditions and found an experimental value of 24.90 lb per cu ft, with which the calculated values agree within 3 per cent. The density calculated from the perfect gas law, $PV = RT/M$, is found to be 13.89 lb per cu ft, which is 44.25 per cent in error, compared with the observed value of 24.90. In the article referred to[4] the *P-V-T* relationship just discussed was employed to calculate the enthalpy of a hydrocarbon vapor. However, the method there developed breaks down at high pressure. It has been found that at high pressures and temperatures above the critical, the data of Figs. 2 and 3, replotted as isometrics, i.e., P_R plotted against T_R at constant values of V_R, fall on substantially straight lines. These lines are shown in Fig. 4. This plot may be used for the determination of volume relationships at high pressures and is sometimes more convenient than the μ curves of Figs. 1, 2, and 3. However, the main reason for the construction of Fig. 4 is to make possible the development of a method for

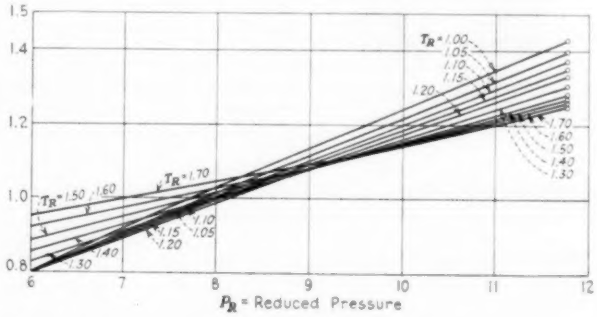

FIG. 3 *P-V-T* RELATIONS FOR HYDROCARBONS (HIGH-PRESSURE RANGE)

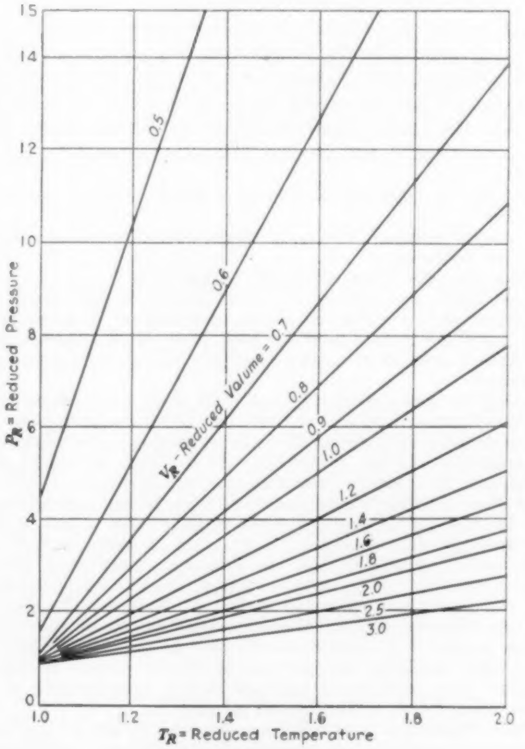

FIG. 4 REDUCED ISOMETRICS

calculating the enthalpy of hydrocarbon vapors in these high-pressure ranges. This is discussed below.

B—THERMAL PROPERTIES OF HYDROCARBON VAPORS

So long as any substance or mixture of substances exists in the form of a vapor at a pressure low enough so that it follows the gas laws, its internal energy and enthalpy are both independent of its pressure and volume and dependent upon the temperature only. This rule is the one usually used in the computation of the enthalpy of hydrocarbons, both pure and mixed, in the problems of refinery design. However, when the pressure is sufficiently high to produce deviations from the gas laws, the internal energy and total heat vary with the pressure at constant temperature. Since the coefficient μ is the measure of the deviation from the gas laws, it is clear that in any range in which μ begins to deviate appreciably from unity, it becomes necessary to apply corrections for the influence of pressure on the thermal properties. The article referred to[4] gave the following expressions for the pressure corrections of the internal energy and enthalpy:

$$E_1 - E_0 = -(S-1)FRT(1-\mu) \qquad [1]$$

$$H_1 - H_0 = -(S-1)FRT(1-\mu) - RT(1-\mu) \qquad [1a]$$

where E_0 and H_0 are the internal energy and enthalpy, respectively, at a pressure sufficiently low so that the vapor does not deviate appreciably from the gas law $PV = RT$, and E_1 and H_1 are the corresponding values at the high pressure and at the same temperature. In the foregoing expressions, S can be evaluated from Table 1. The quantity F is a complex function of the reduced temperature T_R and of a criterion $z = \dfrac{RT}{P_cV} = \dfrac{P_R}{\mu}$, and may be evaluated from Fig. 5. It should be noted that for values of z less than 2.5, F is unity. μ may be obtained from Figs. 1 or 2. T is the absolute temperature in degrees Kelvin or Rankine. R is equal to 1.985, both in calories per degree Centigrade and in Btu per degree Fahrenheit. Consistent units must be employed throughout the equation.

TABLE 1

T_R	S	T_R	S
1.50	4.36	1.05	3.82
1.45	4.36	1.00	3.71
1.40	4.36	0.95	3.66
1.35	4.36	0.90	3.50
1.30	4.36	0.85	3.16
1.25	4.36	0.80	2.74
1.20	4.36	0.75	2.74
1.15	4.34	0.70	2.74
1.10	4.07	0.65	2.74

However, Equations [1] and [1a] break down at values of P_R in the range to the right of the dotted line of Fig. 2. On the other hand, the *P-V-T* relations in this high range of P_R are expressed by the straight isometrics of Fig. 4. At these high values of P_R, the pressure corrections for the internal energy and enthalpy are given by the expression:[12]

$$E_2 - E' = -3.23T_c\left(\frac{1}{V_{R_2}} - \frac{1}{V_R'}\right) \qquad [2]$$

$$H_2 - H' = -3.23T_c\left(\frac{1}{V_{R_2}} - \frac{1}{V_R'}\right) - RT(\mu' - \mu_2) \qquad [2a]$$

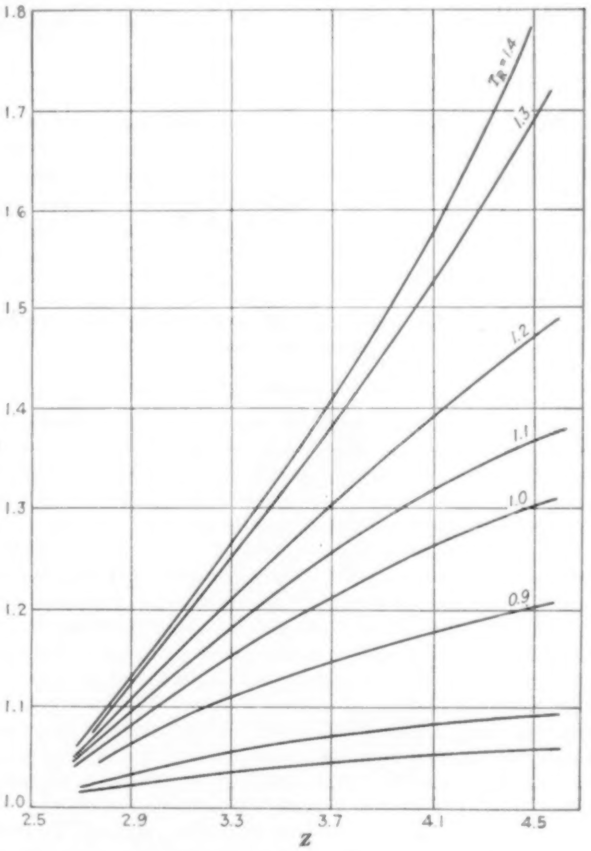

FIG. 5 PLOT OF F AS A FUNCTION OF Z AND T_R

In Equations [2] and [2a] E', H', V_R', and μ' are the internal energy, enthalpy, reduced volume, and gas-law deviation factor, respectively, at the value P_R given by the dotted line of Fig. 2, and E_2, H_2, V_{R_2}, and μ_2 are the corresponding values at the higher pressure.

Unfortunately, the isometrics of Fig. 4 do not remain straight to low values of P_R, so that Equation [2] breaks down at the low pressures, whereas exactly the reverse is true of Equation [1]. The problem of calculation can be solved by using each expression in its proper range.

Thus, assume that one wishes to obtain the enthalpy above an arbitrary reference point of benzene vapor at a temperature of 457 C and a pressure of 200 atm abs. The enthalpy of the benzene vapor at 457 C and 1 atm may be readily calculated by any of the accepted methods, most of which depend on low-temperature heat of vaporization data and low-pressure specific heat data for the vapor. From this point on, the equations developed may be used to compute the enthalpy at the high pressure.

The final conditions of the vapor correspond to $T_R = 730/561.6 = 1.30$ and $P_R = 200/47.9 = 4.18$. Inspection of Fig. 2 shows that one must use Equation [1a] up to a value of $P_R = 1.42$, and Equation [2a] from $P_R = 1.42$ to $P_R = 4.18$. Hence, by combining the two equations,

$$H_2 - H_0 = -3.23T_c\left(\frac{1}{V_{R_2}} - \frac{1}{V_R'}\right) - (S'-1)F'RT(1-\mu') - RT(1-\mu_2)$$

When $P_R' = 1.42$ and $T_R = 1.30$, $\mu' = 0.781$, $F' = 1.00$, and

---

[12] Phillips, H. B., *Jour. Math. and Phys.*, Mass. Inst. of Tech. 1, 42 (1922).

$S' = 4.36$; $V_R' = \dfrac{3.78\ \mu' T_R}{P_R'} = 2.70$. When $P_{R2} = 4.18$ and $T_R = 1.30$, $\mu_2 = 0.690$ and $V_{R2} = \dfrac{3.78\ \mu_2 T_R}{P_{R2}} = 0.811$.

Substituting these values in the foregoing expression, $H_2 - H_0 = -3074$ cal per gram-mol $= -1.8(3074) = -5540$ Btu per lb-mol. Hence, if one were to calculate the enthalpy of benzene vapor at this temperature and pressure by assuming the gas laws, i.e., by assuming that pressure has no effect on the total heat at constant temperature, the result would be too high by 5540 Btu per lb-mol.

C—PROPERTIES OF VAPOR MIXTURES AT HIGH PRESSURES

1 Volume Relations of Mixtures

The properties of gas and vapor mixtures at low pressures are usually given in terms of Dalton's law, which states that each component in such a mixture exerts a partial pressure equal to the pressure that it would exert were it present alone in the same concentration, the total pressure being equal to the sum of the partial pressures of all the components. At high pressure this rule breaks down completely, and the concept of partial pressures loses its physical significance. However, an alternative way of expressing the behavior of gas and vapor mixtures at low pressures is to say that if such substances be mixed at constant pressure, the volumes are additive, and in the absence of chemical action, the heat effect of mixing is zero. The data indicate that this rule is substantially valid for the mixing of gases and vapors up to appreciable pressures. From the thermal point of view it is equivalent to saying that on mixing components at constant pressure the internal energies and enthalpies are additive. Since the curves and equations outlined in parts A and B put one in a position to calculate volumes and enthalpies of pure components, the rules just given make it possible to calculate the corresponding quantities for mixtures, however complex, when the compositions are known.

Assume that one has a mixture containing 56.8 per cent by weight of benzene and 43.2 per cent of toluene. These figures correspond to 60.8 mol per cent of the former and 39.2 mol per cent of the latter. This mixture is at a pressure of 25.4 atm and a temperature of 260 C.

The critical temperature of benzene is 288.5 C and of toluene 320.6 C; the critical pressures are 47.9 atm and 41.6 atm. The reduced temperature of the benzene is therefore $T_R = 533/561.6 = 0.949$, and of the toluene $T_R = 533/593.7 = 0.899$. The corresponding reduced pressures are $P_R = 25.4/47.9 = 0.531$ and $25.4/41.6 = 0.610$, respectively. At these values of P_R and T_R for benzene, one finds from Fig. 1 that $\mu = 0.708$ and for toluene, at $T_R = 0.899$ and $P_R = 0.610$, $\mu = 0.515$. Consider as a basis 100 grams of the mixture. This contains 56.8 grams of benzene, which is $56.8/78 = 0.728$ mol of benzene. It also contains 43.2 grams of toluene or $43.2/92 = 0.470$ mol. From the corrected gas-law equation $PV = \mu nRT$, under the pressure in question of 25.4 atm, the volume of the benzene in the mixture, in the form of pure benzene vapor, would be $V = \mu nRT/P$. Using the gas constant in cubic centimeter-atmospheres per degree Centigrade, $R = 82.07$, $V = (0.708)(0.728)(82.07)(533)/25.4 = 888$ cc. Similarly, the volume of the toluene in the mixture, measured at the same pressure and temperature, but in the pure state, is $V = 416$ cc. According to the foregoing rule, the volume of the mixture is the sum of these two individual volumes, i.e., 1304 cc. Since this is the volume of 100 grams of the mixture, the density is $100/1304 = 0.0766$ gram per cc. This is numerically equal to the specific gravity of the mixture. Since the density of water in English units is 62.3 lb per cu ft, the density of this mixture in English units is $0.0766(62.3) = 4.77$ lb per cu ft. This density might have been calculated directly by considering, not 100 grams of the original mixture, but 100 lb of that mixture, expressing the pressure in lb per sq ft, the temperature in degrees Rankine, and using the corresponding gas constant, $R = 1543$. The density of this particular mixture under these conditions has recently been measured in this laboratory and found experimentally to be 0.0785 gram per cc, corresponding to a volume of 1064 cc per mol. The difference between the experimentally determined and the calculated density is seen to be 2.42 per cent. However, had one calculated the density from the gas laws, one would have found a value of 0.0485 gram per cc, only 61.8 per cent of the actual value.

Had one used Dalton's law, one would have assumed the partial pressure of the benzene in the mixture to be its mol-fraction times the total pressure, i.e., $0.608\ (25.4) = 15.43$ atm. Similarly, the partial pressure of toluene would have been 9.97 atm. The value of μ for benzene at this partial pressure would be 0.835 and for toluene 0.856. The volume of 1 mol of the mixture calculated from the equation $v = \mu n\ RT/P$, using this new value of μ for benzene, is found to be 1437 cc. Similarly calculated for toluene, the figure is 1472 cc. It is seen that neither of the computed values checks the experimentally determined value, 1064 cc per mol.

2 Thermal Relations of Vapor Mixtures

As previously outlined, when the components of a vapor mixture are mixed at constant temperature and pressure, the heat of mixing is essentially zero and the internal energies are additive, i.e., the internal energy of the resultant mixture, at the same temperature and pressure, is the sum of the internal energies of all the components. Likewise, the enthalpies are additive.

Suppose one wishes to expand the benzene-toluene mixture of the preceding problem isothermally from the pressure there given down to a pressure sufficiently low so that the vapor obeys the gas laws. No work, mechanical or otherwise, will be done during the expansion. How much heat must be added during expansion per mol of the mixture?

Inasmuch as the operation is isothermal, only Equations [1a] and [2a] need be considered. From the preceding calculations, for benzene, $T_R = 0.949$, $P_R = 0.531$, and $\mu = 0.708$; for toluene, $T_R = 0.899$, $P_R = 0.610$, and $\mu = 0.515$. Obviously, the range here considered is covered entirely by Equation [1a]:

$$\Delta H = -(S-1)FRT(1-\mu) - NRT(1-\mu) \ldots. [1a]$$

For benzene, S at $T_R = 0.949$ is equal to 3.66, and for toluene at $T_R = 0.899$, $S = 3.50$. For both benzene and toluene, $F = 1.00$ so that Equation [1a] reduces to

$$\Delta H = -SNRT(1-\mu) \ldots\ldots\ldots\ldots. [1b]$$

Substituting the foregoing values in Equation [1b], $\Delta H = 1130$ cal per gram-mol for benzene and 1795 for toluene. Hence for 1 mol of mixture, equivalent to 0.608 mol of benzene and 0.392 mol of toluene, $\Delta H = 0.608\ (1130) + 0.392(1795) = 1390$ cal per gram-mol. In engineering units, the result is $1.8(1390) = 2502$ Btu per lb-mol.

3 Vapor-Liquid Equilibria

It is well recognized that at low pressures Raoult's law affords an excellent method of estimating the volatility of the constituents in a liquid mixture of hydrocarbons. This law demands that the partial pressure p of a given constituent shall equal its mol fraction in the liquid times the vapor pressure of the constituent in question in the pure state at the same temperature, i.e., $p = Px$. It is usually combined with Dalton's law in the form $p = \pi y = Px$. Since Dalton's law breaks down at high pressures, it is to be expected that Raoult's law will likewise become invalid. The physical chemist has proposed modifying these solution laws at high pressures by substituting for the pressure a corrected pressure, called the fugacity.[13] The fugacity f of any pure gas or vapor at any pressure whatsoever is defined by the differential equation $(\partial \ln f/\partial p)_T = V/RT$. Granting knowledge of the P-V-T relationship, this integral can be determined graphically. This has been done from Figs. 1, 2, and 3, and the results are plotted in Figs. 6 and 7. Choosing as ordinates the dimensionless ratio f/p makes it possible to represent on these two diagrams the relationships for all hydrocarbons which follow Figs. 1, 2, and 3.

NOMENCLATURE

P = vapor pressure of a pure component
π = total pressure on the system
f_P = fugacity of a pure liquid component under its own vapor pressure at the temperature of the system
f_π = fugacity of a pure vapor component at the temperature and total pressure of the system
x = mol fraction of a component in a liquid
y = mol fraction of a component in a vapor.

The fugacity of any component in a liquid must of necessity be equal to the fugacity of the same component in the vapor in equilibrium with that liquid. Hence, one can calculate the fugacity of a pure liquid f_P by calculating the fugacity of its saturated vapor. Furthermore, the fugacity f of any component in a vapor mixture may be estimated by multiplying the mol fraction of that component in the mixture y times the fugacity of the pure component at the temperature and total pressure of the mixture, i.e., $f = f_\pi y$. Raoult's law now becomes,

$$f = f_\pi y = f_P x \qquad [3]$$

instead of the more familiar form,

$$p = y\pi = xP \qquad [4]$$

It will be noted that the only change is the substitution of the fugacity for each pressure term in Raoult's law.

That which makes this equation of vital interest to the refinery engineer is the fact that it enables one to estimate the equilibrium between vapor and liquid phases at high pressure. Furthermore, these equilibria may in special cases differ greatly from those calculated by Raoult's law, although in other cases the distinction between the results obtained from the two expressions is entirely negligible.

Suppose one has a straw oil which is contacted sufficiently intimately with a gas containing ethane at 32.2 C, so that the oil comes into equilibrium with it. This particular temperature is the critical temperature of ethane. Assume three cases: In the first, the gas is pure ethane at a pressure of 1 atm abs. In the second, the gas contains 2 mol per cent of ethane and 98 per cent of hydrogen, but the total pressure on the mixture is 50 atm. In the third case, the mol per cent of ethane is 0.5 and of hydrogen 99.5, but the total pressure on the mixture is 200 atm. What will be the mol fraction of ethane in the oil in equilibrium with it in the three cases?

Using the ordinary nomenclature, inspection of the data shows that in each of the three cases the partial pressure of the ethane, i.e., the mol fraction of the ethane in the vapor times the total pressure, is 1 atm. Consequently, Raoult's law in its ordinary form would require that the solubility of the ethane in the oil be the same in all three cases. Since the critical pressure of ethane is 48.8 atm, Raoult's law indicates that the solubility of the ethane in the oil, $x = \pi y/P = (1/48.8) = 0.0205$ in each of the three cases.

Using the corrected form of Raoult's law in which the pressures are replaced by the corresponding fugacities, one obtains an entirely different result. The fugacity of pure liquid ethane f_P at this temperature is calculated as follows: It is at its critical point, and consequently from Fig. 6 one sees that $f_P/P = 0.645$. Since its saturation pressure, i.e., the critical pressure, is 48.8 atm, its fugacity in the pure state is $f_P = 0.645\ (48.8) = 31.5$ atm. The fugacity f_π must be calculated at the total pressure on the system. In the first case, this is 1 atm. Hence, $\pi_R = 1/48.8 = 0.0205$. The corresponding value of f_π/π at $T_R = 1.00$ is 0.995, or $f_\pi = 0.995$ atm. Hence, $x = f_\pi y/f_P = [(1)\ (0.995)/31.5] = 0.0316$. It will be noticed that this mol fraction, i.e., the solubility of pure ethane gas at this temperature and 1 atm pressure, is approximately 50 per cent greater than that calculated by Raoult's law.

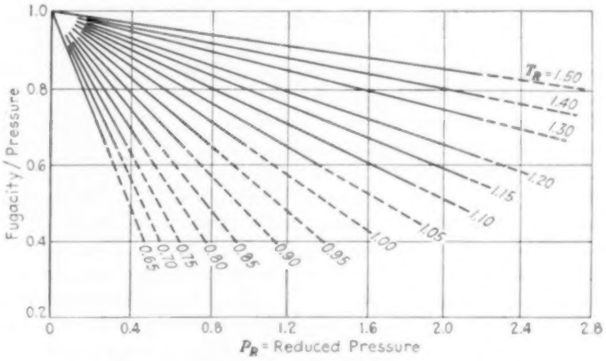

FIG. 6 FUGACITY PLOT (LOW-PRESSURE RANGE)

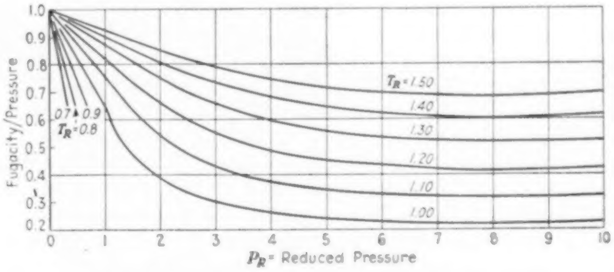

FIG. 7 FUGACITY PLOT (HIGH-PRESSURE RANGE)

Turning to the second case, the value of f_P remains unchanged, but f_π must be calculated at a total pressure of 50 atm, where $\pi_R = 50/48.8 = 1.025$. The corresponding value of f_π/π is 0.635, whence $f_\pi = 31.7$. Substituting this in the equation for x gives $x = 0.0201$. In this case the solubility is practically the same as that calculated by Raoult's law. It would have been absolutely identical had the chosen total pressure equaled the critical pressure. At the third condition mentioned, at $\pi = 200$ atm, $\pi_R = 200/48.8 = 4.10$ and, from Fig. 7, $f_\pi/\pi = 0.257$, or $f_\pi = 51.4$ atm. Hence, $x = 0.00815$. In other words, at this high pressure the solubility of ethane is roughly 40 per cent of that calculated by Raoult's law.

This illustration emphasizes the point that pressure makes a great difference in gas solubility, even at what one would normally consider identical partial pressures. Furthermore, it is well to note that at low pressures the solubility is abnormally high and at high pressures it is abnormally low. This is in a sense unfortunate, because the engineer resorts to high pressure when he wants to force a gas into a liquid and turns to low pressure when he wants to strip it out. In both cases, the direction of the deviations from the gas laws is such as to tend to defeat his purpose. Clearly, however, the magnitude of the variations is such that they can by no manner of means be ignored in engineering calculations in the refining industry.

---

[13] Lewis and Randall, "Thermodynamics and the Free Energy of Chemical Substances," McGraw-Hill Book Co., New York, 1923, pp. 190–201, 221–227, 232–235.

Inspection of Figs. 6 and 7 will make it clear that corrections to Raoult's law are unnecessary so long as the total pressure on the gas π and the vapor pressures of the pure components at the temperature in question P are small, because under these conditions f/P is always nearly unity. These are the conditions under which Raoult's law has been tested most carefully in the past. Unfortunately, the amount of data available for testing deviations from it under high values of π and P are meager, but those available fully confirm the general dependability of the computation method here proposed.

Thus, suppose one wishes to calculate the vapor pressure of the liquid and the composition of the vapor in equilibrium with a liquid containing 53.0 mol per cent benzene and 47.0 per cent toluene at a temperature of 290 C. At this temperature, the vapor pressures of benzene and toluene are 49.2 and 28.4 atm, respectively. Inasmuch as 290 C is above the critical for benzene, its vapor pressure must be determined by extrapolating the vapor pressure curve to 290 C. The foregoing data correspond to $T_R = 1.001$ and $P_R = 1.028$ for benzene and for toluene, $T_R = 0.950$ and $P_R = 0.682$, whence the corresponding fugacities are $f_P = 31.5$ and 20.0 for benzene and toluene, respectively. In order to calculate the total pressure π, one must first assume a value of π, calculate f_π for each component, and then calculate the value of y for each constituent from the equation $y = f_P x / f_\pi$. The correct value of π is that which makes Σy, i.e., the summation of the calculated mol fractions in the vapor, equal unity. Following this procedure, one obtains $\pi = 39.4$ atm and mol fractions of benzene and toluene in the vapor equal to 0.596 and 0.404, respectively. The corresponding values observed in this laboratory were $\pi = 37.8$, $y = 0.608$ for benzene, and $y = 0.392$ for toluene. Thus, the calculated π and y for benzene differ from the observed by 4 per cent and 2 per cent, respectively. On the other hand, Raoult's law calculations give $\pi = 39.45$ atm, and $y = 0.661$ and 0.339 for benzene and toluene, respectively. These calculated values of π and y for benzene differ by 4 per cent and 9 per cent, respectively, from the observed values.

TABLE 2

Method	π	Deviation, per cent	y, benzene	Deviation, per cent
Fugacity..........	39.4	4	0.596	2
Raoult's law.......	39.45	4	0.661	9
Observed..........	37.8	..	0.608	..

One will see from Table 2 that the pressure calculated either by Raoult's law or by the fugacity method checks the observed pressure very satisfactorily. However, the vapor composition calculated by the fugacity method checks the observed value much more closely than that calculated by Raoult's law. The data available indicate that this is generally true, i.e., that Raoult's law is passable for calculating total pressures at moderate pressures, but unsatisfactory for calculating vapor composition. Furthermore, the error involved in using Raoult's law increases as one approaches the critical point and becomes excessive when the mol fraction of the component in question in the vapor phase is small.

Most unfortunately there are almost no data available giving experimental determinations of the fugacity of vapors at temperatures below the critical but pressures above it. Furthermore, no satisfactory method of calculation of the values to be expected in this range is known. This is the more serious because this is a range in which the modern petroleum engineer is becoming more and more vitally interested. This laboratory is making experimental determinations in this field and hopes to be able to publish data of value in the near future. However, it is the conviction of the authors that even now one can estimate the behavior of hydrocarbon mixtures in this region by extrapolating both the μ curves and f/P curves to high values of P_R, drawing them parallel to the curve corresponding to $T_R = 1$ and spacing them approximately proportionately between that curve and the horizontal axis. Certainly, this method of estimation will be far more dependable than any of the guesses hitherto employed.

In the design of equipment for both rectification and absorption, the engineer uses over and over again the slope of the equilibrium line y/x. Hitherto, he has employed P/π for this slope. Clearly, in view of the preceding discussion, the correct slope to employ is not P/π, but f_P/f_π. Furthermore, the engineer uses this slope at a given temperature and total pressure. Fortunately, under these same conditions the correct value of the slope f_P/f_π is a constant quantity. The method of calculating it has already been illustrated. In order to have this equilibrium relationship correct in all computations of design, at whatever pressure the operation may be carried out, the engineer has only to substitute this new ratio f_P/f_π, for the ratio P/π, with the use of which he is already familiar.

It is well to call attention to the fact that the fugacity offers an extremely direct method of calculating the net isothermal reversible work of either pure compounds or of mixtures, however complex. Indeed, the fugacity may be defined by the equation,

$$W = nRT \ln f_2/f_1 \quad \text{.................} [5]$$

where W is the net isothermal reversible work of compressing n mols of a gas from the condition in which the fugacity is f_1 to that in which the fugacity is f_2. Furthermore, since the volumes of vapors are additive at constant temperature and pressure, it follows that the foregoing equation can be used for a mixture by applying the equation in succession to each component, the total work of compression of the mixture being the sum of the compression work thus computed for each component.

Thus, it is desired to calculate the net isothermal reversible work of compressing 1 mol of a vapor mixture containing 40 mol per cent ethane and 60 per cent propane from 10 atm to 400 atm at a constant temperature of 120 C. The value of $T_R = 393/305.3 = 1.288$ and $393/370.5 = 1.060$ for ethane and propane, respectively. At $P_1 = 10$ atm, P_{R1} for ethane equals $10/48.8 = 0.205$, and for propane $P_{R1} = 10/44.5 = 0.225$. Hence $f_1 = 9.72$ and 9.36 for ethane and propane, respectively. At $P_2 = 400$ atm, the corresponding values of f_2 are 202.0 and 112.8, respectively. Equation [5] becomes, for this case,

$$W = n_{\text{ethane}} RT \ln \left(\frac{f_2}{f_1}\right)_{\text{ethane}} + n_{\text{propane}} RT \ln \left(\frac{f_2}{f_1}\right)_{\text{propane}}$$

For 100 mols of the mixture, one obtains $W = 2108$ cal per gram-mol, or expressed in engineering units, $W = 1.8(2108) = 3794$ Btu per lb-mol.

4 MECHANISM OF SOLUTION AT TEMPERATURE ABOVE THE CRITICAL POINT

A problem frequently met by the engineer is the necessity for estimating the solubility of gases in liquids at temperatures above the critical points of the gases. It is clear that Raoult's law in its ordinary form breaks down under these conditions. Designers have not infrequently extrapolated the vapor pressure curve, graphically or otherwise, and used the extrapolated values of P in Raoult's law for the estimation of solubilities. It is clear that any such procedure is grossly inaccurate because of the wide differences between fugacity and pressure in these ranges. However, it is interesting to consider the extrapolation of the fugacity curve of the saturation curve beyond the critical temperature.

The fugacity form of Raoult's law, as given, implicitly assumes additivity of volumes and absence of heat effects on mixing liquids. This granted, it is easy to show that, at temperatures sufficiently low that the vapor pressures of a given pure component are low enough so that deviations of the saturated vapors from the gas laws are negligible, the heat of solution of a vapor in a non-volatile solvent is numerically equal to the heat of vaporization of the pure liquid being dissolved. This is true whatever the pressure on the vapor, because the enthalpy of the vapor depends on only the temperature and is independent of the pressure. However, the moment the temperature of the vapor gets sufficiently high so that the saturated vapor deviates from the gas laws, this will no longer be true. Thus, the heat of vaporization of ethane at 32.2 C, its critical temperature is zero, but the heat of solution of ethane in a non-volatile oil at atmospheric pressure and 32.2 C is a very considerable quantity. This heat of solution is the difference in enthalpy between that of the saturated vapor and the low pressure vapor at the same temperature, as given by Equation [1a]. If ethane be compressed at its critical temperature, beyond its critical pressure, its enthalpy becomes less than the enthalpy of ethane at the critical condition. Clearly, therefore, if this super-compressed ethane be dissolved in some liquid at this temperature, the heat of solution will be negative, i.e., heat will be absorbed rather than evolved. Now suppose one considers the behavior of ethane at a temperature above the critical. If the ethane gas is at a low pressure, it becomes highly concentrated on solution, and there is a corresponding decrease in enthalpy. If, however, the original ethane at this high temperature is under an excessively high pressure, it will actually expand on solution in a liquid, and its enthalpy will therefore increase, i.e., there would be heat absorption on solution. There must be an intermediate point at which the heat effect of dissolving compressed ethane in a liquid solvent is zero. While the temperature is above the critical for the ethane, and consequently ethane cannot exist as a liquid in the ordinary sense of that term, it can be conceived as a liquid in the sense that it is in a condition such that it will mix with other liquids without heat effect or volume changes. In this sense, ethane at this pressure may be said to be saturated and the corresponding pressure may be looked upon as an extrapolated point on the vapor pressure curve of the liquid. This concept gives a physical meaning to such an extrapolation.

The small amount of data available indicate that, while this sort of interpretation and extrapolation gives results that are good approximations to the experimental facts, considerable deviations exist. It is probably true that there is not in fact a condition above the critical temperature of a given hydrocarbon at which it will mix with other liquid hydrocarbons entirely without heat effect or volume change. None the less, this method of estimation is suggested as the best at present available for purposes of engineering design.

While all the illustrations given deal with mixtures of a limited number of components, it will be clear that the same methods can be employed in the case of any mixture, however complex, for which one has the true boiling point curve, by resorting to graphical integration. The computation methods here outlined therefore put one in a position to calculate (*a*) the density of any vapor, mixed or otherwise, at any temperature and pressure, (*b*) the heat effect of any heating or cooling operation, whether conducted at constant pressure or changing pressure, (*c*) the equilibrium between vapor and liquid at any temperature and pressure, (*d*) the equilibria and changes in concentration throughout the tower in any operation of rectification or absorption, at whatever pressures they may be conducted, and (*e*) the isothermal reversible work of compression of vapor mixtures, whatever the pressure range. These computation methods enable the refining engineer to design high-pressure equipment and operations with a degree of precision hitherto unattainable.

Design Considerations of a Natural-Gas Transmission System

By CHARLES W. MERRIAM, JR.,[1] BIRMINGHAM, ALA.

Since design is one of the chief factors in the economic success of a transmission system, the engineering principles and the requisite empirical data are discussed herein as employed in the design of a pipe-line system now completed. The maximum day demand in successive years of development is analyzed by component parts, particular emphasis in the domestic element of the load being given to previous usage of manufactured gas in terms of B.t.u. per average meter for range and water-heating purposes and to the probable space-heating element based upon the degree-day deficiency method. A brief discussion is included of basic relationships of the factors in the pipe-line flow formula. Consideration is given to relative physical advantages to be derived from application of an understanding of compressor requirements at varying ratios of pipe-line pressure expansion. The unusual features inherent in the looping of lines are shown graphically. Reasons for using a 24-hour instead of a 1-hour period as the time interval of maximum load in design are explained. A diagrammatic presentation of a part of an actual system is made, and discussion thereof is included, to illustrate the manner in which the several engineering principles apply.

OF ALL the gas utilized in this country (1)[2] in 1929, approximately 82 per cent was natural gas; in the same year over 4.4 times as much potential energy (2) was contained in natural gas utilized as was generated in all of the country's hydroelectric central stations; during 1930 of the money spent in the 16 Southern states for all construction purposes nearly 22 per cent was for the building of pipe lines (3) for the conveyance of petroleum products. These statements are indicative of the important influence that the natural-gas industry exerts on modern life. Furthermore, new systems and vast extensions of existing properties to new centers of consumption that are now in process of construction will make, by comparison, an even more pronounced impression on the economic structure. It may well be said, then, that the problems and economics of the natural-gas business are of national importance because of either the present or future effect upon users of fuel for domestic, commercial, and industrial purposes. Since transportation is one of the chief factors of the cost of gas service in which design of transmission pipe lines is so important an element of that cost, it is hoped that engineers representing either present or potential users of gas, as well as manufacturers of fuel-utilization apparatus, would be interested in a discussion of design considerations of a natural-gas transmission system.

Scope of Discussion

The scope of this paper includes a discussion of the estimation of domestic, commercial, and industrial peak day demands and load factors, an explanation of the most commonly used gas-flow formula, together with certain of its inherent relationships, and also a diagrammatic presentation of the design results of an actual pipe-line arrangement. Several valuable papers have been published (4) embodying theoretical generalizations of some phases of these problems, and it is hoped that by treating upon the specific case of a recently completed system, as illustrated herein, a clearer conception of actual conditions to be confronted may be gained. In order to design a gas-transportation system properly, a rather startling mass of information is required concerning existing plants distributing manufactured gas, the economic feasibility of supplying towns heretofore without local delivery facilities, the variable volumes of natural gas for industrial users that can be procured at different ranges of prices, and also an intimate knowledge of the character of the country as affecting pipe-line-laying costs. No equation including all factors has yet been nor probably ever will be formulated to determine the selection of a system having the maximum ratio of net return to capital investment, in consequence of which the "cut and try" method is employed. It is necessary, therefore, to assume as a basis in each trial set-up for weighing the design and relative economic advantage of each type of system that a given set of rate schedules be effective. For obvious reasons it is appropriate to deal in this paper, treating upon a specific system, only with matters of annual consumptions and peak loads probable under existing rates and with certain aspects of some general economic advantages to be secured by properly employing the several fundamental principles involved in design work.

Elements Composing Peak Demand

Analyzing the component parts of the potential gas load conditioning the line capacity requirements of a system, a general classification points to four major divisions: (1) domestic range and water heating, (2) domestic house heating, (3) commercial usage, and (4) industrial consumption. Inasmuch as the normal, fully developed natural-gas system experiences its largest demand during the household space-heating season, the greatest day of which occurs between November 15 and

TABLE 1 ANALYSIS OF AVERAGE DOMESTIC SALES AND LOAD CONDITIONS OF ACCESSIBLE GAS DISTRIBUTION SYSTEMS EXISTING IN 1929 IN CENTRAL ALABAMA AND WESTERN GEORGIA

	1929[a]	1931	1932	1933	1934	1935	1940
1 Population	618,901	635,000	644,000	655,000	667,000	680,000	715,000
2 Average number of meters	59,780	70,600	73,900	77,100	80,580	84,040	89,380
3 Ratio of population to active meters	10.36	8.99	8.72	8.49	8.29	8.09	8.00
4 Space-heating connections, per cent of total meters	0.14	10.0	25.0	45.0	70.0	80.0	85.0
5 Unaccounted-for, per cent of annual sales	8.62	12.0	10.0	9.0	8.0	7.5	7.0
6 Annual sales per meter, 1000 B.t.u.:							
(*a*) Cooking and water heating	21,340	23,500	25,000	25,800	26,400	27,000	28,000
(*b*) Space heating	[b]	4,416	11,040	19,872	30,912	35,328	37,536
(*c*) Unaccounted-for	1,840	3,510	3,600	4,110	4,590	4,670	4,580
(*d*) Total	23,180	31,426	39,640	49,782	61,902	66,998	70,116
7 Maximum day demand, cu. ft. of 1000 B.t.u. gas per meter:							
(*a*) Cooking, water heating, and unaccounted-for	76.2	82	87	90	92	94	95
(*b*) Space heating	[b]	68	169	308	473	540	574
(*c*) Total	76.2	150	256	398	565	634	669
8 Average daily sales of 1000 B.t.u. gas per meter	63.5	86.1	108.6	136.4	169.6	183.6	191.9
9 Ratio of loads, average daily to maximum day	1.2	1.74	2.36	2.92	3.33	3.45	3.49

[a] Last calendar year with manufactured gas.

[b] Negligible.

March 15, the total peak day for any given city is ascertained by superimposing the largest week-day industrial demand upon the domestic maximum 24-hour period. Each of the four elements of the total anticipated maximum days to be provided for in successive years of development is considered below during the four-month periods in which the maximum 24-hour heating demands occur.

RANGE AND WATER-HEATING FACTOR

Approach to the domestic range and water-heating factor in the cities with existing distribution plants is best made through available statistics in terms of B.t.u. of manufactured gas previously delivered. As shown in Table 1, records establish that in 1929 the average domestic customer in central Alabama and western Georgia consumed 21,340,000 B.t.u., in consequence of which 1,840,000 B.t.u. was lost in effecting delivery. Reports indicate that about 49 per cent of the active domestic customers had water-heating installations. The ratio of population to active meters was 10.36 to 1, which, even considering that 34.1 per cent was negro population, is far from either the normal or the obtainable meter saturation. These sales were made at an average cost to the consumer of $2.68 per 1,000,000 B.t.u. Due to the fact that, under the rate schedules applicable to each customer using natural gas, the first 2500 cu. ft. per month is sold at an average of about $1.65 per 1,000,000 B.t.u., it is estimated that ten years after natural gas has replaced manufactured gas the average annual consumption for domestic ranges and water heating will increase to 28,000 cu. ft. of 1000-B.t.u. gas per meter. As nearly as can be determined the ratio of average daily send-out to the maximum day send-out for the manufactured-gas plants was 1.2, which load factor has been used in subsequent years for the element of range and water heating in estimating natural-gas peak-day demands. It has been assumed that in ten years a ratio of population to active meters of 8 to 1 will be attained. This ratio is based upon existing ratios in other cities where natural gas is used, with due consideration having been given to the ratio of black to white population and to the relative scale of living in the respective communities.

DOMESTIC SPACE-HEATING FACTOR

Study of the domestic house-heating load is unaided by statistical data of past experience because of the inconsequential number of customers using manufactured gas for such purposes in this territory. The most authentic available data on this phase of the problem involving the experiences in the degree-day deficiency method as applied to Dallas, Texas,(5) furnish particularly valuable information. The annual deficiency is defined as the summation of the daily differences between 65 deg. fahr. and the mean temperature when that daily mean is less than 65 deg. It has been found by a six-year investigation in Dallas, whose average temperature deficiency is 2341, that 16,040 B.t.u. per year per degree-day deficiency per average meter, with a plus or minus error in any one year of 2 per cent, is consumed for domestic space heating. The Dallas results, arrived at in a district with a population of 315,000 (15.1 per cent negroes) having a total of 65,650 live meters, also show that for an extremely cold series of days the consumption per degree deficiency per meter ranges from 12,000 to 14,000 B.t.u. per day.(6) Humidity, velocity of winds, and the percentage of sunshine have an influence upon consumption, the extent of which has yet not been ascertained, although the effect due to these causes is noticeable to only a small extent. No weight has been given these latter factors in this paper.

In Table 1 the average annual domestic consumption per meter handling space-heating gas is based upon a consumption of 16 cu. ft. of 1000 B.t.u. gas per degree-day for a total average annual deficiency of 2760. The total average deficiency is based upon records of the U. S. Weather Bureau in each of the several cities now having natural gas weighted with respect to the number of meters in each. In the territory being considered it is interesting to observe the wide fluctuations of average annual deficiencies, Rome, Ga., having 3067 and Montgomery, Ala., 1886. The average annual consumption for each domestic consumer using space-heating natural gas is taken in Table 1 as 44,160 cu. ft., whereas the peak day has been assumed at 12.5 cu. ft. times the difference between 65 deg. fahr. and the coldest day's mean temperature of 11 deg. fahr., or 675 cu. ft. The percentage of domestic consumers using gas for space heating has been assumed rather arbitrarily at 10 per cent in the first full year of operation after an eight months' development program following introduction of natural gas to the old manufactured-gas systems. In the tenth year reasonable expectancy permits the assumption that 85 per cent of all live meters will be passing domestic-space-heating gas. The speed(7) with which this portion of the load is added to a pipe-line system is dependent on a number of factors, the principal of which are (1) the relative cost of other fuels, (2) the economic condition of the people, (3) the effective aggressiveness of local distribution managers in the securing of new business and the servicing of installations, and (4) the equipment-merchandizing policies adopted.

Along the route of every large natural-gas system are numerous relatively small towns unfavored with gas whose size is insufficient to support a manufactured-gas system. The sales per consumer obtainable will parallel those of the cities discussed, with a tendency to be somewhat larger initially, but smaller in later years of development, due in general to less wealth per capita. Generally speaking, financial success of small-town distribution systems is possible only when industrial consumers may be secured or when towns are so located as to permit group operation.

COMMERCIAL AND INDUSTRIAL FACTORS

An accurate forecast of possible commercial and industrial consumptions demands a detailed survey of each individual plant. The highly competitive nature of this element of the load requires adequate fuel cost analysis and, from the point of view of peak conditions, precise data on the largest probable fuel demand in week days during the domestic heating season. The difference between what a concern could afford to pay for gas on a "break even" basis with present fuel used and what a plant's average earned gas rate would be under existing price schedules is the measure of the plant management's readiness to purchase natural gas. The development of the sales of a newly constructed natural-gas system is attended usually by a marked degree of reduction in other fuel prices akin in many instances to an actual price-cutting warfare. In the determination of a "break even" gas rate for a company, costs should be surveyed in the light of the production expenses and the enhanced sales value of the output, if any, whether the commodity be pounds of steam, tons of steel, barrels of lime or cement, or the renting of hotel rooms. It is the gas industry's general experience that, in the majority of cases, industrial plants will purchase gas only upon a strictly tangible savings or direct-gain basis. In the case of boiler plants, savings normally allowed by the managers include relative fuel-handling costs, percentage of weight lost in transit of coal from point of billings, moisture in fuel as received, relative annual overall firing efficiencies of respective fuels on an "as fired" basis, differences in equipment and furnace maintenance, and interest on fuel inventories. Unless a plant's earned gas rate is appreciably under the "break even" rate based upon competitive fuel prices actually to be confronted, considerable time will be required to secure the bulk of the potential load. Generally speaking, natural gas is more quickly sold where full analysis of costs with other fuels is known. Analysis of the potential securable industrial load on the system under consideration indicates that during the domestic heating season the load factor of industrial business will be between 70 and 80 per cent, or the industrial-peak day load to be superimposed on the domestic-peak day load will be 1.41 to 1.25 times the average industrial daily load. The commercial sales, which include apartment houses, office buildings, bakeries, and other similar loads, have approximately the same load factor as the total domestic sales.

DUMP-GAS SALES

Examination of the ratios of the maximum daily demand to the average daily load of the varieties of gas sales to be made in the fifth year of development conditioning the pipe-line capacity requirements permits the following comparison: (1) The domestic and commercial is 3.45 to 1.0; (2) the industrial is about 1.3 to 1.0. The fact that the pipe-line flow capacity necessary to deliver a given annual volume of domestic or commercial gas is about 2.65 times larger than that required to deliver an equal volume of industrial gas is the principal cause of the greater expense per m.c.f. to a pipe line in transporting domestic gas. In addition to the foregoing classes of sales, that of so-called "dump" gas constitutes an important factor in the economic aspects of a transmission system. A pipe line must have sufficient flow capacity to meet the maximum coincident demand of all customers entitled, by virtue of prices paid, to continuity of service. In order to augment earnings, recourse is taken to effect the sales of gas at low prices to large industrial plants under the condition that service may be suspended temporarily on short notice in order to meet firm gas demands. To permit such conditions of dump service, industrial plants must maintain secondary fuel supply and equipment. Provided a pipe line has an installed capacity to meet firm peak demands, the only significant costs of selling off-peak gas is the cost of gas at the source, added compressor fuel and engine operation, maintenance and repair expenses, and also incidental metering and servicing charges, inasmuch as overhead, interest on investment, and pipe-line maintenance expense are sustained irrespective of dump-gas sales. Load of this character is desirable particularly from March 15th to November 15th, to raise the annual ratio of maximum load to average daily sales.

In designing a transmission system wholesaling gas at border meter stations for retail distribution inside of cities, the estimation of peak demands at any given point is the element in pipeline design most susceptible to error. Knowledge of the factors determining present and future conditions and judgment and experience on the part of the engineer are of the utmost importance in dealing with this phase of the gas design problem.

GENERAL FLOW FORMULAS

Of the several flexible and workable gas pipe-line flow formulas accepted and employed in practice, that set out below (8) has been demonstrated (9) to be the most accurate:

$$Q = \frac{K\sqrt{P_1^2 - P_2^2}}{\sqrt{L}} \qquad [1]$$

or in a more convenient form for design purposes:

$$\left(\frac{Q}{K}\right)^2 L = P_1^2 - P_2^2 \qquad [2]$$

in which

Q = flow of free gas, cu. ft. per 24 hours
L = length of pipe line, miles
P_1 = initial or starting pressure, lb. per sq. in., abs.
P_2 = terminal pressure, lb. per sq. in., abs.

$$K = \frac{433.5 \times T_o d^{8/3}}{P_o\sqrt{T\,G}} \qquad [3]$$

in which if the following assumptions, based upon probable operative conditions in times of expected peak demands, are made

T = 520 = temperature of flowing gas, deg. fahr., abs.
P_o = 14.65 = pressure base of gas measurement, lb. per sq. in., abs.
T_o = 520 = temperature base of gas measurement, deg. fahr., abs.
G = 0.6 = specific gravity of gas relative to air.

where d is the internal diameter of pipe in inches.

Then from [3]

$$K = 871.12\, d^{8/3} \qquad [4]$$

Fig. 1 indicates graphically (10) the extent to which variations from the foregoing assumed constants in the value of K will modify formulas [1] and [2]; e.g., an increase in the average flowing gas temperature of 40 deg. fahr. to 560 deg. fahr. will decrease the pipe-line flow capacity to 96.4 per cent of the previous capacity.(11) At the beginning of design work on a system, it is advisable to make a tabulation of K values for standard pipe sizes of each commercial thickness, having determined first the probable values of other functions of K, as in formula [3], under conditions to be met on the occasions of peak load.

Examination of the foregoing formulas bearing upon flow capacity reveals that

(a) Q varies directly as K; see [1]
(b) Q varies inversely as the square root of L, or, conversely, that L varies as the inverse of $\left(\frac{Q}{K}\right)^2$; see [1]
(c) Q varies directly as the square root of the difference of squares of the absolute end pressures; see [1]

- (*d*) The drop in pressure in any given length L is a function of the difference in the squares of absolute end pressures; see [2]
- (*e*) K varies as the 8/3 power of d; see [3] or [4]

LARGER FLOW OBTAINABLE THROUGH HIGHER PRESSURES

The condition of pressure drop emphasized in *d* is attributable to the compressibility of gas, a circumstance unlike that in hydraulics, in which Q varies directly as the square root of the difference in hydraulic pressures instead of as the square root of the difference in the squares of the absolute gas pressures. Upon this condition also hinges the explanation of why, at progressively higher pressures, greater volumes of gas can be transported even though the ratio of pressure expansion in a line remains constant. Transmittable quantities increase faster proportionately than actuating pressures (see *a* and *b*). The plotting of pressure conditions against distances from the starting point will illustrate graphically the more rapid falling off of pressure at successive points as the terminus of the line is approached.

QUANTITY VARIES DIRECTLY AS K

Reference to formulas [4] and [1] shows that Q, instead of varying directly as d, varies as the 8/3 power of d. In other words, the capacity of a 16 × $^1/_4$-in. line is 87.3 per cent greater than a 12$^3/_4$ × $^1/_4$-in. line. The relationship of Q as a direct function of K offers a ready means of selecting the requisite size of multiple river-crossing lines required to equal or to exceed by any given percentage the capacity of a given single main line.

To illustrate, suppose it is desired to select five multiple lines to have as nearly as possible 140 per cent of the flow capacity of a 20 × $^3/_8$-in. main line whose K = 2,318,210. Then K_{20} ÷ 5 = 463,642, which is approximately equal to K for a 12$^3/_4$-in. pipe similar to that frequently used for river-crossing work.

PIPE-WALL THICKNESS

Comparing the value of K for 20 × $^1/_4$ in. with that for 20 × $^3/_8$ in. indicates that the thinner wall pipe has 3.66 per cent greater carrying capacity. The larger internal diameter pipe also has a 2.57 per cent greater storage capacity. Carried down into terms of net revenues, the larger flow capacity of the thinner wall pipe has an appreciably beneficial effect. These are points frequently overlooked by many exponents of higher tensile-strength, thinner-wall pipe.

It is pointed out in *c* that higher average pressures result in increased flow capacity, but such procedure necessitates, of course, the use of thicker wall pipe to withstand added internal stresses. The wall thickness necessary to carry given maximum pipe-line pressures is to be calculated by Barlow's equation as follows:

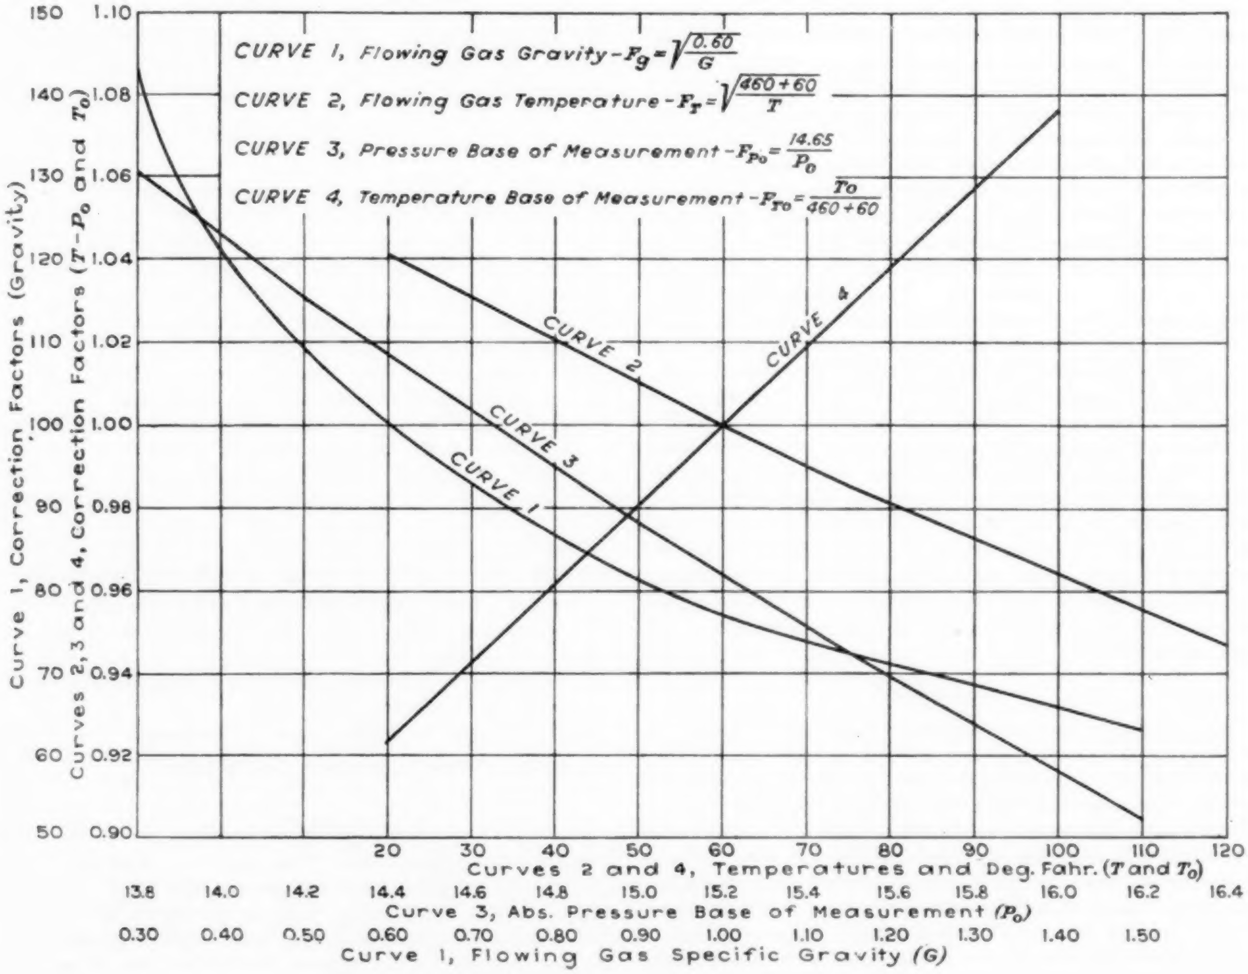

FIG. 1 GAS PIPE LINE CORRECTION FACTORS FOR FLOW CAPACITIES

$$T = \frac{DP}{2P + \dfrac{2UE}{F}} \quad \text{[5]}$$

in which

T = thickness on pipe wall, in.

D = internal pipe diameter, in.

P = maximum gas pressure, lb. per sq. in., gage

U = ultimate minimum tensile strength of pipe steel under advisement, lb. per sq. in.

E = minimum percentage of longitudinal weld and/or method of joining-pipe-lengths efficiency relative to pipe, provided the percentage < 100

F = allowable factor of safety.

The trend in the natural-gas industry is toward thinner walls, with due consideration being given to certain minimum practical limits bases on fragility and bending qualities of the pipe. Some engineers permit an allowable factor of safety in formula [5] of as low as 3. Change from one wall thickness to another due to variations in tensile strength causes a large alteration to required pipe tonnage. In the steel industry, premiums per ton are demanded for high tensile strength, thereby partially offsetting tonnage reductions secured by the use of thin wall pipe.

DOUBLING LINE

Due to the conditions mentioned in *b*, the paralleling of a gas line does not increase the flow-carrying capacity in direct proportion to the percentage of line so looped. Fig. 2, curve 1, is a plotting of the formula for looping with pipe of the same size

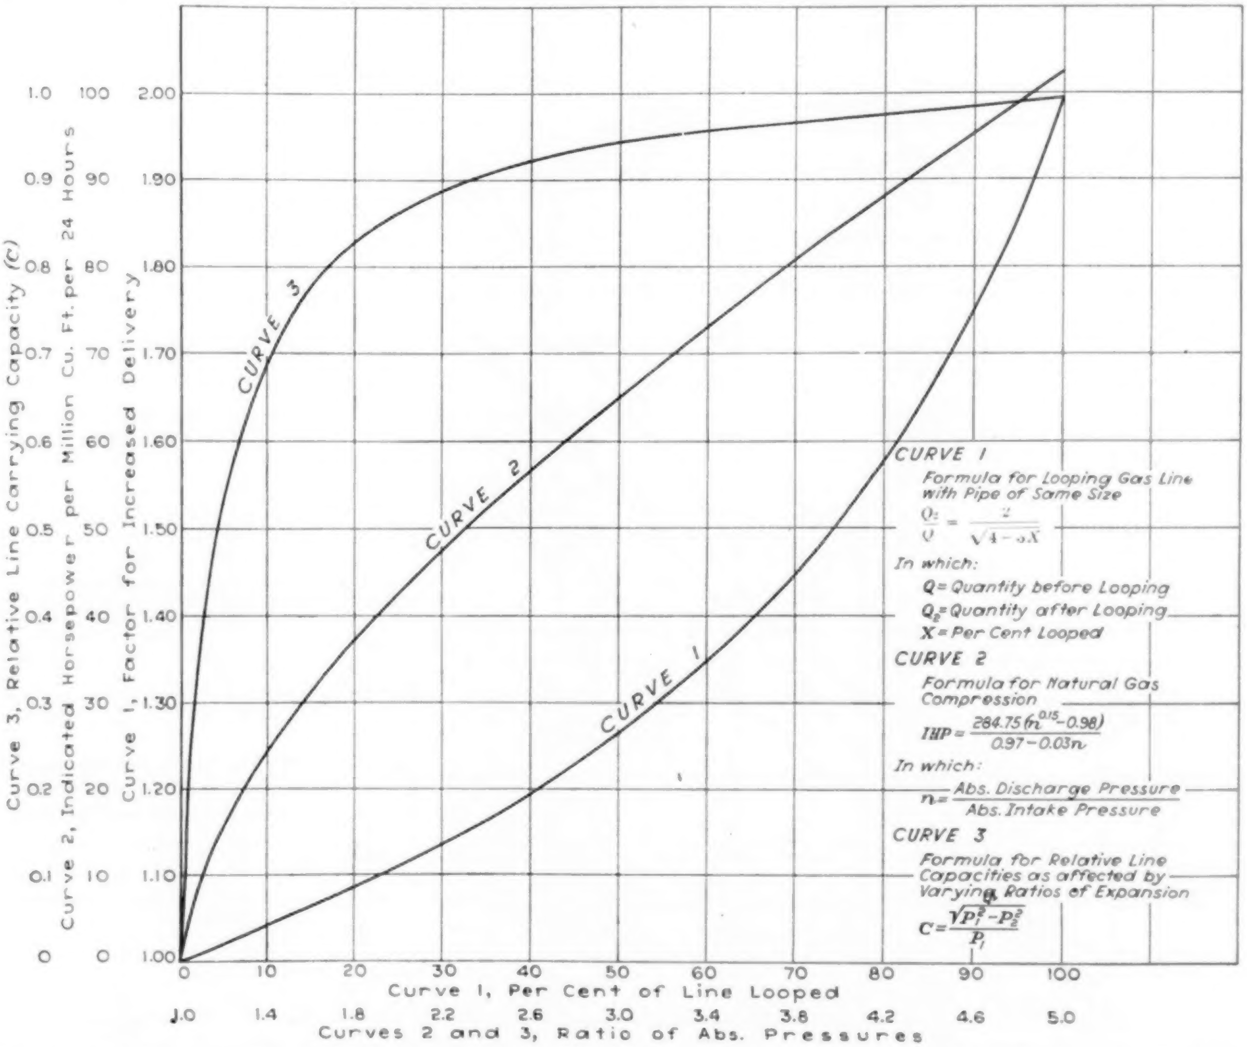

FIG. 2 POWER REQUIREMENTS AND RELATIVE FLOW CAPACITIES AT VARIABLE PRESSURE RATIOS, ALSO FLOW CAPACITIES AT VARIABLE PERCENTAGE OF LOOPED LINE

$$\frac{Q_2}{Q} = \frac{2}{\sqrt{4-3X}} \quad \text{[6]}$$

in which

Q = quantity of gas before looping

Q_2 = quantity of gas after looping

X = per cent of line looped

Curve 1 reveals that by looping 50 per cent of a line the flow capacity of the entire section is increased only 26.5 per cent. Examination of formula [6] and also of curve 1 indicates that after two-thirds of the line is doubled a further increase in the percentage looped is accompanied by a greater proportionate increase in the quantity factor until a self-evident result is apparent in that a doubled line will transmit twice the quantity of a single line. The tangential point of greatest slope in curve 1, since Q varies as $\frac{1}{\sqrt{L}}$ is at the point of the square root of 3, or at 1.732.

Whether the line is looped at the discharge of one compressor station or at the intake of the next successive station does not affect the flow-carrying capacity provided a constant volume of gas is transported over the entire line section between such compressors.

Relative Pressure Expansion and Compression Ratios

In the progress of gas through a pipe, pressure is lost in accordance with formula [2], thereby necessitating for long-distance lines the operation of stations at various points to compress to higher pressures for further transportation. Pressure loss in a gas pipe line is analogous in many respects to energy dissipation in power transmission. Curve $3^{(12)}$ in Fig. 2 illustrates the relation of the ratio of gas expansion, in terms of the ratio of initial to terminal pressure, to the relative maximum flow capacity of a pipe line. Curve 2 in Fig. 2 illustrates the relation of horsepower required to compress 1,000,000 cu. ft. of free gas per day to the ratio of intake to discharge pressures, commonly called the compression ratio. Comparison of curves 2 and 3 explains a vital element in pipe-line design. At a pressure ratio of 2.5, the horsepower required for compression is 54 and the percentage of line carrying capacity relative to the maximum 91.5 per cent; whereas at a 4 pressure ratio the values are 84.5 hp. and 97 per cent, respectively, or an increase of 69.4 per cent in compressor horsepower required to gain only 5.5 per cent in relative line flow capacity. In other words, to pass a slightly larger Q between two fixed points—see (c)—or to slightly increase the distance L between two stations—see (b)—the sacrifice to additional power requirements is disproportionately large. The compressor ratio of 2.38 has been found by experiment to be the most economical on fuel consumption. The normal

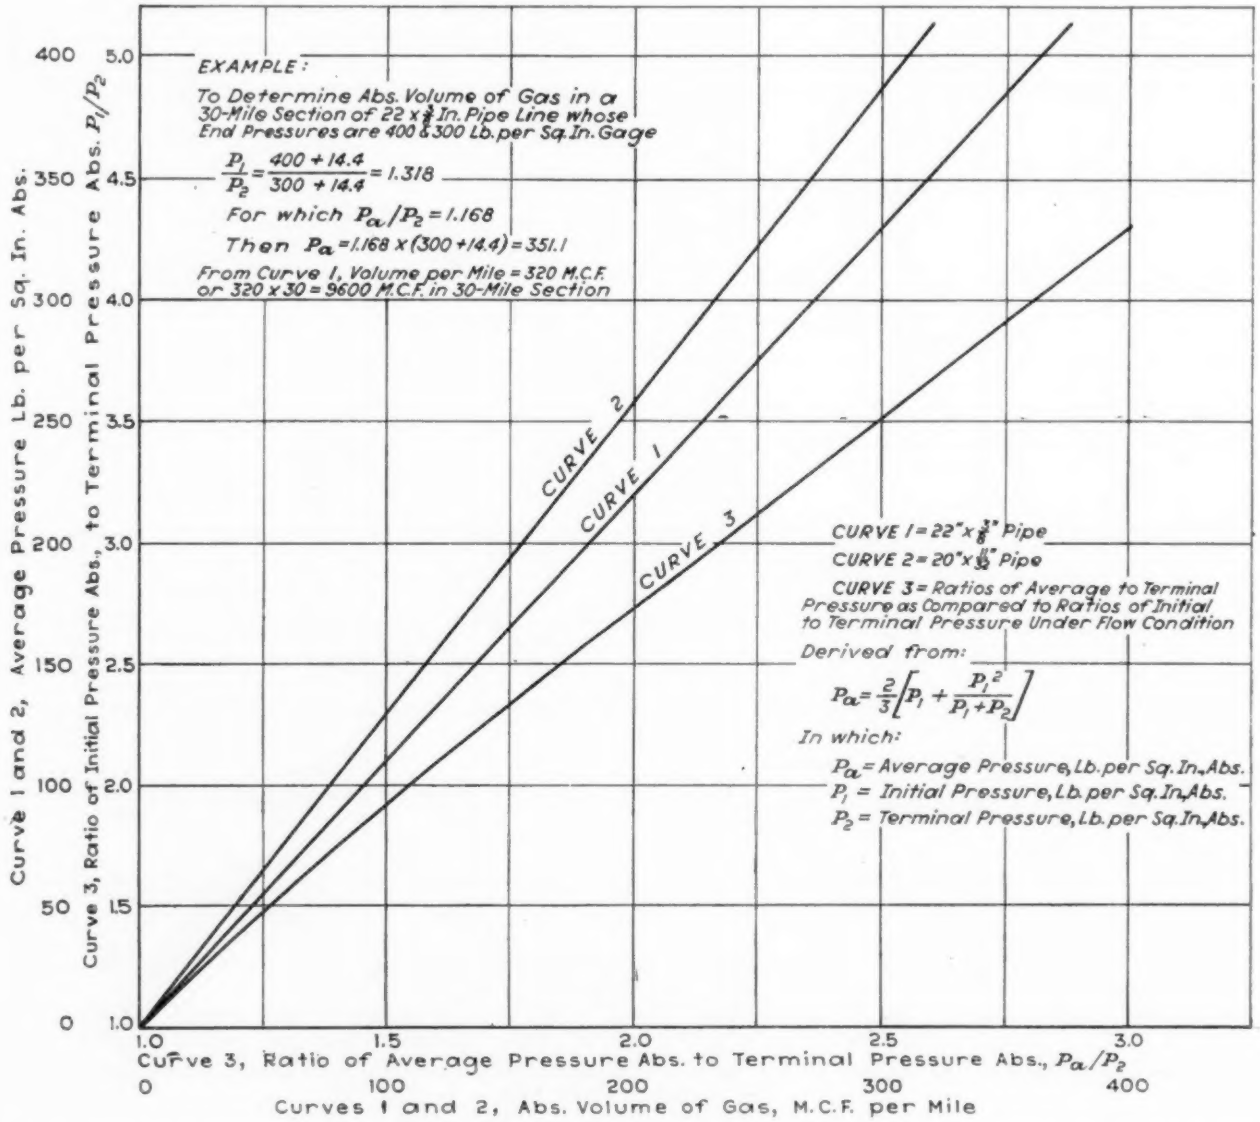

Fig. 3 Absolute Volume of Gas per Mile of Main at Variable Average Pressures, Also Average Pressure of Variable Ratios of Expansion

practice in the industry is to use natural gas out of the pipe line itself as fuel for the engines driving the compressors. Approximately 1.25 per cent of the gas pumped in any one station is used as compressor fuel for a compression ratio of about 2.5, thereby causing a cumulatively greater fuel-gas withdrawal, either as the number of stations is increased or as the distance from field to delivery point is greater.

Measure for Design Is Peak 24-Hour Period

The analysis of maximum loads in the foregoing discussion of long transmission lines has been confined to treatment on a daily basis, whereas the hourly peak is the basis used ordinarily in distribution-system design. Experience in comparable climates has indicated that at a border station of a city with practically complete domestic heating saturation the ratio of maximum hour to average hour on the coldest days is about 1.6 to 1.0 for the domestic and commercial elements of the total load. The ratio of the minimum hour to the average hour on the coldest day will range between 0.25 and 0.45 to 1.0 for the domestic and commercial business. No generalization of this nature can be made for the industrial sales, but the range is usually between 1.3 and 1.8 to 1.0. Due to the fact that inside of cities the small amount of free gas per cubic foot of pipe at the low pressures carried restricts the storage volume, distribution mains are designed for hourly gas quantities. The storage capacities per mile of normal 22-in. and 20-in. pipe at varying pressures is shown in curves 1 and 2 in Fig. 3, indicating, among other things, that the absolute volume of 22-in. pipe at 414.4 lb. per sq. in. abs. is 320,000 cu. ft. By means of "packing" the main lines to an average pressure between compressor stations greater than that required under peak 24-hr. uniform-flow conditions, sufficient excess-gas storage can be accumulated to provide for the hourly peaks. Through local weather agencies advance notice of extremely low temperature can be secured thus affording an opportunity to "pack" the lines for peak deliveries. Curve 3, Fig. 3, shows graphically the fundamental equation(13) for determining the average pressure between two points in a pipe line under uniform flow condition:

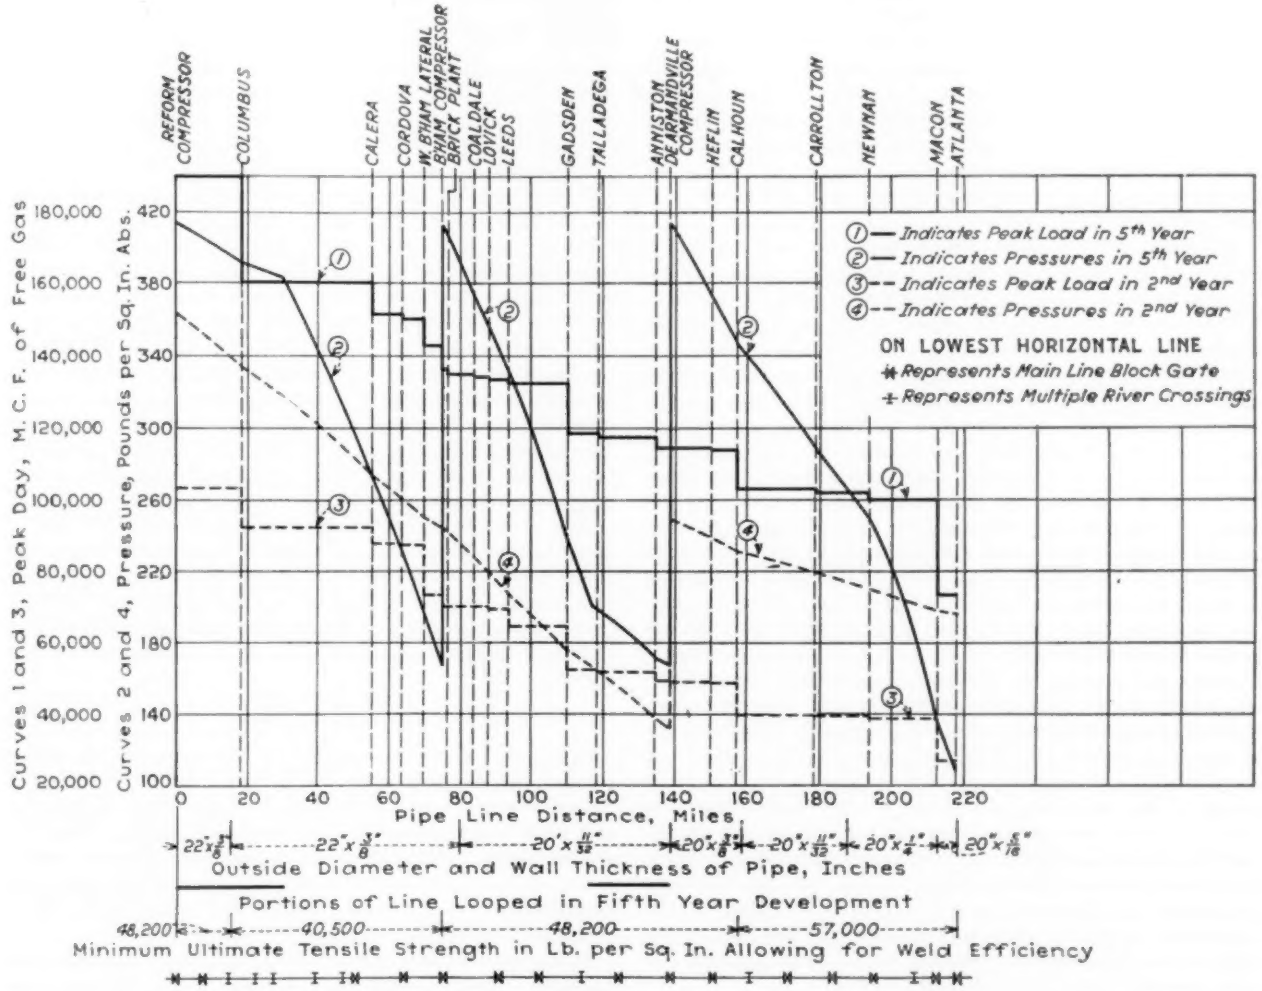

Fig. 4 Diagrammatic Plan of Pipe Sizes and Thicknesses, Pressure, and Peak-Load Conditions of a Recently Completed Section of a Southern System

$$P_a = \frac{2}{3}\left[P_1 + \frac{P_1^2}{P_1 + P_2}\right] \qquad [7]$$

in which

P_a = average pressure, lb. per sq. in., abs.
P_1 = initial pressure, lb. per sq. in., abs.
P_2 = terminal pressure, lb. per sq. in., abs.

It was stated in effect in (*d*) that the average and mean pressures differed; e.g., from curve 3 if 400 lb. per sq. in., abs., is the initial pressure and 150 lb. per sq. in., abs., the terminal pressure, then $P_a/P_2 = 1.86$, or $P_a = 1.86 \times 150 = 279$ lb. per sq. in., abs., whereas the mean pressure is 275 lb. per sq. in., abs. In view of the factors as stated, long-distance pipe lines are designed with peak demands considered in 24-hour periods.

Application to an Actual System

The basic data and formulas discussed were used in the design of a natural-gas transmission system recently completed in the South, a plan of the eastern half of which is presented in Fig. 4. This diagram depicts the anticipated progressive peak loads and pressure conditions in the second and fifth years of development plotted against pipe-line mileage. The latter is subdivided to show block valves at both main-line gates and river-crossing headers, pipe diameters and thicknesses actually installed, as well as the portions looped and the pipes' effective tensile strength. On the side opposite to the mileage are designated the successive points at which tap lines or branch systems take off from the main line.

Heretofore most published papers have been based upon the theoretical condition that all gas entering the system, other than compressor fuel, has been delivered at the pipe-line terminus. The transportation system studied here is the largest single system involving numerous branch lines ever built in a continuous construction program and which was conceived in practically all of its details before the first pipe was laid, thereby necessitating careful preliminary designing. Any variation in main-line pressures caused by the developments in the peak demands affects the required sizes of the various branch lines carrying gas from the main line to actual delivery points. As the maximum demands increase from year to year, additional compressor stations at predetermined sites along the main line are required to insure proper gas deliveries. Due to these fluctuations in pressure at any given point at different stages of development, the tap lines must be so designed as to accommodate the anticipated demand in any year on such taps with the pressure available in the main line. In some instances it is economically advisable to locate compressor stations in later years on branch systems to reduce the initial pipe-line investment. Undoubtedly on a system of such a complicated nature the sum of the peak days in any year occurring at each delivery point will be in excess of the peak day experienced at the gas-field receiving station. It has been assumed that each tap line, branch system, and the last section of main line requires pipe capacity sufficiently large to carry the calculated maximum load, but that the peaks experienced on the main line proper, due to the theory of the probability of the coincident occurrence of such maximums, will decrease progressively westward from 3 to 10 per cent less than the total sum of the calculated peaks.

Observations on Results

Among the most important features of the part of the completed system shown in Fig. 4 is that the peak in the second year at the eastern end of the pipe line is about 14 per cent of that at the starting point in the fifth year. Under maximum flow conditions the section of line shown in Fig. 4 contains approximately 66,000 m.c.f. of free gas. The ultimate minimum terminal pressure is 100 lb. per sq. in. gage, whereas the maximum compressor discharge is 400 lb., working on a 2.5 compression ratio. Although the compression ratio selected for peak day is slightly above the point of minimum fuel consumption, the theoretical horsepower requirements are reduced thereby and the stations allowed to run at a lesser ratio on off-peak days, which more nearly approaches the average operating condition. It is interesting to note that in the fifth year it is essential, in order to carry the peak load, to loop a part of the pipe line in two of the three sections between the compressors shown. With loads coming off the line progressively in a manner similar to that shown, the investment due to looping can be reduced generally by laying pipe on the discharge instead of the intake side of compressor stations, thereby accommodating the larger volume of gas. In the second section of the line shown, however, because of the extremely rugged country, it is less expensive to achieve results in the fifth year by laying, instead of 18.98 miles on the discharge side of the upstream compressor, 21.93 miles on intake side of the downstream station. The necessity for considering branch-line sizes in terms of the most advantageous relation of load to main-line pressures is illustrated in Fig. 4 at several taps, as, for example, at the 55-, 70-, 93-, and 157-mile points. In the second year of development it is necessary at the 212-mile point to have a pressure of 188 lb. per sq. in. in order to properly supply the Macon branch system.

This condition may be accomplished by several means: (1) delivering gas at the main-line terminus at the minimum of 100 lb. by operating the main-line station next upstream at a 1.133 compression ratio, thereby requiring a separate station to be installed on the branch line to operate at a 1.677 compression ratio or (2) delivering gas, as shown, at the terminus at 186 lb. by operating the main-line station next upstream at a 1.89 compression ratio. Distinct savings are to be effected by the latter method, for instead of installing two stations to operate on highly inefficient rates of fuel consumption and with unusually large diameters of compressor cylinders, one station may be installed to operate with intake and discharge pressures more nearly those to be required with its ultimate compression ratio. The discussion of (*b*) and the general flow formula [2] is illustrated forcibly by Fig. 4, in which it is established that in order to meet increased gas demands from 103,000 m.c.f. in the second year to 189,800 m.c.f. in the fifth year, or an 84 per cent increase in capacity requirements, it is necessary to increase the theoretical compressor-station power installations(14) from 1336 horsepower to 13,526 horsepower, or an increase of 1012 per cent.

Conclusion

In order to select the system installation susceptible to the greatest percentage of return on investment it is necessary to design a separate pipe-line layout for each series of volumes and peak loads procurable on various rate scales. From the system design, estimation of the approximate ultimate investment can be made with due allowance for depreciation and capitalization of operating expenses and taxes, from which investment the ratio of return may be determined.

In the operation of a pipe line the application of the engineering principles discussed assists in economically meeting peak-load contingencies by "packing" at opportune times and also in the manipulation of dump-gas transportation through expert dispatching to secure the sale of a maximum volume. Not only is an accurate survey of potential load essential in preliminary design plans, but continual study of anticipated demands during the years of development is necessary to reduce expenditures to the minimum in the providing of adequate compressors and line capacity to supply peak requirements.

(6) It is interesting to note that the total average annual consumption in Dallas for range, water heating, and space heating per domestic meter of 79,960,000 B.t.u. per year was sold at an average rate of about $0.807 per 1,000,000 B.t.u. In this Dallas rate schedule the first 2500 cu. ft. per month cost the consumer at the rate of $0.80 per m.c.f. Due to a large part of Dallas' water supply coming from wells of unusually high temperature being used for domestic hot water, the gas requirements for this purpose are uncommonly low. The ratio of population to active meters is 4.81 to 1.

Discussion

P. McDonald Biddison.[3] As is usually the case in actual practice, the requirement to keep the initial cost within such limits that the project can at an early date make a satisfactory return has in this case forced a design which at the larger quantities to be transported in later years is far less economical than some other design might be. It may be demonstrated that the steel required in a transmission line increases with operating pressure and that the economical pressure is the lowest pressure that will utilize the full strength of the minimum wall thickness of pipe. A suggested equation for minimum wall thickness in inches is $T = 0.00904D + 0.087$, where D is the outside diameter in inches. It cannot be claimed that this is generally accepted in the natural-gas industry as there is a wide diversity of opinion on the question of minimum wall thickness. If this equation is accepted, however, then for pipe materials suitable for 16,000 and 13,000 lb. wall stress there would be the following equations for pressure on walls of minimum thickness: For 16,000 lb. wall stress, $P = 289.2 + (2794.6/D)$. For 13,000 lb. wall stress, $P = 235.0 + (2270.6/D)$.

From the foregoing may be derived the following wall thicknesses and corresponding operating pressures:

Outside diameter, in.	Wall thickness, in.	Gage pressures	
		13,000-lb. stress	16,000-lb. stress
20	0.269	349	429
22	0.287	338	416
24	0.305	330	406
26	0.323	322	397

In any given line and at any given operating pressure the minimum horsepower requirements for compression are obtained at a compression ratio of about 1.35, corresponding to about 20 i.hp. per million cubic feet per station. With such a pressure ratio and with pressures and wall thicknesses as outlined, a capacity of 150,000 m.c.f. per day could be obtained with 13,000 lb. wall stress from a 24-in. line with compressor stations spaced 36 miles apart, or from a 26-in. line with compressor stations spaced 53 miles apart, each station requiring but 3000 operated i.hp. With 16,000 lb. wall stress, the same conditions could have been met with a 22-in. line with compressor stations spaced 35 miles apart, a 24-in. line with compressor stations spaced 54 miles apart, or a 26-in. line with compressor stations spaced 79 miles apart. Some of these alternates, especially in view of the probable development beyond a capacity of 150,000 m.c.f. per day, would doubtless have produced ultimately a more economical installation.

J. M. Naiman.[4] By far the most important "design consideration of a natural-gas transmission system" is "market," the analysis of which requires an intimate mixture of (1) careful geographical fuel survey, (2) comparative combustion engineering, (3) intelligent rate making, and (4) sales engineering.

Next in importance to the question of the "market" comes that of the "load factor." As is well known by now, long-distance natural-gas pipe lines would be economically impossible without industrial load for flattening the peak effects of domestic load. But not enough stress is being laid on the fact that industrial load has its own peaks, the ratio of such peak load to the average industrial load being in some cases a very serious handicap to project feasibility.

It is only because the problem of getting the most out of a new pipe line does not become acute until after the maximum compressor station capacity is built and utilized that the importance of storage for taking on additional load and improving the load factor is not as well appreciated as it deserves to be. Dump load does not take the place of storage capacity, but rather supplements it, by taking care of seasonal load variations. Pressure-tank storage can only be most economically used to care for hourly and weekday to week-end load variations. Subterranian storage in depleted gas fields, if close enough to market and if proved to be tight, offers the most economical means for offsetting seasonal load variations, more so than even a dump-load rate system.

A. B. Dunning III.[5] Especially interesting is the degree-day deficiency method of estimating domestic space heating load. The emphasis placed on the economics of design is commendable and of ever-increasing importance.

An analysis of the gas-flow formulas used by the natural-gas industries might be of some value, as the formula set forth (Weymouth's) is of a type that has certain definite limitations in its application.

Weymouth's formula is based on the assumption that the coefficient of friction f in Unwin's formula varies only with the diameter. It is actually much more complex, being a function of the velocity or quantity of flow, the density and viscosity of the gas, and the surface condition or roughness of the pipe as well as a function of the diameter.

Quoting from Reports of Investigations, Department of Commerce, Bureau of Mines Serial No. 2942, June, 1929, "Flow of Natural Gas Through High-Pressure Transmission Lines:"

"For Weymouth's pipe-line flow formula, $Q = C\sqrt{[(P_1^2 - P_2^2)d^{5^1/_3}/GTL]}$. Comparisons of the percentage differences between the measured volumes and the volumes calculated from Weymouth's formula for different rates of delivery indicate that there is a variation in the proportional relationship between Q and $\sqrt{(P_1^2 - P_2^2)}$."

The writer has been making studies of gas-flow theory and practice for several years, and although not yet ready to make public the full results of these studies, sufficient work has been done to establish the following formula for Unwin's coefficient of friction as being dependable for air and ordinary commercial gases flowing through reasonably clean and smooth cast-iron or wrought-steel pipe:

$$f = \frac{0.00746\, d^{0.08}\, T^{0.14}}{Q^{0.14}\, G^{0.105}}$$

The entire formula follows:

$$Q = \frac{1075\, d^{2.645}}{G^{0.461}\, T^{0.613}} \left[\frac{P_1^2 - P_2^2}{L}\right]^{0.538}$$

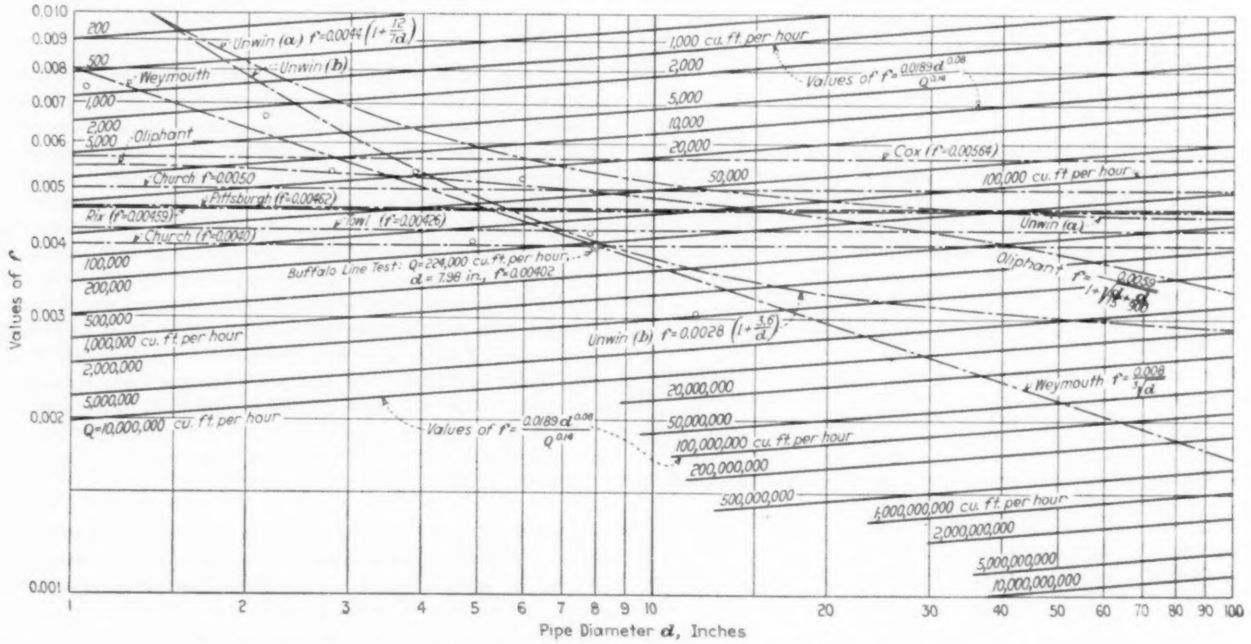

FIG. 5 VALUES OF f COMPARED WITH BEST-KNOWN FORMULAS FOR HIGH-PRESSURE GAS FLOW

[Showing values of coefficient of friction $f = \frac{0.00746\ d^{0.08}\ T^{0.14}}{Q^{0.14}\ G^{0.105}}$. $f = \frac{0.0189\ d^{0.08}}{Q^{0.14}}$ when $G = 0.60$ and $T = 519.6$ (60 deg. fahr.) compared with values of f derived from eight best-known formulas for high-pressure transmission of gas. Note: Substituting for f in $Q = \frac{\sqrt{3245\ (p_1^2 - p_2^2)d^5}}{fGTL}$ gives the complete formula $Q = \frac{1075\ d^{2.645}}{G^{0.461}\ T^{0.613}}\left[\frac{p_1^2 - p_2^2}{L}\right]^{0.539}$. Notation: Q = flow, cu. ft. per hour at 60 deg. fahr. and 30 in. Hg; d = diameter of pipe, inches; L = length of pipe, miles; p_1 = initial pressure, lb. per sq. in. abs.; p_2 = final pressure, lb. per sq. in. abs.; G = specific gravity of gas-air = 1; T = temperature of gas, fahrenheit absolute; o = tests upon which Weymouth's formula was based.]

The symbols are the same as in the paper except Q, which is expressed in cubic feet per hour at 60 deg. fahr. and 30-in. mercury pressure.

This formula is based on a carefully laid theoretical structure coordinated with the results of several hundred experiments involving pipe sizes up to and including 36 in.

Fig. 5 shows values of f as determined by the foregoing formula compared with the best-known formulas for high-pressure gas flow:

In order to show the formula graphically, temperature T is assumed at 519.6 (60 deg. fahr.) and specific gravity G at 0.60, which are average figures in natural-gas transmission practice. This leaves:

$$f = \frac{0.0189\, d^{0.08}}{Q^{0.14}}$$

The experiments on which Weymouth's formula is based are also spotted in on the chart and the value of f for the Buffalo line test is shown. It will be noted that this test gives almost the identical value as Weymouth's formula, also Church's formula with $f = 0.004$; but this is the only size pipe for which these two formulas (Church's and Weymouth's) agree.

The chart is largely self-explanatory and shows clearly why Weymouth's formula is the favorite in the gas fields where maximum flow is the rule. Weymouth's is the only one of the commonly used formulas which gives approximately correct results at large flows through the larger pipe sizes, while other formulas (Oliphant's or Unwin's for instance) are more accurate at lower velocities.

A study of Weymouth's formula indicates that reasonably accurate results may be expected when applied to gases of near 0.60 specific gravity flowing through pipes from 4 to 24 in. in diameter and with actual mean velocities from 15 to 30 ft. per sec. and temperatures near 60 deg. fahr. Any considerable departure from these limits will bring uncertain results. For example, an actual test on a 24-in. gas main carrying 420,000 cu. ft. per hour of coke-oven gas, specific gravity 0.38, and velocity about 40 ft. per sec., gave for the coefficient of friction $f = 0.00424$, whereas Weymouth's formula gives $f = 0.00278$. This difference is largely due to the low specific gravity and viscosity of the coke-oven gas. The chart indicates for any given size of pipe the flow for which Weymouth's formula is correct.

Considering everything, Weymouth's formula has served its purpose remarkably well in view of the fact that it was based on but nine rather uncertain experiments with compressed air flowing through pipes varying in size from 1 to 12 in.

Author's Closure

The tendency in the natural-gas industry has been toward the use of steel pipe walls unnecessarily thick to withstand peak operating pressures. The majority of these overly conservative selections have been attributable to uncertainty concerning the efficiency of welding processes and to engineers' natural inclination toward large factors of safety. Although the degree of effectiveness of commercial protective coatings is a much-debated subject, the use of excessive weight of pipe as a rust-resistant agent, except under extremely corrosive conditions, is uneconomical. The formula introduced by Mr. Biddison has an excellent application in large-diameter transmission lines, but for all sizes smaller than $10^3/_4$ in. o.d. would lead to the selection of wall structures too thin to withstand normal construction practices. Distribution-system engineers are the most persistent in adhering to erroneous policies of specifying steel pipe of superfluous weight.

Subsequent to the date of the discussion, Mr. Biddison presented an excellent paper to the American Gas Association entitled "Compression and Transmission of Natural Gas," embodying a mathematical demonstration that about 1.35 is the economical compression ratio. It is probable that the necessity for a standby unit in each compressor station would tend toward increasing this ultimate design ratio of a compression to about 1.7.

Too much emphasis cannot be placed on what Mr. Naiman has said with reference to "market" analysis and "rate making." Conclusions drawn from any source other than thoroughly accurate studies of the fuel economics of each plant are necessarily misleading. In situations where town distribution systems operate as entities not affiliated financially with the pipe-line system, the desirability of soliciting the load of an industrial prospect must be weighed in the light of the investment required by the distribution concern to serve the individual customer. Not the least important factor in "market" analysis is (inasmuch as a considerable period of time elapses between the preparation of initial load data and completion of large pipe-line systems) the forecast of the general economic trend of the entire area to be supplied. Due to the recent expansion of the natural-gas business, many pipe-line systems are faced with strangulation in developmental stages by adverse influences of general decline of prosperity in the service area.

The existence of "Reynolds' criterion" as a factor conditioning the coefficient of friction for the flow of fluids in pipes has been long recognized. Mr. Dunning's chart has emphasized graphically the important bearing the criterion has on this coefficient, but it should be remembered that this factor modifies Q inversely as the square root. Principal errors (in addition to those mentioned in the footnote and above) in the Weymouth formula as applied to natural-gas transmission occur when any of the following conditions obtain: (1) Welding "icicles," (2) abnormal internal pipe roughness, (3) unusual specific gravities, and (4) radical departures from ordinary gas velocities. In normal cases these refinements to the empirical coefficient of friction used in Weymouth's formula are largely academic in interest to the natural-gas industry, but the development of a technically accurate formula having mathematical facility is one of the steps of progress yet to be made.

PME-54-10

Modern Oil-Lubrication Methods as Applied to Rolling-Mill Equipment

By JOSEPH A. MERRILL,[1] CHICAGO, ILL., and EDWIN M. MAY,[2] NEW YORK, N. Y.

Jos. A. Merrill

The paper traces the improvement made in lubricant-application methods for rolling-mill machinery from earlier days to the present. The increase in size, speed, and capacity of rolling-mill machinery necessitated the use of heavier oils and of better methods of application. The modern heavy-oil circulating system is described, and common practice in the selection of oils for various types of equipment is indicated. Modern oil conditioning and application give maximum safety and protection against involuntary shutdowns and cut costs of lubrication as much as 80 per cent.

Edwin M. May

NO INDUSTRY has had greater problems of lubrication than the steel industry with its rolling mills. Massiveness of machinery; all machines in exposed positions subjected to dirt, to metal scale, and to abnormal heat and cold; enormous consumption of power; large acreage of plants; necessity of continuous operation; necessity of automatic machinery for handling hot and cold metal—all are most important factors of the problem. With this heavy equipment working under the strains of constantly increasing production, the fact has been many times evident that lubrication consists of three elements: the machine, the lubricant, and the method of application. When either the machine or the lubricant has reached its limit of endurance, further advance is possible only through the development of the systems of oil application.

Early Rolling-Mill Lubrication

The evolution of the rolling mill from the period of animal and water power to that of steam power brought along the ancient methods of hand-applied lubrication with the animal and vegetable fats and greases. Only 40 years ago the cast pinions were lubricated by hand, at intermittent intervals, with stiff tar products. Pinion and mill bearings were made with recesses or pockets in which tallow or grease could be packed. Roll necks were packed with sides of pork, with tallow, or with hard lime greases. During the period when the mineral oils were being introduced, many mill bearings were packed with wool waste saturated with the cheapest black oil. Later, due to the availability of the better mineral oils, ring-oiling bearings were introduced for the reduction gears and other large shafts. Pinion and other large bearings were lubricated by large oil cups, and cast housings permitted dip or bath lubrication by the use of the semi-plastic lubricants for both reduction gears and pinion gears. From the standpoint of lubrication this era was one of transition from the use of the animal and vegetable oils and fats and the heavy tars and greases to mineral oils; from the mill standpoint it encompasses a change from the crude, inefficient, short-lived machinery to modern highly developed, efficient machinery.

Every improvement in machine design that embodied a new method of oil application allowed of the use of a better lubricant, with greater production results for the unit. Tremendous strides have been made in this direction; otherwise production never could have grown from 5,236,000 tons of finished material in 1887 to 41,070,000 tons in 1929. Those familiar with the present trend can plainly see that the economic production of steel depends not so much upon the volume of equipment employed as it does upon the design and arrangement that will make each unit produce the greatest tonnage. Larger ingots are now going through the blooming mills with greater speed than ever before. Continuous mills are being rapidly installed wherever production can be speeded up. Electric power is rapidly replacing steam. Every such advance in the mechanics of the situation requires an advance to be made in lubrication, either through an improvement in the oils themselves or in the methods of their application.

Early Rolling-Mill Oiling Systems

The first rolling-mill oil-filtering and oil-circulating systems using light oil served only the ring-oiled bearings of the reduction gears, the bevel-gear-drive bearings, pedestal bearings, and in some cases the pinion bearings. Pinion and reduction gears were lubricated by dipping them in a bath of heavy gear lubricant.

The major objection to this practice of using light oil for the bearings and heavy-gear lubricant for the gear baths is the tendency of the light oil to work into the gear lubricant and of the

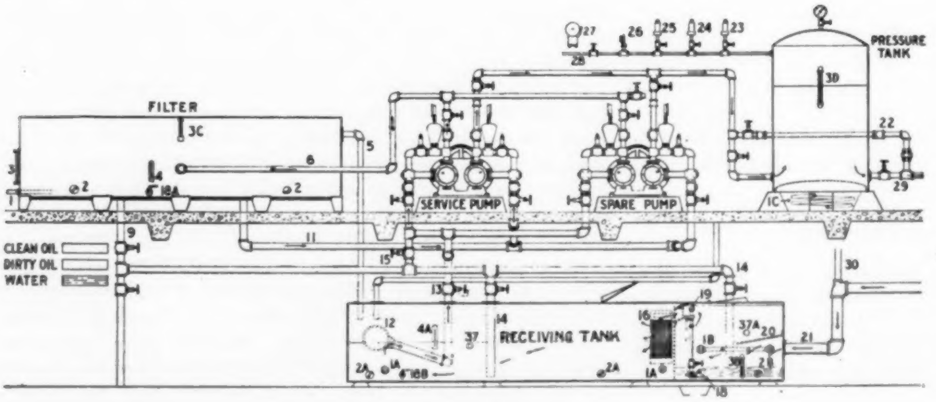

Fig. 2

gear lubricant to work into the oil, with the result that the mixture becomes too heavy for use in a ring-oiled bearing and too thin for the bath-lubricated gears. To offset this, elaborate sealing arrangements using oil slingers and grease wipers have been designed, but generally speaking, a mixture of the light and heavy lubricants is likely to occur sooner or later. In the pinions especially, where overall length must be kept down to a minimum, the extra length required for the sealing arrangements is obviously undesirable.

This practice of dipping gears in a bath of very heavy lubricant on large mills results in two other difficulties, the importance of which varies with the conditions in each mill. These are excessive power consumption, especially during the warming-up period after a shutdown in winter, and the tendency to excessive heating due to fluid friction when dipping gears in heavy lubricants. If the gear lubricant selected is too heavy or if the teeth dip too far in the bath, this heating may become so excessive as to reduce greatly the viscosity of the gear lubricant under continuous operating conditions.

Lubrication of Gears and Bearings With a Single Comparatively Light Oil

As the modern continuous mill developed, great improvement was made in the design, material, and methods of machining gear teeth, thereby providing uniform contact between accurately cut high-carbon-steel surfaces.

Hoping to provide adequate lubrication for both gears and bearings with a single grade of oil, a number of oil-application systems were installed in which pinion gears and reduction gears were sprayed with oil of 500 to 600 sec. Saybolt viscosity at 100 deg. fahr., the same oil being used for the bearings. With the introduction of the fully housed spiral-bevel-drive gears from main shafts to pinion stands, these gears were also spray-lubricated with oil of about 500 sec., the first example being the 14-in. Morgan mill for the Inland Steel Company at Indiana Harbor. As an additional safety factor, gears and pinions were permitted to dip in a bath of light oil on these early systems.

Where the gear teeth were properly cut, of suitable hardness, and run at fairly high speed, these early lubrication systems were amazingly successful, showing little wear on the gear teeth and providing ideal lubrication for the bearings. They demonstrated the advantage of a single light lubricant and a single-oil circulating and oil-filtering system for important parts of the mill.

These early circulating systems for rolling-mill gears and bearings were similar to the gravity-type filtering systems used on steam engines and on other big machines, except that they were much larger.

Increased Mill Size and Higher Tooth Pressures Demand Heavier Oils

With the rapid and tremendous increase in size, speed, and capacity of continuous rolling mills, it soon became apparent that oil of 500 to 600 sec. Saybolt viscosity at 100 deg. fahr. was not heavy enough to cushion some gear teeth properly and not nearly heavy enough for blooming-mill or universal-mill high-tooth-pressure gear lubrication. As a consequence the large oil companies developed heavier and heavier oils, with excellent cold test and good water-separating ability, to meet this increased service demand. At the present time almost any viscosity of oil desired may be obtained, and these will be suitable for nearly all normal tooth pressures. Using these heavier oils in the modern completely automatic circulating and filtering system, the largest blooming-mill, universal-mill, and continuous-mill pinions are being most successfully lubricated with the same oil for both bearings and gears.

MODERN HEAVY OIL-CONDITIONING AND APPLICATION SYSTEM

Briefly, a modern central oil-application system for any type of rolling mill consists of the same essential apparatus, varying in size and detail design with the mill served, and particularly with the viscosity of the oil selected. A typical automatic circulating system is shown in Figs. 1 and 2. A large receiving tank placed in the basement or in a pit receives all used-oil drainings from the gear cases and bearings. This tank has three distinct purposes: to remove and eject water from the oil in the system, to maintain a temperature of the oil of approximately 100 deg. fahr. minimum in cold weather, and to settle out as far as possible all heavy foreign matter from the oil. In addition, this tank must have sufficient capacity to receive the drainage of all oil piping and gear cases when the mill is shut down.

This large receiving tank is equipped with ingenious baffles, steam coils with automatic temperature control, and floating suction pipes, and is sometimes very useful when used for heating the entire batch of oil to remove traces of temporary emulsion that may occur through excessive water leaks at some point on the mill.

Service and spare pumps automatically controlled by pressure switches draw oil from the floating suction pipes in the receiving tank and deliver it to an overhead tank, as shown in Fig. 1, or with the full forced-feed systems, as shown in Fig. 2, to a cylindrical air-pressure tank of considerable size located in the oil cellar or on the mill floor above it, automatically maintaining a working pressure of about 35 lb. in this tank. The upper third of the tank capacity is occupied by air under 35 lb. pressure, and to this air space are connected pressure switches for starting and stopping the service and spare pumps, a third pressure switch for an automatic alarm, a pressure gage, and a safety valve.

In a full continuous-feed system all oil is forced through pressure filters, which remove any foreign matter that might pass the receiving tank. However, very large systems generally operate on the partial-filtration principle in which about 25 per cent of the oil actually circulated is continuously pumped through pressure filters by means of separate filter pumps. It has been found that this effectively keeps the entire batch of oil in perfect condition.

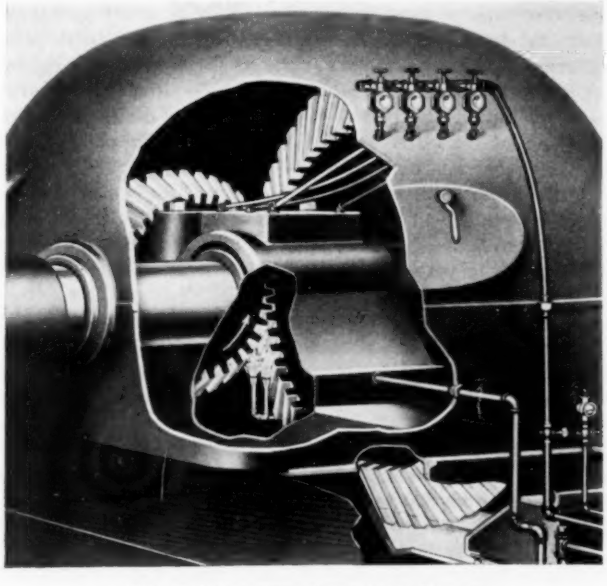

FIG. 3 FLATTENED-STEEL-PIPE SPRAYS

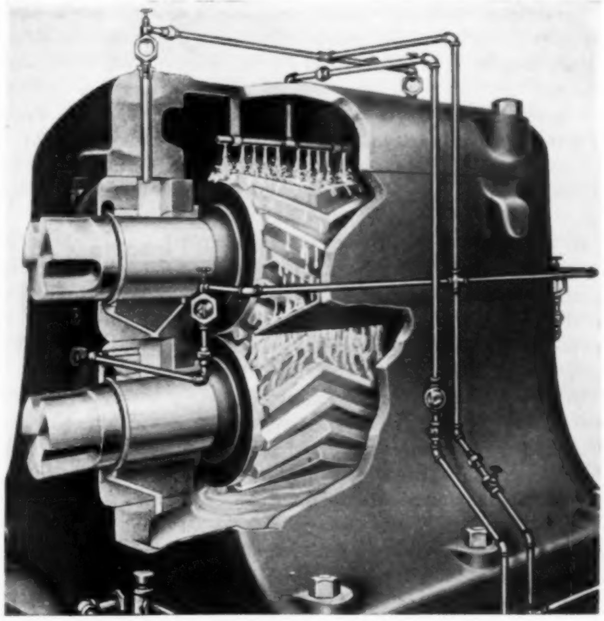

FIG. 4 PERFORATED-PIPE LUBRICATOR FOR BEVEL GEARS, PINIONS, AND BEARINGS

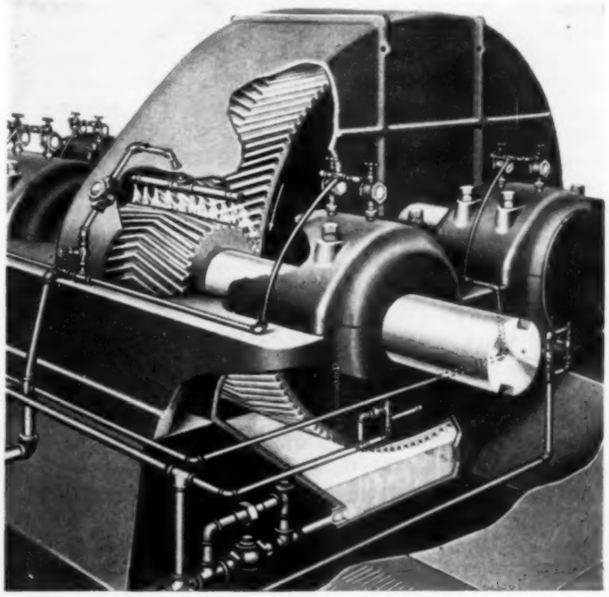

FIG. 5 FLOOD AND BATH LUBRICATION APPLIED TO LARGE HIGH-SPEED GEARS

In a partial-filtration system, therefore, the main service pump delivers oil directly through the pressure tank to the mill bearings. In either type the supply to the bearings is controlled by large needle-valve sight feeds, which are vented. The supply to the gear sprays is controlled by globe valves, using sight flow indicators to indicate whether oil is flowing to the sprays.

The continuous application of an adequate volume of cool, clean oil to the gear surfaces over their entire length and at the point of mesh is very desirable and efficient in the lubrication of gears with even heavy oil. This is accomplished by one of these methods:

1 Flattened-steel-pipe sprays (see Fig. 3) which throw a sheet of oil into the gears at the point of mesh, now generally used for all reduction-gear drives, for bevel-gear drives, and for many pinions.

2 A perforated pipe of all-welded construction (see Figs. 4 and 5) is introduced directly above the point of mesh for some down-running single-reduction gears and above the top center line of the upper pinions in pinions housings, where pinions are reversing.

In the latter case, oil from the perforated pipe is thrown off against the side of the pinion housing and led back as near to the point of mesh as possible by means of sloping baffle plates bolted to the inside of the housing. The advantage of this design on reversing pinions is that only one set of sprays is necessary, regardless of the direction the gears are traveling.

Once started, the heavy-oil-application system is entirely automatic. A pressure switch controls the service pump, automatically maintaining the desired pressure in the pressure tank; a second pressure switch cuts in on a slight reduction of air pressure in the pressure tank and starts the spare pump; and a third pressure switch is provided to operate on a further reduction in pressure to sound a horn, light a red lamp, or ring a gong to warn the operator that both service and spare pumps have stopped.

Should both pumps fail, there still remains in the air-pressure tank a large volume of oil under air pressure, sufficient to supply the gears and bearings during the interval between the final alarm and the shutting down of the mill. So far as is known, it has never been necessary to shut down a mill due to failure of both pumps.

With heavy-oil-application systems it is of course necessary to protect the drain lines, and in fact much of the supply lines, from extremely low temperatures. Where these lines are exposed, a small low-pressure steam line can be run parallel to them, all three lines being wrapped with insulating material, usually wool felt wrapped with roofing paper.

Classification of Mills for Lubricants

For purposes of selecting lubricating oil for the modern application systems, rolling mills might be classified as follows:

1 Blooming, heavy skelp, heavy structural, plate, rail, slabbing, universal, wide strip (over 30 in.).

2 Bar, billet, heavy merchant, light skelp, medium strip, medium structural, tin-plate mills.

3 Cluster, light merchant, light strip, rod, wire, both ferrous and non-ferrous.

Without going into the subject of oil analysis, it may be useful to indicate in a general way the common practice in the selection of oil on the basis of viscosity alone for the following various types of equipment:

Blooming, Heavy-Skelp, Heavy-Structural, Plate, Rail, Slabbing, Universal, Wide-Strip Mills. Gears and bearings of these heavy mills are being successfully lubricated with oil averaging 1700 to 2600 sec. Saybolt viscosity at 100 deg. fahr., either with or without dipping of the lower gear in a bath and with two sets of sprays or two baffle plates on reversing mills for each point of mesh. This oil should be a high-grade straight mineral oil with a suitable pour test and excellent demulsibility, the viscosity selected depending a good deal on the actual tooth pressures anticipated. The oil should be free from animal or vegetable fats to avoid emulsion trouble in case of water leaks.

On very large heavy-duty continuous mills where the roughing-mill pinion speeds are extremely low and the pinion-tooth pressures very high, as on certain exceedingly large recent mills, it is desirable from every standpoint to provide a separate application system using a very heavy oil, say, 2600 sec. Saybolt viscosity at 100 deg. fahr., for the pinion gears and their bearings, and a lighter oil, say, 1500 sec. Saybolt viscosity at 100 deg. fahr., for the reducing gears and their bearings. While this arrangement of two systems on a single mill costs a little more to install, it is frequently well worth while and avoids excessive tank and pump sizes. An example of this is the 60-in. continuous strip mill of the Wheeling Steel Company at Steubenville, Ohio.

On very large continuous mills tooth pressures may be so high on the roughing-end pinions as to make lubrication with mineral oil undesirable. In such cases the bearings and gears of the roughing-end pinions can be supplied with a special leaded lubricant from a separate oiling system operating at normal temperature. These parts may be also lubricated with a very heavy gear compound, using steam coils in the gear cases and automatic temperature controls. This will allow the heavy gear compound to be pumped from the bottom of the gear case into each point of tooth mesh, filtering it by means of a pressure filter in batches at intervals and at high temperature to reduce the viscosity for ease of filtering.

Generally speaking, if the gear teeth are made of a high-carbon steel, accurately machined and aligned, heavy oil lubrication of the teeth is entirely practical, provided the unit loadings are within the load-carrying capacities of the materials used. But with low-carbon-steel gears within excess of the load-carrying capacities of the materials used, it is probable that wear will occur with either heavy oil or heavy gear lubricants due to overloading. A very heavy soap-thickened oil using lead oleate or sulphur compound is suggested for such cases.

Bar, Billet, Heavy-Merchant, Light-Skelp, Medium-Strip, Medium-Structural, Tin-Plate Mills. Bearings and gears on these modern continuous mills are successfully lubricated with the continuous application system and with a straight mineral oil, viscosity ranging from 800 to 1700 sec. Saybolt viscosity at 100 deg. fahr., depending on the pinion-tooth pressures and provided the mill is of average size and speed.

Cluster, Light-Merchant, Light-Strip, Rod, and Wire Mills, Ferrous and Non-Ferrous. High-speed, light-duty rolling mills with comparatively low tooth pressures and high-carbon-steel gears properly cut are still being very successfully lubricated by central oil-circulating systems using oil of 500 to 800 sec. Saybolt viscosity at 100 deg. fahr.

Vertical Edgers, Isolated Drives, and Auxiliary Equipment, Such as Reel Winders, Scale-Breaker Drives, Etc. Vertical edgers are quite likely to have water leaks and are generally set so low that drainage from the base is difficult and the gear-tooth pressures involved are usually low. For all of these reasons a lighter oil, of 800 to 1200 sec. Saybolt viscosity, easily circulated and with excellent water-separating ability, may be very desirable, and in some recent mills the vertical edgers have been placed on a separate oil-circulating system.

If the vertical edgers are placed on a separate oiling system, there is no objection to including other small units on the same system, and on a recent very large installation at South Chicago this was done with excellent results. Sometimes an isolated gear case is best handled by a very small individual full-continuous heavy-oil application system to avoid excessive length in the drain and supply lines and to avoid lowering the basement-floor level where necessary for draining such isolated cases by gravity. On the general run of mills, however, all units should be and in most cases are successfully served by a single large central system.

Cold-Rolling Mills. In general, cold-rolling mills are being lubricated with individual or central application systems, using oils ranging from 800 to 2500 sec. Saybolt viscosity at 100 deg. fahr. The selection of oil depends very largely on the tooth pressures and on the kind of steel used in the gears.

Cold-rolling mills frequently present a combination of relatively low pressures and fairly high speed on the reduction gears, which makes this part suitable for light oil lubrication with very high tooth pressure on the pinion gears, which run at very low speed and require the heavier lubricants. In designing systems for cold-rolling mills great care should be taken to check the tooth pressures accurately, providing oil heavy enough for the pinion gears, even if it is necessary to supply these gears with a separate lubrication system. Many large cold-rolling mills are now being lubricated with a single oil in the system supplying all gears and bearings. This oil averages around 1500 sec. Saybolt viscosity at 100 deg. fahr., or lighter where possible.

Rolling-Mill Tables, Hot Saws, and Cold Saws. The gear drives used on saws and mill tables run with relatively low tooth pressures and operation is intermittent, so the oil never overheats through fluid friction. The lubricant is also exposed to the lowest temperatures in the mill. For these reasons gears and bearings of these units are satisfactorily lubricated by means of small application systems, circulating oil of about 500 sec. Saybolt viscosity at 100 deg. fahr., using bath or spray lubrication for the gears and sight-feed lubrication for the bearings. Flexible tubing is employed to take the oil to and from the sliding parts of the big saws, and the oiling system is located in a small pit adjacent to the equipment. Most table rolls are now designed for single connection to the circulating oiling system for each section, oil distribution to the gears and bearings within the table being accomplished by rather elaborate small pressure piping inside the table or by dipping the gears in a bath and providing wipers to scrape the oil off the gears and feed it to the bearings. In the latter type, oil may be continuously changed, heated or cooled, and filtered while keeping the bath at a constant level. Oil for either of these types of equipment must have a suitable cold test and should be a straight mineral oil with excellent water-separating ability.

OTHER ROLLING-MILL OIL-APPLICATION SYSTEMS

Roller-Bearing Lubrication. On modern four-high mills the large roller bearings have been successfully lubricated by means of circulating-oil systems which automatically provide a large volume of clean, cool oil averaging about 500 sec. Saybolt viscosity at 100 deg. fahr. to each bearing.

Four-high mills equipped with roller bearings are also being lubricated with light grease applied with any of a number of ingenious hand-operated or automatic grease systems.

With the development of very large and high-speed roller bearings for mill drives, it is evident that a most important function of the oil is to continuously flush the bearings, cleaning out any abrasive dirt or material, as well as to carry off the heat developed in the bearings; and for this purpose a special type of system is already in use, feeding oil to the bearings under pressure and drawing it out of the bearings under pump suction, the oil being continuously settled and filtered and afterward cooled with a surface cooler during each cycle.

Large Motor-Generators and Motor-Bearing Lubrication. On modern large flywheel motor-generator sets without water cooling in the bearings, there is a tendency toward high operating temperature in the inboard bearings, due partly to the heavy load, but particularly to induced heat along the shaft from the generator. Lubrication systems designed to provide and apply cooled oil to these particular bearings are usually extended to include the outboard bearings of the flywheel motor-generator sets and the ring-oiled bearings of the other large motors driving the mill. Ordinary motor bearing oil is usually recommended, having a viscosity of 300 sec. or less at 100 deg. fahr., and an overflow fitting is provided to maintain the oil level in each bearing.

This oil is delivered through sight feeds from a central pressure system under a pressure of about 35 lb., and instead of a large receiving tank, a special unit is provided to accomplish full, continuous filtration, cooling, and clean-oil storage in a single filter-tank shell. The first compartment of this tank contains the filter units which discharge filtered oil to a cooling compartment, where the oil passes over an ingenious system of baffled coils, finally collecting in a large clean-oil compartment, from which it is pumped through a pressure tank, with automatic pump control, to the bearings.

Besides furnishing cooled oil in large volume to the bearings that tend to operate at high temperature, this system has the advantage of providing continuous make-up and change of oil for all of the principal motor-generator and motor bearings. A considerable saving in lubricant and labor is therefore provided.

Lubrication of Prime Movers in Steel Mills. Steam turbines are frequently equipped with a continuous bypass batch-oil-filtering system in which a large percentage of the turbine oil is continuously circulated through a filter to remove water and insoluble sludge. At regular intervals the entire batch is drawn off into a large two-compartment tank and allowed to settle for about 14 days to remove any trace of moisture and sludge that would be in solution at operating temperature.

Large gas engines driving generators and blowers in steel mills are equipped with individual oil-circulating systems of large size, which automatically separate and eject water and filter the oil continuously.

CONCLUSION

In reviewing the development of rolling-mill lubrication during the last 15 years, one cannot escape the conclusion that the continuous oil-application systems that supply the oils for the lubrication of both gears and bearings offer very important economic advantages that can well be considered by all the mechanically equipped industries. In general the use of these modern systems has the following results:

(*a*) Makes lubrication of all large units an orderly automatic engineering function, thereby completely eliminating all dangers due to the careless failure to apply lubricant or to the misapplication of lubricant; eliminates also the dangers of dirt and water contamination of the oil and to damages due to these various causes.

(*b*) Eliminates the dangers resulting from the use of heavy gear lubricant which has been thinned by the light oil from the bearings; likewise prevents undue heating of the bearings, with consequent loss of power through the heavy gear lubricants working into the bearings.

(*c*) Lowers gear-case temperatures by reducing the friction, thus lowering the power required for the operation. It is well known that gear friction is almost directly proportional to the viscosity of the lubricant, temperature rise above the room temperature being a true indication of friction loss. Circulating systems will supply oil to the parts to be lubricated at any desired uniform temperature, thereby maintaining the proper oil viscosity for the job.

(*d*) Eliminates dirt and gritty material from the bearings, and through continuous lubrication with clean, cool oil the gears and pinions and all bearings have a longer life.

(*e*) Eliminates the cause of costly shutdowns due to machine and part failures through improper lubrication.

(*f*) The starting load, particularly in cold weather, is materially reduced.

(*g*) Lubrication economy. The important gears and bearings in many large mills are being adequately lubricated with a total consumption of approximately one barrel of oil per month, indicating cost savings of as much as 80 per cent against all former methods.

Generally speaking, the high-carbon heat-treated gears that have been properly machined and aligned show little or no wear over long periods when force-feed-lubricated with a clean and cool oil of suitable character. Modern heavy mineral oils, when delivered in volume and at the proper temperature at the point of tooth mesh, have remarkable good cushioning and lubricating properties for gears.

Such oil-conditioning and oil-application systems also provide maximum safety and protection against involuntary shutdowns, and it is for all of these reasons that the modern oil-application systems are in service on the majority of modern ferrous and non-ferrous mills, thus pointing out a very obvious line of lubrication development work for other branches of industry where lowering the costs of operation is desirable.

Discussion

William F. Parish.[3] There is a growing conviction that the continuous application of the proper lubricant through the modern oil-circulating system will reduce maintenance charges and lower the power required to drive production machinery. The saving in oil is slight compared to the value of the better and more continuous lubrication. The principles involved are simple. Keeping a continuous flow of clean, cool lubricant, under pressure, to all of the bearings of a machine is a rational thing to do. Up to the acceptance of these systems it was the custom to apply oil at irregular intervals to all hand-oiled bearings. Most of the oil was wasted. Dirt and contamination was never considered. No thought was given to the main function of the oil in its power of carrying the heat away from the bearing. In bearings that are not heated externally, the heat developed in the bearing is due, first, to fluid friction of the oil itself and then to the striking of the parts of the opposing bearing surfaces as the film becomes too thin for the load conditions. The heat thus generated is in the film of oil, which is immediately affected and before the heat can dissipate to the metal and through it to the air. With the ring-oiled bearing there is a continuous flow of oil to the film, but the backflow of heated oil is to a small reserve in a confined sump. This, however, allows the heat to be dissipated over a wide area. These bearings in special cases can be much improved by increasing the oil supply, having it in contact with greater surface of bearing housing so that there will be a greater path for conductivity of the heat of friction, by turbulence of the oil over a greater metal surface, or by putting a water coil in the sump.

The bearings in industrial machines that are the most difficult to lubricate are those where heating is applied to the shaft externally. This must be done in nearly all industries, either in the first process of handling heated materials, as in steel or iron rolling, or in the finishing process, as with paper and textiles. Hot rolls and their heated necks have always required the heaviest lubricants, with their heavy friction drags, their features of separation, and general danger due to thickening and drying. Shafting between a bearing and a fan that must work in a furnace flue is an extreme example of such a case. Such a shaft is always hard to lubricate. From a strictly engineering standpoint, without considering what can be done with lubrication, the first thought is to put in a water-cooled bearing. The next is to put in a hollow shaft and secure an induced draft of cool air with a blower. Both of these ideas come from a conviction that the excessive heat from the outside is the cause of the lubrication difficulties, which is right. The cure is applied after the damage has been done. The trouble is always caused by the heat effect on the working oil film, making it thinner, causing it to be reduced to a point where the high parts of the opposing bearing surfaces strike through. This sets up greater local heats, which can accumulate until there is film and bearing rupture.

As the flow of heat is always along the shaft, through the oil film to the outer bearing surfaces and then out through the housing tc the air, the hollow shaft will not entirely cut this flow from the film of oil. It will reduce it by effecting some radiation to the air from the inner surface of the shaft. There will always be heat flowing along the shaft, through the oil to the outer bearing. In the case of the water-cooled bearing, the heat flows through the oil film unrestricted, but at some increased speed due to its greater radiation through the circulating water, plus the bearing surfaces of the housing. When heat from the outside is allowed to be added to the heat of friction of the oil itself, the film of a very thick oil, which is always used on such a bearing, is not greater than the film of a very light machine oil that is kept properly cooled.

As all troubles with such heated bearings are caused by the film becoming too thin through the addition of external heat to the natural internal heat of oil friction, the obvious manner of correcting the condition is to treat the oil itself. All that is necessary is to apply a continuous stream of cool oil to the bearing surface and arrange that the oil supply be properly cooled by having a large amount of oil in the supply tanks or by putting a heat exchanger directly in the supply feed to the bearing. Then the oil should be as light as possible, so that it will work with reduced internal friction and will quickly absorb and carry the heat flowing along the shaft, this heat to be then easily liberated through the tanks or exchangers to the air.

Small circulating systems can be made locally with what is available around the plant—two tanks made out of oil drums, a small pump, a cooler (which can be a coil of pipe in one of the tanks), and the necessary piping. Hose can be used for a temporary job. The oil from the bearing flows to the under tank, which is the sump. The pump drives it to the upper tank, and from there it flows through the cooler, if an extra one is used, directly to the bearing.

In all new equipment, where it is known that extreme temperatures of operation will be encountered, it is just as well to include a circulating system properly engineered for the installation, even if there is only one bearing involved. This will pay for itself many times over and will allow the job to be put in operation with the full assurance that even if the heat encountered should be more than anticipated the flexibility of the system will fully compensate for it and there will be no danger to the operation.

In bearings where high heats are to be encountered, it is not wise practice to use grease. A bearing packed with grease retains its heat through the grease, which can only dissipate this heat through the metal of the housing to the outside air. This heat will so thin down the greases that some kinds will separate into their oils and thickeners, which may include large amounts of non-lubricating limes. Such thickeners will close the oilways or other clearances, will act as mild abrasives or polishes, and while smoothing the bearing surfaces will change the measurements gradually until they will have to be compensated for. When the grease film is heated, it becomes thin, the same as an oil film. The high spots of the bearing surfaces then strike and set up high local heats that still further reduce the film thickness. The surrounding grease that is packed in the housing of course rushes in and replaces the ruptured film, and this is the only security offered by the practice. As the grease thins through heat or separation of the solids, it leaks out of the bearing. As the amount decreases, the heat of the operation is absorbed by a smaller amount and conveyed through less housing surface, so that the changes which take place can be expected to be greater the longer the bearing is allowed to run on the single filling of grease.

---

[3] Consulting Lubrication Engineer, New York, N. Y. Mem. A.S.M.E.

Consider the fundamental functioning of a circulating system attached to a bearing or a machine of many bearings. The oil is fed under pressure. The outlet of the feed pipe at the bearing is larger than the outlet of the clearances of the bearing. The clearances therefore govern the flow of oil through the bearing.

There is always a great supply back of the bearing of cool, clean oil waiting to flow through. Under normal conditions, those that exist most of the time, there is a steady flow of oil at the bearing, and its temperature is sustained in its established equilibrium. Then the temperature of the film, and of the surrounding metal, and of the oil in and out of the bearing is some degrees above the temperature of the surrounding air, with which it rises and falls.

Then comes a period of undue stress or of some interference with the film, and as a consequence the high points of the opposing bearing surfaces strike. Momentarily a very high degree of heat is possible through the pressure and rupture of the metal, as small parts of the oil will decompose, leaving a tar or carbon residue accompanied with the liberation of some gas. In the still at the refinery it is necessary to have temperatures in excess of 600 deg. fahr. at atmospheric pressure to liberate gas and form the tar and carbon residues. Few realize the existence of these high local temperatures that are the combined result of abrasion and pressure in the presence of the reduced oil film. These temperatures are not capable of measurement except by their residual effect. They are at best but momentary, but the heat is quickly absorbed by the surrounding film, raising its temperature and reducing its viscosity and film thickness. This, unfortunately, with all heating bearings lubricated by hand or drop oilers or that are packed with wool or grease, is at a time when the striking metal should be separated by a cooler and a thicker oil film instead of just the opposite. As there is no way of carrying the extra heat away or of increasing the thickness of the film, abrasion, once started, generally proceeds with these bearings until the film and then the metal ruptures.

In the case of a bearing attached to a circulating system, there is a much more favorable set of conditions existing. Should stress damage the film and allow the high points to strike and set up local heating, the oil becomes thin and flows faster in consequence. This brings in a greater amount of cool oil from the outside supply to add to the heated film at a time when it is needed. The increased outward flow of the heated oil, due to its being thinner, carries heat away just that much faster. The heated oil film, when there is a circulating system involved, has its own automatic and thermostatically controlled feed through the actual condition of the oil film itself. When this film suffers through overheating, it automatically cools down through its increased flow. When it is too cold, the oil flow is reduced, and internal friction sets up enough heat to bring the bearing back into equilibrium where the generation of internal heat exactly balances its absorption and radiation through the oil flow and bearing metals. This is one of the hidden reasons why there is so little trouble with machinery that is lubricated by the circulating system. From examination of the oil in such systems it is apparent that local heating has occurred at times. This has not been noticed by the attendants or indicated by the instruments. The automatic thermostatic control inherent in the system corrected the matter, although the oil showed every indication of having suffered severe punishment.

In the marine service, with the hand-oiled bearings and parts of the reciprocating steam engines, all bearings were fitted so that water could be turned on them to keep them cool in case of trouble. When such engines were modernized with a forced-feed system, condensed-water leakages from the steam glands and salt water from other leakages would get into the circulating systems and cause some trouble through forming emulsions that would cause stoppages of flow. There seldom were corrosion troubles on these older engines. This was undoubtedly due to the fact that the metal surfaces were so completely saturated with oil that it acted as a protection.

On many new ships fitted with circulating and forced-feed systems for the steam engines, turbines, or Diesel engines much damage was caused to the shafts and to all bright parts of the engines by a series of events that were the result of simple uncleanliness and of a lack of appreciation of the fact that the best protection against rust and corrosion is a good and penetrating film of oil.

In putting in a circulating system for a large machine of whatever type, the piping is threaded by the use of lard or similar cutting oil. The joints are red-leaded, and this carries linseed or some other vegetable oil. There also would be white lead from the shafts or cutting oils from the machined parts, with all the incidental metal chips, dirt, and foreign matter that can get into tanks and pipes during fabrication, shipment, and erection. Then upon heating the engines with steam and putting them slowly into service, leakages of water would always occur. The oil in the circulating system would churn up the combination of animal and vegetable matter, with other kinds of dirt acting as binders and possibly catalyzers, with the result that these first emulsions were very bad. They would settle on all bright parts of the shafts and machines, and the water oxygen contents, with the free fatty acids and possibly salts and other acids, would cause etching and pitting of the metal and general corrosion of all bright parts. This always happened during the first few days after starting the machinery. Examination of the bearings usually disclosed an unhappy state of affairs. In many cases several days of hard work would be necessary to stone the bearing surfaces back into shape. In other cases the original pitting and etching of the shafts, causing a change in bearing condition, undoubtedly explains some of the later trouble encountered with the bearings.

In several very large marine power plants, as well as in some of the earlier land turbine and steam plants, it was found that it was possible to prevent corrosion and serious emulsions simply by properly cleaning the entire circulating system before the power unit was started or the steam turned on. The method was to fill the system with a light spindle oil and allow it to be circulated freely by the pumps. This was done for at least a day. Then all of the oil was removed and put into the fuel. This practice had two objects: to thoroughly clean the system of all of the accumulated foreign material and to saturate all bright parts reached by the oil. On duplicate installations, where this practice would be carried out on one and not on the other, any cost involved by the cleaning and saturation process was repaid many times due to the entire lack of corrosion of parts and emulsification of oil. Where this cleaning was not done, shafts had to be taken out or stoned, lines had to be taken down and steamed out, and tanks had to be cleaned, and there was enough loss of circulating oil in the process of cleaning up afterward and in the emulsions that would not settle to more than pay for a preliminary cleaning of the system. In the study of these cases it was found that a circulating system attached to any machine, the bright parts of which have been corroded, subsequently gives continuous trouble until all of the iron oxide has been removed. Iron oxide acts as a sort of binder in the emulsion of water and oil.

In any new machine all bearing surfaces and other bright parts should be thoroughly impregnated with mineral oil before the machine is started. Any circulating or other lubricating system attached to the machine or bearing should certainly be thoroughly cleaned. The best manner of cleaning is to operate with a light mineral oil for at least 24 hours.

When erecting engineers are impressed with the necessity before starting up the machinery of having everything made as clean as hospital operating rooms, then corrosion will be almost a thing of the past so far as it affects bearings and the bright parts of all machinery reached by oil from a circulating oiling system.

A. G. **Witting.**[4] Fully realizing the importance of efficient lubrication, but on the other hand also the first cost of installation and maintenance and operating costs afterward, the writer would like to ask the question where the limit would be set for increased efficiency to offset the costs of a circulating system.

At one of our merchant mills there is a set of reduction gears running in a bath of oil. The speed at the pitch line is 1864 ft. per min. The gear teeth show no sighs of wear. The following is a comparison of the oil when new and after $2^{1}/_{2}$ years of operation:

	New oil	Used oil
Date of sample	Sept., 1927	April, 1931
Water	None	None
Sediment, per cent	None	0.08
Viscosity at 210 deg	128	134
Neutralization number	0.03	0.053
Flash, deg	470	480
Emulsion	Complete separation	

Leo Kresser.[5] For the lubrication of roll-neck bearings a simple and reliable apparatus has been built by this company. A number of small but powerful pumps are combined in one machine, with a common drive and a common container, which press the lubricant into the bearing with a pressure that will secure positive delivery. A pressure up to 3000 lb. per sq. in. can be overcome by these pumps, which is far more than the lubrication of the roll necks requires.

The amount of lubricant delivered to each feed point can be adjusted to the exact needs of the bearing. The apparatus is easy to install, requires only a fraction of a horsepower to drive and when installed and adjusted needs no further attention.

F. P. **Dahlstrom.**[6] Oil-circulating systems have been applied very extensively to mills of our manufacture for the past ten years. At first some of the main drives were lubricated with a gear-shield type of lubricant, but during the last five years practically all installations have been designed so that all gears and bearings in the mill proper are lubricated with oil from circulating systems such as those mentioned in the paper. Such systems have been operating with entire satisfaction.

Because of the comparative transparency of the oil used, it was early noticed that certain gears in these installations were pitting. In many cases this was incipient and soon stopped, and in certain other cases where pitting appeared abnormal there was the expected reaction that the use of oil as a lubricant for heavy loaded gears was the cause of such pitting. Research has shown, however, that this condition is the result of exceeding the compressive fatigue limit of the material from which the gear is made. Below such limits gears will operate indefinitely without wear, and above this limit pitting (which is oftentimes wrongly called wear) is certain to occur. The dislodged particles in being scraped across the surface of the teeth often score the teeth and thus conceal the real cause.

It is obvious that the surface stresses between the cylindrical tooth surfaces in contact are very high and may be from about 100,000 lb. per sq. in. in some of the better grades of steels used in rolling-mill work up to as high as 250,000 lb. per sq. in. where small case-hardened automobile gears are used. During the past year wear tests on different gear materials have been conducted for us with the Lewis gear-testing machine at the Massachusetts Institute of Technology under the direction of Professor Buckingham. Severe loads have been applied to test gears made of different materials. These loads cause equal reacting loads on hardened and ground master gears in the Lewis machine. These master gears have been used for several thousand tests in the course of such work during the past six years and have broken down many surfaces of various materials. During all these tests the gears have been intermittently lubricated with oil. It is interesting to note that the surface of these teeth, even under a microscope having 25 magnifications, shows only a few minor scratches.

Investigation shows that slow-speed mill pinions of heavy-duty mills are stressed beyond the compressive fatigue limit. Correction of such difficulties is largely an economic one. It is probably cheaper to discard the pinions after many years of use rather than to design disproportionately large pinions and housings which would require valuable space. The writer has examined the pinions in a sheet-bar mill which ran through the World War and which were lubricated by dipping in a light gear shield. After five years of wear the tooth thicknesses of these pinions were about from one-half to two-thirds of their original value. He also has observed the tooth thickness of mill pinions on a similar mill which also ran through the World War, but which were lubricated by dipping in a light oil, approximately 400 sec. at 100 deg. The tooth thickness of these pinions was practically the same as those in the mill first cited.

During the last few years certain special oils have been developed for highly stressed gears. The introduction of the hypoid gear with its more pronounced sliding tooth action was one of the first factors in creating a need for such lubricants. Subsequently, special testing machines have been exhibited, and the resulting data show that ordinary oils break down at about 8000 lb. per sq. in., while the recently developed lubricants apparently show a very much higher film strength.

Knowing that gears made from ordinary steels can easily withstand surface stresses of nearly 100,000 lb. per sq. in. without lubrication failure, it is our belief that high local temperatures in several of these testing machines actually break down the film and not pressure alone. A lubricating film is a very strong and tenacious thing provided we do not burn it and thus destroy it. There is no such tendency in modern, correctly designed gears.

Sulphur and other such substances that now are introduced into special lubricants tend to prevent welding, which again seems to prove that localized heat and not pressure in itself must be considered. Until these temperatures are known, existing pressure data in connection with the determination of oil film strength are not absolute, but only comparative.

It would be interesting to see the results of such pressure data recompiled with respect to the flash and fire points of the oils instead of their viscosities.

Once-Through Series Boiler for 1500 to 5000 Lb. Pressure

By H. J. Kerr,[1] New York, N. Y.

The paper covers the development of series-type boilers from the early stages which resulted in the Calumet steaming economizer type now in extensive use to the once-through series boiler. It describes the operation of the latter units from 1500 to 5000 lb. per sq. in., and test data are given. The limiting factors of this type of unit, such as equalization of flow, control with variable capacity, and operation, are discussed. Heat-transfer data on high-pressure superheated steam are presented.

An increase in steam pressure has always been accepted as a means of increasing the efficiency of power generation. The disagreement between those favoring a lower pressure of, say, 300 or 400 lb. per sq. in. and those favoring a higher pressure has been due largely to the commercial question of the final total cost. The curve in Fig. 1, which shows the cycle efficiency for various pressures, may be open to some question as to the exact value, but it is felt that the general form of this curve, which shows decreasing rates of the efficiency gain with an increase in pressure, will be accepted as correct.

Obviously if higher-pressure plants are built of apparatus designed for low pressure, with the various parts increased in thickness to withstand the higher pressure, the cost of such plants will increase materially with pressure increase. As the increase in efficiency to be obtained with increased pressure is a decreasing quantity, the highest pressure which will prove to be commercial will depend largely on the ability to design and build apparatus for the production and use of high-pressure steam at a minimum increase in cost.

Recognizing these principles, the Babcock & Wilcox Company has been engaged on the problem of developing types of boilers to meet these requirements so as to permit of the highest possible commercial pressure.

One of the first developments was the series or two-stage boiler (Fig. 2), as described by Dr. D. S. Jacobus in his paper, "Present Practices in Steam Generation in the United States," presented at the First World Power Conference in London in July, 1924.

The first commercial installation of the type of unit shown in Fig. 2 was at the Calumet Station of the Commonwealth Edison Company, the unit being put into service in November, 1926. The success of this type of unit is perhaps best demonstrated by the number of high-pressure installations now in service, such as the last units at Edgar Station in Boston, Deepwater, Holland, State Line, and other stations. Fig. 3 shows the side elevation of the new units now under construction for the State Line Station extension for 1400 lb. pressure. This illustration also shows the latest slag-tap furnace and dust screen beneath the boiler.

The next development was the drumless series boiler (Fig. 4), described by Dr. Jacobus in his paper, "Developments in High-Pressure Boilers," presented before the Engineers' Society of Western Pennsylvania in October, 1927. In this boiler all boiler drums were eliminated, forced circulation was used, and various percentages of excess water were passed to a separator. Water was drained continuously from the separator, and the rate at which the boiler was fed was adjusted so as to hold the height of the water in the gage glass within a given range. While no commercial installations of this type of boiler have been made, the test unit was operated over long periods of time at 600 to 650 lb. pressure and was of sufficient size to determine various unknown quantities so that a commercial unit of this type can be built where conditions would warrant.

It will be noted from the preceding statements that investigations were started along a certain path in boiler design leading to a boiler which would consist of a set of tubes only, into which water would be pumped and from which steam at the desired pressure and temperature would emerge.

FIG. 3 NEW UNIT FOR STATE LINE STATION

The purpose of this paper is to present certain facts dealing with the design and the operation of a boiler with straight-through flow without drums. While four of these straight-through units have been built for investigation, a description of the last one will serve the present purpose.

Fig. 5 shows this unit as erected and tested at Bayonne Works. It has been in successful operation at steam pressures from 1500 to 5000 lb. per sq. in. at a capacity which is limited by that of the pump. This capacity is about 5000 lb. per hour, with a final steam temperature of the order of 800 deg. fahr. The unit consists of seven circuits made of 1-in. tubes, $^1/_2$-in. inside diameter, the particulars of which are as follows:

Economizer surface (convection bank), sq. ft.	189
Exposed length of economizer tube per circuit, ft.	103
Furnace surface, semicircumference of tubes, sq. ft.	98
Furnace surface, projected area of tubes, sq. ft.	62
Exposed length of tube per circuit in furnace, ft.	107
Furnace volume, cu. ft.	87
Diameter of furnace at bottom, ft.	4
Height of furnace inside, ft.	$7^2/_3$

The flow diagram for the unit is shown in Fig. 6. The water enters the economizer section at the top, passing down through seven circuits (each circuit consisting of four double coils). At the end of the economizer section the circuits join and pass to the bottom of the furnace-wall tubes, where the flow is again subdivided into seven circuits, forming the furnace-wall tubes, which become the steaming section and superheater. There are ten coils per circuit in the furnace. Steam leaves the top of the furnace at the desired superheat temperature.

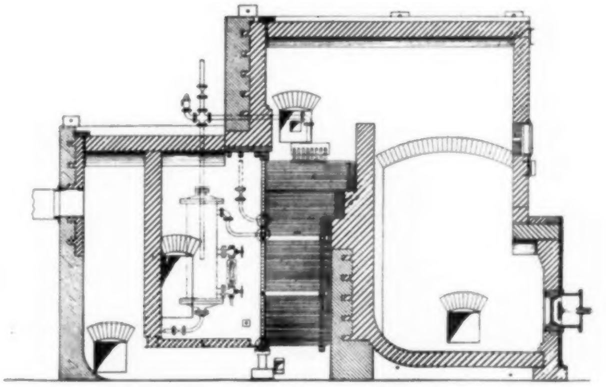

Fig. 4 Drumless Series Boiler Fired With Oil

Table 1 shows typical test data for various pressures at approximately 5000 lb. of steam per hour, 800 deg. fahr. outlet steam temperature, and pressures from 1500 to 5000 lb. per sq. in.

With reference to Table 1, the following points are of interest:

1 All temperatures (except furnace temperatures) were taken with iron-constantan thermocouples. Tube temperatures were taken with the couples peened to the tube in the usual manner. For taking steam temperatures the arrangement was virtually a thermocouple well of small diameter made integral with the tube, with the two wires welded to the bottom of the well. It seems conservative to state that steam temperatures taken in this manner are accurate to within 5 deg. fahr.; all checks that have been made indicate that the error is less than 5 deg. fahr.

2 Of interest in this table is the difference between the average steam temperature and the maximum steam temperature from any one circuit, these differences being 45, 35, 21, and 12 deg. at 1550, 2500, 3200, and 5000 lb. per sq. in., respectively. Undoubtedly this could be further improved where desirable.

This boiler has been in successful operation for a considerable period of time under the conditions noted in Table 1 and with variations in capacity of the order of 30 per cent.

Some of the problems involved in the design of this type of boiler are as follows:

Distribution of Flow

Such a unit consists of a number of tubes connecting the common feed supply with a common steam discharge, and it is desired to have equal flow in all circuits. At first thought this would seem to be quite simple with a reasonable pressure differ-

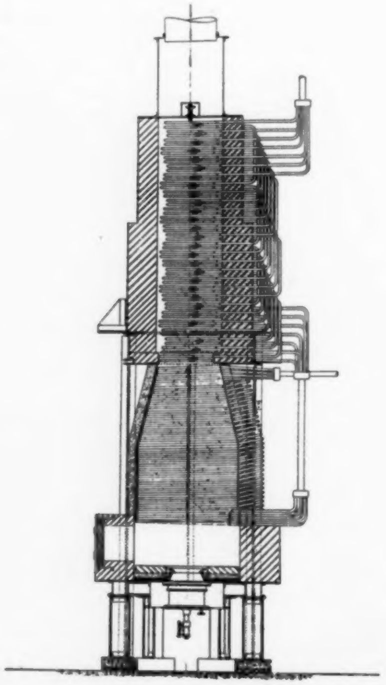

FIG. 6 ONCE-THROUGH SERIES BOILER
(Seven-circuit tube arrangement and flow diagram.)

ential, and as a matter of fact it might be expected that, if the circuits were exactly the same, such a condition would exist irrespective of the pressure differential. This, however, is not the case, as an unstable condition of flow may take place even with a uniform application of heat. To state it briefly, if there are a number of identical circuits between a common water supply and a common saturated- or superheated-steam outlet, with all of the circuits equally heated, there may be an unstable condition which will result in an unequal flow in the different circuits. Again, the amount of this inequality in the flow will vary and can reach such proportions that the temperature of the outlet of a circuit may increase to a point where the tube will be burned.

Fig. 7 shows the effect at 2500 lb. pressure of various feedwater inlet temperatures, together with various outlet-heat contents per pound. Taking the case of 200-deg. feedwater inlet, the curve on the left shows that up to an outlet-heat content of 800 B.t.u. per lb., the temporary slowing down of flow of one circuit or a number of circuits will tend to cause a decrease in pressure drop across those circuits, which would of course result in increased flow, tending to bring the circuits back to a stable condition. As the average heat content of the emerging fluid is increased—that is, as more heat is added per pound, the total remaining constant—this equalizing effect becomes less and less, until finally at an average heat-content condition of 1000 B.t.u. per lb. in the emerging fluid, it is evident from this curve that there will be no tendency toward an equilibrium condition; but on the contrary, a definite tendency for the circuits to become further unbalanced. On increasing the inlet temperature, the form of the curves changes, until finally when the feedwater-inlet temperature reaches 400 to 500 deg. fahr., the entire curve, as shown in dotted line, becomes smooth and of such form as to show that any tendency to unequal flow with equal heat application will be corrected by the tendency to change the pressure drop.

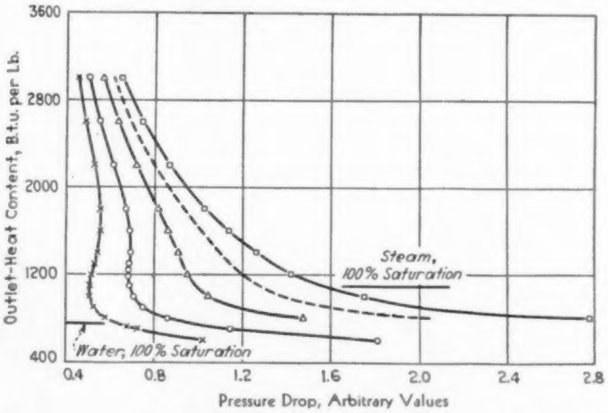

FIG. 7 PRESSURE DROPS FOR VARIOUS VALUES OF B.T.U. PER POUND

(Added in a circuit receiving a constant total B.t.u. per pound input evenly distributed along the length. Pressure is 2500 lb. per sq. in. abs. Legend: Crosses, 200 deg. fahr. inlet temperature; circles, 300 deg. fahr.; triangles, 400 deg. fahr.; squares, 500 deg. fahr.; dotted line, 460 deg. fahr. minimum inlet temperature for smooth curve.)

Fig. 8 is a similar set of curves at 3200 lb. pressure, again showing by the dotted line that an inlet temperature of between 400 and 500 deg. fahr. gives a definite smooth curve of proper form.

Fig. 9 shows the effect on a test unit of the conditions described in Figs. 7 and 8. In this particular unit four circuits were used. Circuits *A* and *B* show an outlet condition at saturation temperature, undoubtedly with some percentage of water in the steam. Circuits *C* and *D* show a superheat temperature starting around 820 deg. fahr., increasing with time to temperatures above 960 deg. fahr., with all conditions on the unit maintained as near constant as possible. In this test the feedwater-inlet temperature was 200 deg. fahr.

Fig. 10 shows the minimum inlet temperature for stable operation from 1500 to 3200 lb. This curve assumes interconnecting circuits from the inlet to the outlet of equal dimensions, the heat application being equal throughout the length of the circuits and equal for all circuits.

Under certain conditions it may not be desirable to increase the temperature of the entering material to such a value as to produce natural stability of the circuits. In such cases stability can be produced by interposing sufficient resistance at the entrance to the circuits to bring about this condition.

The foregoing deals with the natural instability of circuits caused by the change in volume of fluid which takes place as heat is applied. Another factor, however, is involved in this general problem—namely, the unequal heating of circuits. This can be eliminated in certain cases by so designing the unit that unequal heating will not take place. Data from Table 1 give a fair measure of the results that can be obtained with small oil-fired units. In many cases, however, particularly with larger units, this will not be possible. Where this unequal heating is sufficient to produce too great a difference in the heat content of the material leaving the circuits with equal flow, unequal resistance will be required so as to produce greater flow in those circuits receiving the greater amount of heat, so as to give approximately an equal heat content in the material leaving all circuits. Obviously, as the size of unit increases, the problem becomes somewhat more difficult. The problem also becomes further complicated in the case of pulverized coal, involving the question of uneven slag accumulation on the furnace walls.

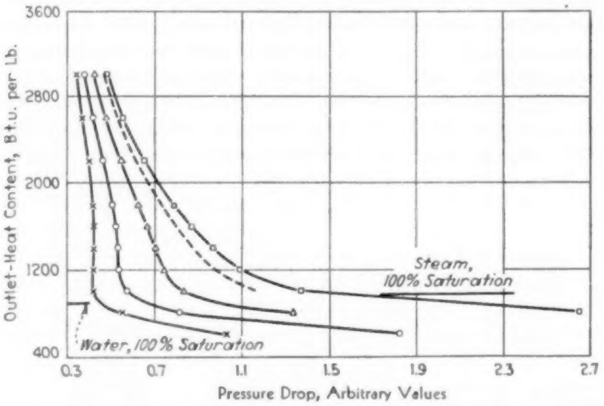

FIG. 8 PRESSURE DROPS FOR VARIOUS VALUES OF B.T.U. PER POUND

(Added in a circuit receiving a constant total B.t.u. per pound input evenly distributed along the length. Pressure is 3200 lb. per sq. in. abs. Legend: Crosses, 200 deg. fahr. inlet temperature; circles, 300 deg. fahr.; triangles, 400 deg. fahr.; squares, 500 deg. fahr.; dotted line, 473 deg. fahr. minimum inlet temperature for smooth curve.)

CONTROL OF THE UNIT

This type of unit obviously has little if any water- or heat-storage capacity. It is therefore necessary with variable loads to have a quick-acting automatic control which will maintain the supply of feedwater, fuel, and air necessary for the capacity demands. Such a control has been developed on these test units by the Bailey Meter Company.

The control is arranged as follows: The motion of the throttle valve which regulates the steam flow gives the primary impulse to change the oil, air, and feedwater supply. The steam pressure at the outlet readjusts the oil and air flow to maintain the steam pressure. The temperature at a point intermediate between the point where the steam becomes dry and the superheater outlet readjusts the water flow to maintain a constant outlet-steam temperature. The control on the experimental unit operated through Selsyn motors which actuated the hydraulic mechanisms.

With this control no difficulty was experienced in operating with 30-per cent variation in load applied in one to two seconds by opening and closing the throttle valve. The outlet-steam temperature was consistently maintained within 10 deg. with a pressure variation of 50 to 100 lb. at 2500 lb. per sq. in. pressure. It should be understood that in an actual installation variations in the steam flow would actuate a mechanism that would take the place of the throttle valve used in these experiments for giving the primary impulse for regulating the supply of the fuel, air, and feedwater. Further improvements in this control have already

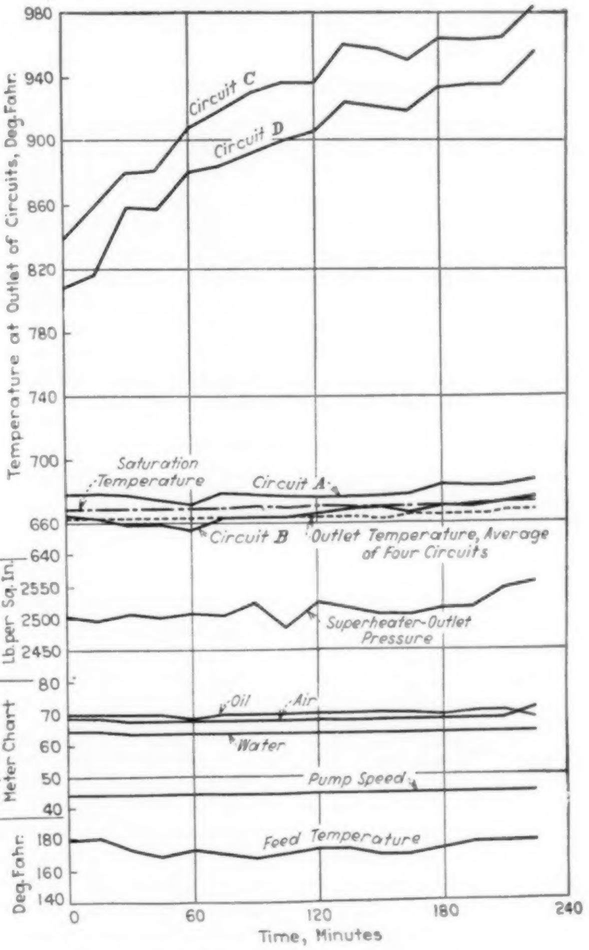

FIG. 9 EFFECT OF INSTABILITY ON THE EXPERIMENTAL BOILER

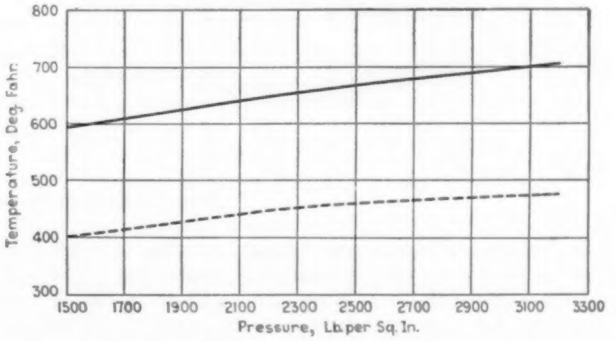

FIG. 10 MINIMUM INLET TEMPERATURE FOR STABLE OPERATION FROM 1500 TO 3200 LB.

(Dotted line, minimum inlet temperature for stable operation; solid line, saturation temperature corresponding to pressure.)

been accomplished, so that this problem has been definitely solved.

Treatment of the Feedwater

The feedwater used in these tests was deaerated condensate maintained slightly alkaline with phosphate and caustic soda. A careful inspection showed that the internal surfaces of the tubes were unaffected by corrosion or scale formation. The amount of hydrogen in the steam leaving the unit was measured at different pressures up to 3270 lb. and was found to be in line with that normally existing in low-pressure units, and of such a low quantity as to be negligible. The quantity of phosphate or caustic required to maintain the desired pH value of 10.5 did not form any scale which remained in the tubes, but was apparently blown through to the condenser and thus recirculated through the system. Thus only very small additions were required.

Conditions for Starting Up

It is obvious that a unit of the type described cannot be started up without circulating water through the tubes. At first thought this might appear to be a disadvantage, but it has a compensation that in some cases will outweigh the complication. This compensation is the ability to bring such a unit up to 3500 lb. pressure and 800 deg. temperature at the outlet in 10 minutes. When it is considered that modern high-pressure practice requires a time of from two to three hours for starting up, the gain in this respect is a valuable one.

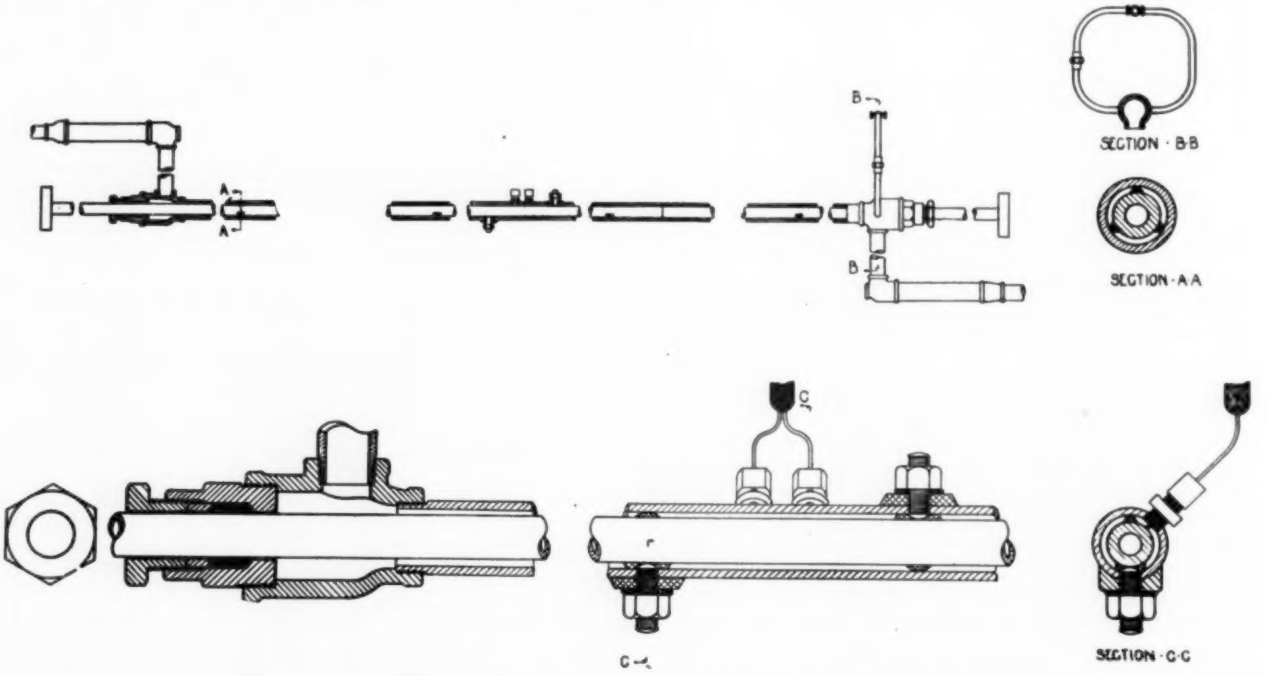

Fig. 11 Experimental Heat-Transfer Apparatus

Triplex-Plunger Feed Pump Used

Throughout this work a triplex-plunger pump with a direct-current motor drive has been used, and no difficulty has been experienced with it. The feed-pump drive must, however, be arranged for small variations in capacity. This has been accomplished in the test apparatus by using a 120-point multiple rheostat. In larger units this will represent some complication, but not a serious one.

Arrangement and Construction

The general arrangement of heating surface is that most suitable for small-sized units and would undoubtedly be entirely different for units of larger size.

The only construction detail which might be considered as worthy of mention is the elimination of all flanges, the unit being completely welded from end to end, using the welds not only for tightness but for the necessary strength. In this work resistance, arc, thermit, and acetylene welding have been used with complete success.

Superheated Steam at High Pressure

It may be of interest to add that a heat-transfer apparatus was operated in conjunction with this boiler in order to obtain heat-transfer data at the higher pressures. The apparatus, which is shown in Fig. 11, consisted of an inner tube of 1-in. external diameter and $^1/_2$-in. internal diameter, through which the high-pressure steam was passed. Surrounding this tube was an outer jacket consisting of $1^1/_4$-in. extra-heavy seamless pipe. Low-pressure superheated steam at approximately 200 lb. per sq. in. pressure was passed through the annular space between the jacket and the inner tube and absorbed the heat given up by the high-pressure steam.

The flow of both high- and low-pressure steam was measured, as well as the temperature differences and the pressure drop through both circuits of the apparatus.

In these tests the high-pressure and low-pressure steam was condensed and weighed, the heat quantity given up or absorbed being thus checked. The transfer rate of the high-pressure steam was then determined from the known data on the transfer rate of low-pressure steam.

Results with superheated steam up to 3300 lb. per sq. in. pressure and 800 deg. fahr. conform to the following formula:

$$h = 0.028446 \frac{W}{A} (T)^{-.05}\sqrt{(fC_p)}$$

h = heat-transfer rate through one fluid film in B.t.u. per hour per sq. ft. of film surface per deg. fahr. of temperature difference across the film

f_a = friction factor from curve corresponding to values of

$$\frac{Dus}{Z} = \frac{D\frac{W}{A}}{224{,}280Z}$$

D = diameter of tube in inches

$\frac{W}{A}$ = mass flow of fluid in lb. per hour per sq. ft. of cross-sectional area

C_p = means specific heat of fluid film at constant pressure

T = mean temperature of fluid film in deg. fahr. abs.

Z = mean viscosity of steam film relative to water at 68 deg. fahr.

It is not the purpose of the author to propose the immediate adoption of 2500 lb. pressure for power generation. The facts appear to be, however, that 2500 lb. steam pressure makes possible higher efficiency. The amount of this increased efficiency which will be available will depend upon the cost of obtaining it, and the type of unit described may make it possible under certain conditions to proceed further in this direction than with standard constructions. One can hardly operate the type of unit here described without developing the definite conviction that 3000 lb. steam pressure with a unit of this type represents little complication as compared with the ordinary 600-lb. to 1500-lb. units so common at the present time. Again, the information developed gives data that can be used for the proper design of units of this type and that prior to the making of these tests were not available.

Discussion

I. E. Moultrop.[2] The paper describes some interesting developments which should have a far-reaching effect in power-plant practice. There can be no question about the increased efficiency and the desirability of going to much higher steam pressures than have been considered standard practice. The increased efficiency obtained by higher pressures has been recognized for some time, but the considerably greater cost of the higher-pressure boiler has doubtless deterred many engineers from adopting it.

The once-through series boiler certainly promises to bring about a great reduction in boiler costs. The writer believes the cost of the drum for a 1400-lb.-pressure boiler is about one-half the total cost of the boiler, and if this is eliminated, it should make a considerable reduction in the cost of the unit. The drumless series boiler should be a very rugged piece of apparatus so far as the boiler itself is concerned. However, the elimination of the drum places a considerably greater responsibility on the boiler-feed pump, and a momentary failure of the pump might result in serious damage to the boiler. It is recalled that one of the principal arguments in the past against the Loeffler and the Benson boilers was the responsibility that these types of boilers placed on the pump. The boiler-feed pump is a fairly reliable piece of apparatus, but it may have a momentary interruption once in a while, and it only takes one of these to burn a drumless boiler. To make the drumless boiler commercial, it will be necessary to find means of absolutely insuring continuity of the feed.

The quality of water supplied to the drumless boiler is another important item. While all power boilers should receive proper conditioned water, this has not been general practice in the past. Using higher pressures makes the proper conditioning of the water imperative or serious trouble may ensue. This is a subject about which far too little is generally known.

This experimental work which the Babcock & Wilcox Company is doing is a very valuable contribution to the art, and in connection with the experiments being made by the Detroit Edison Company on higher temperatures should put in the hands of the power-plant engineers apparatus much more efficient than is available today.

[Further discussion of this paper, jointly with that of A. A. Potter, H. L. Solberg, and G. A. Hawkins, by A. G. Christie, N. Artsay, R. M. Gates and W. H. Armacost, Karl A. Mayr, George A. Orrok, Arthur J. Herschmann, and James M. Taggart, will be found following the latter paper.]

Author's Closure

I would like to thank those who have so kindly contributed to the value of the paper by their discussion.

It seems particularly appropriate that the discussion should be led by Messrs. I. E. Moultrop and George A. Orrok; Mr. Moultrop because he is the man that led the way in America to the use of 1400-lb. steam pressure in power plants; and Mr. Orrok because of his well-known interest in this subject over a number of years.

Mr. Moultrop does not question the gain to be obtained by using high steam pressures. Again his experience in high-pressure practice permits him to place his finger on two very important factors in connection with the unit described—namely; the need for reliability in the feed pump and the necessity for good feedwater conditions.

Mr. Orrok refers to Perkins, to whom we owe a very considerable debt for the things that he accomplished under adverse conditions. In many cases the inability to fully appreciate the advantages of a new development, or trouble that was not fully understood, has been a stumbling block in preventing progress.

An example of a development which failed because of lack of knowledge, and which later has been successful, was the steel economizer. More than 30 years ago quite a number of steel economizers were installed in plants throughout the country, all of which failed due to corrosion. Notwithstanding this experience, there has been witnessed the return to steel economizers with complete acceptance and success.

Mr. Orrok asks what operating difficulties have been experienced with steaming economizers. In the author's experience, he has never seen a new development approaching in extent that of the steaming economizer which has been so free of operating difficulties. Speaking from very close contact with this whole development, he does not know of any operating difficulties that have developed from their use, and this fact is evidence of the value of complete preliminary testing of new ideas before applying them to commercial jobs.

The operation of units of the type shown by Fig. 4 represents no difficulties, but the importance of using a reliable pump becomes greater, as does also the control of feedwater, fuel, and air.

It is true, as Mr. Orrok states, that unequal circulation in water walls, superheaters, etc. has been in some cases straightened out by the application of poorly understood principles, but this is not so in a series boiler, which requires full understanding of the factors involved, and it was necessary to determine these in order to obtain satisfactory results.

Prof. A. G. Christie refers to the question of the purity of the feedwater, which is obviously an important factor with the type of unit described. Throughout the tests and operation of the units, condensate has been used with small additions of sodium salts to maintain the desired alkalinity. Experience has shown that the salts passed through the unit.

The operation of mercury boilers has proved that it is

[2] Chief Engineer, Construction Branch, Edison Electric Illuminating Company of Boston, Boston, Mass. Mem. A.S.M.E.

practical to build a complete unit in such a way that none of the fluid will leak out and other materials will not enter. Units of this type have operated continuously over a period of nine months, and on being shut down show practically the same vacuum as when started and without the loss or gain of any of the mercury.

A steam unit can duplicate these conditions provided the gas formed is taken care of and the solubility of iron in pure water without oxygen is not excessive. The latter condition can be assisted by certain salts which may give little trouble in passing through the turbine.

No difficulty was experienced with the seven-flow boiler which was designed on the basis of our investigations. Figs. 7, 8, and 10 were obtained from theoretical calculations based on experimental data, and the curves are extended beyond permissible values as a matter of interest. Fig. 9 represents actual test data that were used in the theoretical calculations.

The data given on Table 1 on the seven-flow boiler, as well as the data given by Dean Potter and his colleagues on the Purdue unit, furnish a demonstration that, having determined the factors involved, series boilers can be built to give stable conditions.

Dr. Karl A. Mayr questions the values of the efficiency curve given in Fig. 1. In presenting this the author stated that the actual values might be open to question. The values given represent figures obtained from various sources and probably represent as nearly correct values as can be presented. It is not possible to give definite figures that will be ironclad, since the results are much affected by variable conditions not common to all plants.

While it is true that the equilibrium of flow through circuits remains much more constant when the water in the circuit is not permitted to change its state, the units described have shown that it is not necessary for the boiler to be operated at the critical pressure in order to obtain satisfactory equilibrium conditions. Where a pressure of 2500 lb. is desired at the turbine, it is a distinct handicap to be forced to increase the work of the feed pump by maintaining a pressure above the critical. In the case of the unit described in the paper, the maximum pressure drop from the feed pump to the steam available for the turbine is of the order of 200 lb. at 1500 lb. pressure and considerably less at 2500 lb. pressure. Obviously, such a unit will give higher net efficiencies than if it were necessary to operate the pump at a pressure of approximately 4000 lb., as in the case with a critical pressure boiler. Again, while it appears quite simple to maintain critical pressure in the water tubes and thus have no evaporating zone, the expansion of this steam through the superheater beyond the control valve, while applying heat in an amount to prevent formation of water and maintain flow through the circuits, is perhaps not so simple.

Mr. Arthur J. Herschmann, speaking from the experience with Loeffler boilers in Europe, questions the value of exceeding 1900 lb. pressure. Comparing this with Dr. Mayr's discussion, it would appear that European engineers have not as yet reached an agreement on a desirable upper limit for pressure. Perhaps this is due to different values for the efficiency curve as given in Fig. 1. The particular type of boiler involved may also affect their conclusions on the optimum pressure. It would appear as a handicap to have a feed pump operating at a pressure of approximately 4000 lb. for a pressure of 1900 lb. at the turbine, which would be the condition for the critical pressure boiler. Again, the stresses in tubes of ordinary steel containing steam at 2500 lb. pressure and 932 deg. fahr. temperature are not to be overlooked.

Mr. James M. Taggart points out the value of mingling the water and steam at different sections. A careful study of Figs. 7 and 8 will show this effect. The difficulty of applying this method to large units will be obvious.

Mr. N. Artsay questions the stability of flow and the meaning of Figs. 7 and 8, both of which points have been answered in the previous discussion.

Messrs. R. M. Gates and W. H. Armacost misinterpret the meaning of Fig. 9. This figure is simply a demonstration of the facts as brought out by the theoretically determined curves of Figs. 7 and 8 to prove the instability of circuits. Having determined the factors involved, a series boiler can be designed to eliminate this condition as shown by Table 1. The same statement is true of forced-circulation oil stills and without reducing the number of circuits.

Plain carbon steel has been used in all tubes of the series boilers which we have developed, and no growth or difficulty has been experienced with it. Consideration of the metal temperatures given in Table 1 will show that the unit has been properly designed to prevent such difficulties.

To sum up, the factors involved in the design and operation of series boilers have been investigated, and it has been shown that such units can be built for satisfactory operation. The value of such type units for high pressure has been pointed out. It remains to be seen whether the next development will be with the straight-through series boiler or along the lines of an intermediate stage with a greater amount of steaming than is common with present series-flow steaming economizers.

Characteristics of a High-Pressure Series Steam Generator

By A. A. POTTER,[1] H. L. SOLBERG,[2] and G. A. HAWKINS,[3] LAFAYETTE, IND.

The steam generator consists of two parallel circuits of seamless-steel tubing supplied with feedwater at one end, and delivering steam from the other end at any desired pressure up to 3500 lb. per sq. in. and at a maximum temperature of 830 deg. fahr. The changes which take place in the circuit are measured by means of thermocouples and manifolded pressure connections. The unit is controlled automatically by a system which uses the Thyratron vacuum-tube circuit. A set of charts is presented showing the operation of the automatic control on a swinging load. The tests reported in the paper indicate the effect of (a) varying the steaming capacity at constant pressure and temperature, (b) changing the pressure at constant capacity and temperature, and (c) increasing the steam temperature at constant capacity and two different pressures. The temperature and the pressure changes through the water and steam circuit are shown graphically. Data are also presented on the heat-transfer rates through the furnace-wall tubes. The results up to date indicate that this steam generator will operate successfully at any pressure between 1500 and 3500 lb. per sq. in. and at a maximum temperature which is limited by the materials used. Automatic control held the steam pressure and temperature nearly constant throughout the range of operation.

A. A. Potter

H. L. Solberg

G. A. Hawkins

The steam generator, shown in Fig. 1, consists of a cylindrical water-cooled furnace placed immediately beneath a counterflow economizer or convection section. This steam generator is a further development of the Calumet-type unit in that the steaming economizer, or convection element, is continued through the evaporating and superheating sections. There is no steam drum, and the water that enters the unit passes through a continuous coil and leaves it as superheated steam. It can be operated at any pressure between 1000 and 3500 lb. per sq. in. at the outlet, although in the lower pressure ranges the friction loss is excessive by reason of the small tubes used. No throttle valves or other regulating devices are installed between the boiler-feed pump and the steam-generator outlet. By varying the ratio of fuel to water at any load, the final quality of the steam may be changed from saturated to superheated steam at a maximum temperature of about 830 deg. fahr., this being limited by the tube material. The unit is constructed of 1 in. O.D. by $^1/_2$ in. I.D. seamless-steel tubing (A.S.M.E. 1927 Code boiler steel). All joints are gas-welded, using a butt type of weld.

The feedwater is delivered to the top of the convection section, where it is divided into two parallel circuits each 521 ft. in length, and flows downward countercurrent to the gas flow. Fig. 2 shows this section before it was bricked in. The long sets of coils at the bottom are provided to support the section. The vertical pipes and horizontal welded bars shown in Fig. 2 were removed after the brickwork was completed.

The water which leaves the two parallel circuits at the bottom of the convection section is carried to the bottom of the furnace coils by a single downcomer or equalizer which is made of double-extra-heavy $1^1/_2$-in. seamless-steel tubing. The lower furnace-coil section consists of two parallel circuits wound in the form of a cylindrical helix and discharging at the upper end into a common tube or equalizer. The middle and upper furnace-wall sections consist of two parallel circuits wound in the form of a conical helix, with another equalizer connection between the sections.

Fig. 3 shows the entire unit during erection. Fig. 4 illustrates the relative positions of the heating and non-heating surfaces, as well as the location of the 42 thermocouples and 7 pressure connections which have been used in studying pressure and temperature distribution. The heating surface of the steam generator is distributed as follows:

Area of convection section, sq. ft.	259
Surface area of furnace-wall section, sq. ft.	101
Projected area of furnace-wall section, sq. ft.	64.3
Volume of furnace, cu. ft.	84.4
Distance from furnace floor to convection surface, in.	110

The steam generator is fired by a single mechanical oil burner placed underneath the cylindrical furnace, the gases flowing straight upward in a single pass to the stack.

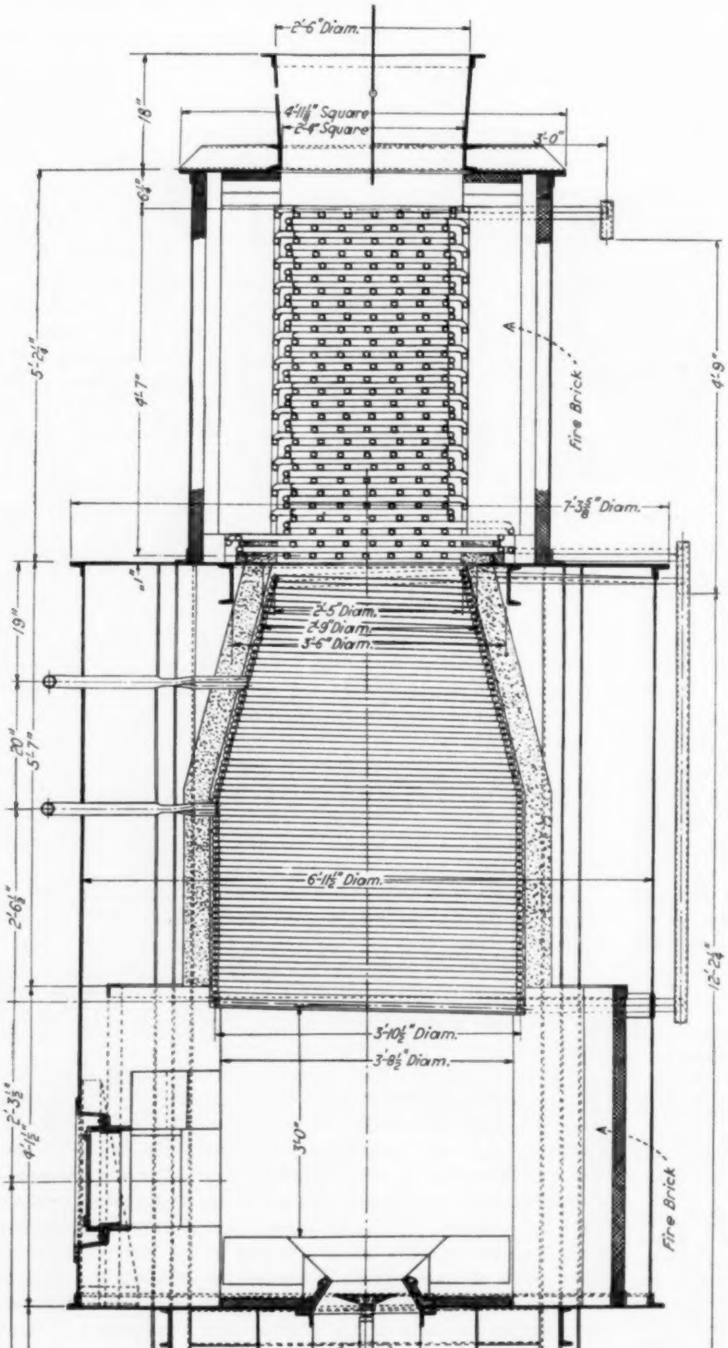

Fig. 1 Cylindrical Water-Cooled Furnace Beneath a Counterflow Economizer or Convection Section

Fig. 5 is a diagrammatic layout of the installation. Feedwater is supplied by a triplex pump driven by a direct-current variable-speed motor. The feedwater from the pump discharge is heated in a special heat exchanger by means of the steam leaving the generator. From the heat exchanger the live steam enters a condenser, which is of the steel-tube floating-head type, designed for a pressure of 100 lb. The condensate is weighed in closed steel tanks mounted on platform scales. These tanks are connected to the piping system by flexible hose. The weight of the condensate is checked by a Bailey flowmeter.

Live steam from the laboratory header is passed through an auxiliary condenser for use as make-up water. Upon the recommendation of the Babcock & Wilcox Company, trisodium phosphate is used to condition the boiler water. Tests are made on alternate days for total alkalinity, sodium phosphate, and the pH value of the water. Dissolved oxygen is also determined frequently. The condition of the boiler water is held within the following limits:

Maximum total alkalinity (expressed as sodium carbonate), p.p.m.	75
Maximum sodium phosphate (expressed as disodium phosphate), p.p.m.	40
pH value	10.0–10.5
Dissolved oxygen (per liter), cc	0.0–0.1
Maximum total solids, p.p.m.	1500

The fuel is stored in an underground tank of 9000 gal. capacity and is pumped to the oil-weighing tanks. The fuel-weighing system consists of two tanks, which are provided with flexible discharge connections and are mounted on platform scales. A constant-speed motor-driven screw-type oil pump discharges the fuel through a duplex strainer, heater, and throttle valve to the burner. Constant oil pressure is maintained ahead of the throttle valve by a Fisher bypass governor.

A motor-driven forced-draft fan is used to supply the air for combustion. The regular laboratory stack is used, being supplemented by a steam jet.

The steam and oil throttle valves are furnished by the Babcock & Wilcox Company; they are both designed to open with 180 deg. of valve-stem rotation and to give a straight-line flow characteristic. The oil throttle valve is shown in Fig. 6. The valve seat has a radial rectangular slot which is covered by the cam-shaped valve disk. The same type of valve and valve seat is also used in the steam throttle valve, but the connections are flanged and there are no screwed joints subjected to pressure.

The ring type of lap joint is used on the high-pressure valves and has proved very satisfactory. A set of 2-in. companion flanges of this type at the boiler outlet was pulled up while warm by one man without sledging, using a 24-in. socket wrench, and has shown no sign of leakage during six weeks of service, starting from cold every morning and with frequent shutdowns. No insulation has been applied to the joint so far, but it is expected to insulate the flanges and to watch their behavior under the changed conditions.

Several 6000-lb. standard screwed forged-steel tees are subjected to the full steam pressure and temperature. The $^1/_4$-in., $^3/_4$-in., and 2-in. screwed

connections of this type were made up with No. 3 Smooth-On iron cement without back-welding and have shown no signs of leakage at any joint.

Double-extra-heavy class B seamless-steel tubing is used for the feedwater piping, while a chromium-molybdenum-steel alloy tube is employed for the steam piping.

Automatic Control

The steam generator is fitted with an automatic control system developed by the Bailey Meter Company, which regulates the fuel, feedwater, and air supply. The problems involved in the control of this type of steam generator are indicated by P. S. Dickey, research engineer of the Bailey Meter Company, in the following statement:

> Two features of the series steam generator are important, at least in so far as automatic control is concerned, and while they are each a result of the elimination of the drum, they should be considered separately:
>
> First, with the conventional type of steam generator, in the drum and in the natural circulation system, there is an appreciable storage of water at a saturation temperature corresponding to the pressure. The water thus stored is capable of releasing or condensing steam upon a change in pressure, and this release or absorption of steam tends to counteract or rather to retard pressure variations. While in the conventional type of steam generator this tendency is reduced as the pressure is increased, the series type, with only a very small amount of water in the steaming zone, permits almost no accumulator action to take place, and it is therefore essential that practically instantaneous changes in water and heat input be made upon load changes if the pressure is to be kept within reasonable limits. The available energy storage within this type of steam generator approaches that of the flywheel effect of the turbo-generator, and the control system must accordingly resemble the turbine governor in so far as speed of operation is concerned. This requires not only

Fig. 6 Oil Throttle Valve

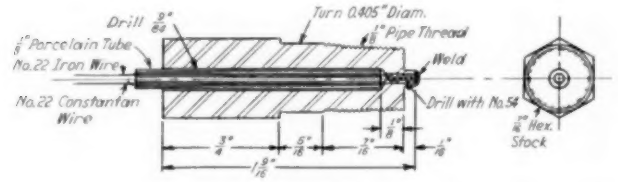
a rapidly responding control system, but a quick response from the combustion and feedwater supply systems as well. It almost demands automatic control if the boiler is to carry a fluctuating load.

The second important feature of this steam generator which differentiates it from the standard boiler is that there is no fixed steam separating surface similar to the water line of the conventional boiler, and the amount of heating surface used for superheating may be widely variable. It is this feature of the series steam generator which makes it possible to maintain any predetermined outlet steam temperature with different steam pressures and output ratings without altering the initial arrangement of the heating surface.

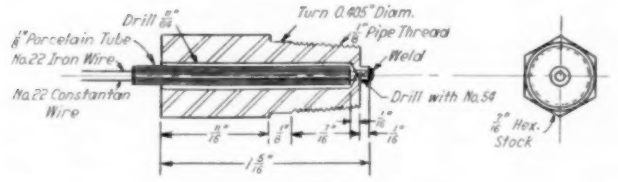
The foregoing features necessitate a control system which is suitable not only to proportion rapidly the fuel, air, and water supply with load variations, but also to maintain at all times a definite relation between the fuel and water input which will give the desired final steam temperature. Since variations in pressure affect the specific heat of the superheated steam and variations in steam temperature affect the specific volume of the steam, the control must be sensitive to small changes in order to prevent variations in pressure from affecting the temperature and vice versa.

The necessary sensitivity for pressure control is obtained by an automatic indicator of the dead-weight loaded-piston type. The dead-weight piston is rotated by a motor and has a range of 400 lb. pressure with a given loading on the piston. A scale beam and weights make it possible to load the piston for any desired pressure up to 4000 lb. Pressure variations are transmitted from the dead-weight piston to the control system by means of Selsyn motors.

The pyod type of thermocouple (Fig. 7) has proved satisfactory for rapid and fairly accurate measurement of steam temperatures. A standard Leeds & Northrup temperature recorder is used to transmit the temperature changes to the control system through Selsyn motors.



ORIGINAL DESIGN



FINAL DESIGN

Fig. 7 Pyod Type of Thermocouple

A Selsyn motor mounted on the throttle valve causes the controls to function in case of load changes.

The fuel-oil throttle valve and the boiler-feed-pump motor rheostat are driven through reducing gears by small reversing direct-current motors. Each of these motors receives its power supply through two Thyratron vacuum tubes which control the direction of rotation and will stop the motor instantly. Variations in pressure, temperature, or load will change the position of contactors in the vacuum-tube circuits and thus control the movement of the motors regulating the fuel and water supply.

A standard Bailey flowmeter is used to control the proportion of oil and air. The displacement of the oil-flow and air-flow pens on this meter shifts the position of the contactors in the circuits of the Thyratron vacuum tubes which supply power to a reversing direct-current motor geared to the fan damper.

The use of the Thyratron vacuum-tube circuit makes it possible to eliminate overtravel and to build a control system which must develop only sufficient power to open and close light electrical contactors. The system therefore responds very quickly to small changes in operating conditions.

Push-button operation is provided for manual control of the supply of oil, water, and air. In all tests reported in this paper, automatic control was used on the oil and air. Full automatic control was used on all tests numbered above ten.

Measurement of Pressures and Temperatures

The triplex boiler-feed pump used in this installation produces pressure pulsations which are quite severe and which continue well into the steaming zone. The accurate measurement of high pressures under such conditions requires a sensitive gage which will hold its calibration. A standard Bailey power-pressure-measuring device has been modified for this purpose by equipping it with a scale beam and weights to give it the necessary range of capacity. It is a motor-driven dead-weight piston-loaded gage similar to the one used on the automatic control system already described. It has a 600-lb. range and can be loaded to bring this range to any place between 1500 and 4100 lb. per sq. in. It drives a 17-in. pressure indicator through Selsyn motors. The indicator dial is graduated in 20-lb. increments with about 1 in. between graduations. This gage is very sensitive to pressure changes and has proved to be quite satisfactory. The seven pressure taps (Fig. 4) are connected to a common manifold. The Bailey dead-weight gage and a Crosby Bourdon-tube gage are connected in parallel to this manifold, while a second Crosby gage serves the boiler outlet. Pressures throughout the unit are thus measured on the same gages.

The measurement of water and steam temperatures in a small thick-walled tube subjected to high pressures requires a device which is small, mechanically rugged, and not subject to errors caused by heat conduction through the tube. The pyod type of thermocouple has been used for this purpose. Fig. 7 illustrates the design of the first thermocouples that were installed as well as the design that is now being used. When checked against the saturation temperature, as determined by pressure measurements, it was found that the original thermocouples read high by an error which increased with the rating and which amounted to as much as 6 or 7 deg. In the final design of thermocouples more metal was removed from the body of the pyod in order to improve the cooling at the hot junction. These thermocouples show little or no tendency to read high.

One of the original thermocouples was checked in the university physics laboratory against a platinum, platinum-rhodium thermocouple and was found to agree very closely with the standard Leeds & Northrup calibration curve for iron-constantan. The other thermocouples were checked against the calibrated couple in an electric furnace and indicated no appreciable error. At present, when new couples are required, they are installed without calibration and are checked by operating the unit on saturated steam at moderate pressure, comparing the observed temperatures with the saturation temperature as determined from the pressures.

All thermocouple leads are carried down to a jackboard where a Leeds & Northrup potentiometer is used to determine the temperatures throughout the system. The cold junctions on the back of the jackboard are shielded against radiation from the boiler and piping.

In the first tests which were conducted on the steam generator, the flue-gas temperatures were measured by a calibrated iron-constantan thermocouple installed between the convection surface and the damper. Since the uptake connection is made of steel plate, this thermocouple is entirely surrounded by relatively cold black-metal surfaces which are not far from the thermocouple in any direction. In order to determine the effects of

radiation to the cold surfaces, a suction gas thermometer was constructed by placing a thermocouple in a piece of $^3/_8$-in. pipe with the hot junction of the couple drawn back into the pipe a short distance. A steam ejector was used to draw the hot gases through the pipe. The suction gas thermocouple was used in most of the subsequent tests, although in some cases both were used. The difference in the reading of the two thermocouples is indicated in Fig. 8. When the hot junction of the suction thermocouple was pushed some distance beyond the end of the pipe and set close to the junction of the bare thermocouple, the two were found to check. It should be understood that in testing commercial boilers it is not customary to have the flue-gas thermocouple so closely and completely surrounded by cold surfaces, and consequently such discrepancies in flue-gas temperatures as are shown in Fig. 8 are seldom encountered. The flue-gas temperatures reported in tests 2 to 10 inclusive (Table 1) were obtained by correcting the bare thermocouple reading in accordance with Fig. 8. In some cases this involved extrapolation of the curve which the authors realize to be only approximate, but it is believed that these results are more nearly correct than the temperatures as determined by the bare thermocouple.

OPERATING PROCEDURE

In bringing the steam generator up to operating conditions from cold, the feed pump is started and its speed is adjusted according to the flowmeter in order to develop the capacity desired for the test. With the throttle valve wide open, the fire is lighted and the oil flow is regulated so as to raise the pressure to 1500 lb. and give saturated steam in about 20 min. The throttle valve is then closed sufficiently to bring the pressure to within about 400 lb. of the desired operating pressure, after which the oil flow is gradually increased in order to produce superheated steam. As the steam becomes superheated, the pressure increases also. An experienced operator can so manipulate the controls as to bring the unit up to operating pressure and temperature by the adjustment of the oil feed once the throttle valve is set. When the desired pressure and temperature are reached, the automatic control is cut in and the unit will take care of itself. Normally, it takes about 40 minutes to bring the cold boiler up to operating conditions and put it on automatic control, although it can be done by one man in 20 minutes.

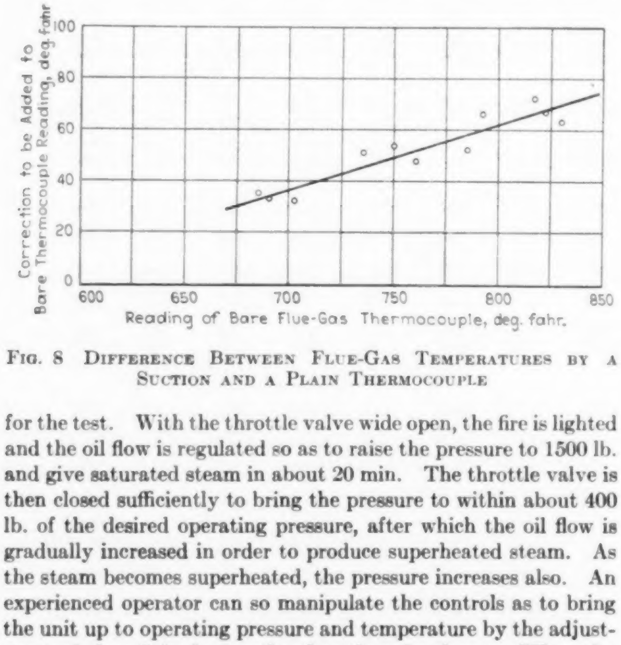

FIG. 8 DIFFERENCE BETWEEN FLUE-GAS TEMPERATURES BY A SUCTION AND A PLAIN THERMOCOUPLE

In shutting down the unit, the oil valve is closed, the dampers are shut, and the boiler-feed pump is kept in operation. Within five minutes the steam gage will register the friction loss through the throttle valve and piping due to the flow of water. The pump is kept in operation for about $1^1/_2$ hours or until the brick furnace is black and the final water temperature is under 250 deg. fahr.

Insufficient draft has proved to be the factor which limits the rating obtainable from the unit. This matter is now being taken care of. The desired flexibility of operation has not been secured as yet because of the limited speed range obtainable from the boiler-feed-pump motor. This is a 230-volt d.-c. motor which is operated with either 115 volts or 230 volts on the field circuit. The maximum speed obtainable with the lower voltage is less than the minimum obtainable with the higher voltage, and the motor becomes unstable in operation when the field voltage is reduced too much. On account of automatic control, it is desirable that the motor speed shall be stable at any given rheostat position and should not be materially affected by changes in pump discharge pressure. A new field winding is being installed on the motor to overcome this difficulty and to give a 3-to-1 speed range. The maximum range of capacity obtainable with a given oil-burner tip is about 2 to 1.

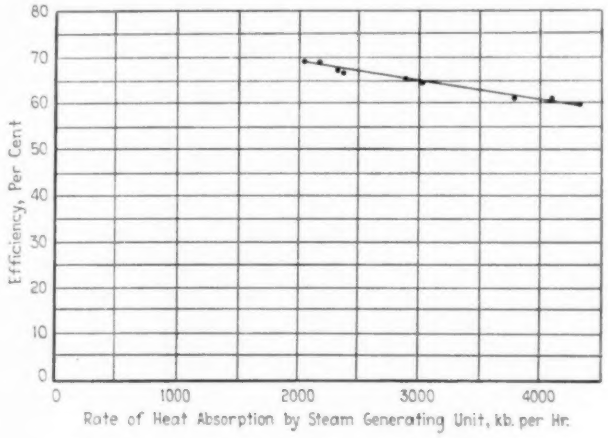

FIG. 9 STEAM-GENERATOR EFFICIENCY, SERIES I

OUTLINE OF INVESTIGATIONS

All tests that are reported in this paper have been conducted with a reasonably constant feedwater temperature and with sufficient excess air to maintain a clean stack. These tests are grouped as follows:

Series I—2550 lb. per sq. in. discharge pressure; 750 deg. fahr. final steam temperature; variable capacity of 2000 to 4280 lb. of steam per hour.

Series II—750 deg. fahr. final steam temperature; 2600 lb. of steam per hour; variable pressure of 1500 to 3520 lb. per sq. in.

Series III—2500 lb. per sq. in. discharge pressure; 2600 lb. of steam per hour; 700 to 820 deg. fahr. final steam temperature.

Series IV—3250 lb. per sq. in. discharge pressure; 2600 lb. of steam per hour; 730 to 800 deg. fahr. final steam temperature.

The steam generator was fired up each morning about two hours before it was planned to begin the testing. Test conditions were established within one hour after starting from cold, and these conditions were maintained constant for at least an hour before the first test readings were taken. Each test was continued for a period of $1^1/_2$ hours, with about $^1/_2$ hour allowed between tests for changing conditions. Since the unit is oil fired and has very little energy storage in the water and steam circuits as compared to the conventional types of boilers, it is believed that the time allowed for tests and for changes in conditions is ample.

Condensate and oil were weighed in tanks on calibrated platform scales. Pressure and temperature readings were recorded at 10-min. intervals, thus giving ten readings to be averaged for

TABLE 2 TEMPERATURES AND ABSOLUTE PRESSURES IN THE STEAM-GENERATOR CIRCUIT

each test. The data, together with the calculated results of these tests, are recorded in Tables 1 and 2.

A single shipment of oil was used in all tests reported in this paper. The analysis of the oil was as follows:

Carbon, per cent	88.83
Hydrogen, per cent	10.75
Nitrogen, per cent	0.14
Sulphur, per cent	0.57
Gravity (A.P.I.)	15.9
Viscosity at 100 deg. fahr. (Saybolt Universal), sec	172
Pour point, deg. fahr	Below 0
Flash point (Cleveland open cup), deg. fahr	260
Fire point (Cleveland open cup), deg. fahr	320
Heating value, B.t.u. per lb	18,650

Discussion of Results

The efficiency of the steam generator, as reported in Table 1 and Fig. 9, is between 60 and 70 per cent within the load range at which it was operated. High efficiencies cannot be expected from a unit of this size having a short single-pass convection section. In a commercial installation this type of steam generator would undoubtedly be equipped with air heaters.

The pressures and temperatures in the circuit of the steam generator, while operating at several different conditions, have been plotted in Figs. 10 to 13. The abscissa represents the length of the circuit in feet in each of the various sections of the steam generator. It should be noted that the furnace-wall section has been plotted on a scale which is five times that of the convection section and that a break exists on the diagram between the two sections. The pressure curves in the convection section have been shown as dotted lines, since only the initial and final pressures have been measured. The shape of this curve can be determined by connecting the pressure gage into the thermocouple taps. The pressure-temperature relationships which exist in the various parts of the steam generator under several different conditions of operation indicate the following:

The temperature curves for the variable-load tests (series I) show the position of the evaporating zone as a straight line in which the temperature decreases slightly due to the effect of friction. The furnace and heating surfaces are so proportioned that the length of tubing utilized to superheat the steam is practically constant within the range of capacities at which the unit was operated. As the output is increased, a larger percentage of the total heat absorption takes place in the convection section, with the result that at the higher capacities the water enters the furnace section at a temperature not far from the saturation temperature. The increased temperature in the evaporating zone at higher ratings is due to the additional pressure drop in the circuit.

The effects of operating at a variety of pressures (series II) and the consequent pressure-temperature relationships in the circuit are illustrated in Fig. 11. The difference between maximum and minimum flow in pounds per hour during this series of tests is about 4 per cent, but the difference in heat absorption is considerably greater. The pressure drop through the system varied from about 700 lb. at 1500 lb. final steam pressure to 260 lb. at 3500 lb. final steam pressure. While the steam generator operates as satisfactorily and is as easily controlled automatically at the lower pressures as at the high pressures, it would be desirable for operation at the lower pressures to divide the surface into a greater number of parallel circuits of shorter length or to use tubes of larger diameter. Four tests were conducted with final steam pressures below 3200 lb. and the same number at final pressures above 3230 lb. At the four lower pressures a distinct evaporating zone is noticeable where the temperature curve is a straight line which drops off slightly due to a decrease in the saturation temperature caused by friction in the tubing. Above 3230 lb. final pressure the temperature curves show a gradual and continuous increase in temperature, indicating the apparent absence of an evaporating zone. Additional thermocouples will have to be placed in the first 50 ft. of furnace-wall tubing in order to locate the temperature curve more definitely in this section. However, the tests up to date seem to indicate that the critical pressure is between 3200 and 3300 lb. per sq. in. The pressure range between 3000 and 3500 lb. per sq. in. will be investigated in the near future much more extensively than has been done.

In Fig. 12 is illustrated the effect of varying the final steam temperature at 2500 lb. pressure with a fairly constant evaporation in pounds per hour (series III). Increasing the superheat means burning more fuel. The friction loss through the furnace-wall section is increased considerably, as are also the pressure and temperature in the evaporating section and the temperature of the water leaving the convection surface. Any degree of superheat is obtainable from zero to that which is limited by the materials of the tubes, and the unit operates equally well under the conditions reported. The principal difference is an increase in the amount of furnace-wall tubing used for superheating the steam as the outlet temperature is changed. Some unbalance apparently exists in the two parallel circuits of the lower furnace-wall section. It is not sufficient to be serious, and from the experience gained in variable-load operation it has been found that it becomes less at the higher ratings where the furnace temperatures are the highest and when the heat-transfer rate through the tubes is the greatest. All tests were run on automatic control, and it is noticed that an increase in steam temperature tends to raise the final pressure slightly. The pressure control could have been adjusted between tests to avoid this tendency, but it was not considered of sufficient importance.

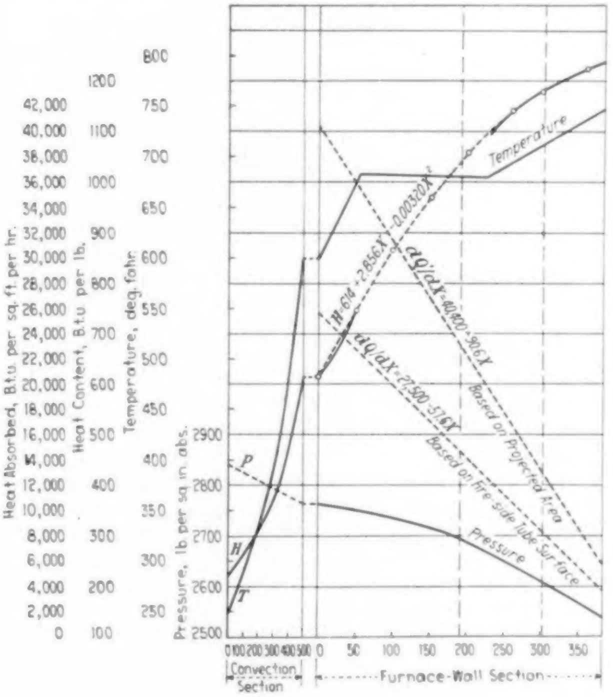

Fig. 14 Heat-Transfer Curves
(Test 4.)

The pressure and temperature changes when operating at about 3250 lb. per sq. in. final pressure, fairly constant flow, and final temperatures between 730 and 800 deg. fahr. (series IV) are illustrated in Fig. 13. The friction loss through the unit is of course increased at higher steam temperatures, due to the greater specific

TABLE 3 HEAT-TRANSFER RATES IN FURNACE-WALL TUBES

(Results Are Given in B.t.u. per Square Foot per Hour, Expressed as a Function of the Length of Furnace-Wall Circuit X in Feet)

Test	No.	Final steam pressure, lb.	Final steam temperature, deg. fahr.	Evaporation, lb. per hour	Enthalpy per pound	Heat-transfer rate based on external surface	Heat-transfer rate based on projected area
Series I	2	2554	751	2003	$H = 593 + 3.074X - 0.00364X^2$	$dQ/dX = 23520 - 55.7X$	$dQ'/dX = 37000 - 87.5X$

	34	3256	768	2638	$H = 719 + 2.159X - 0.00235X^2$	$dQ/dX = 21700 - 47.3X$	$dQ'/dX = 34100 - 74.4X$
	32	3253	788	2462	$H = 734 + 2.253X - 0.00250X^2$	$dQ/dX = 21200 - 47.0X$	$dQ'/dX = 33300 - 73.8X$
	33	3281	796	2486	$H = 746 + 2.246X - 0.00250X^2$	$dQ/dX = 21350 - 47.5X$	$dQ'/dX = 33500 - 74.6X$

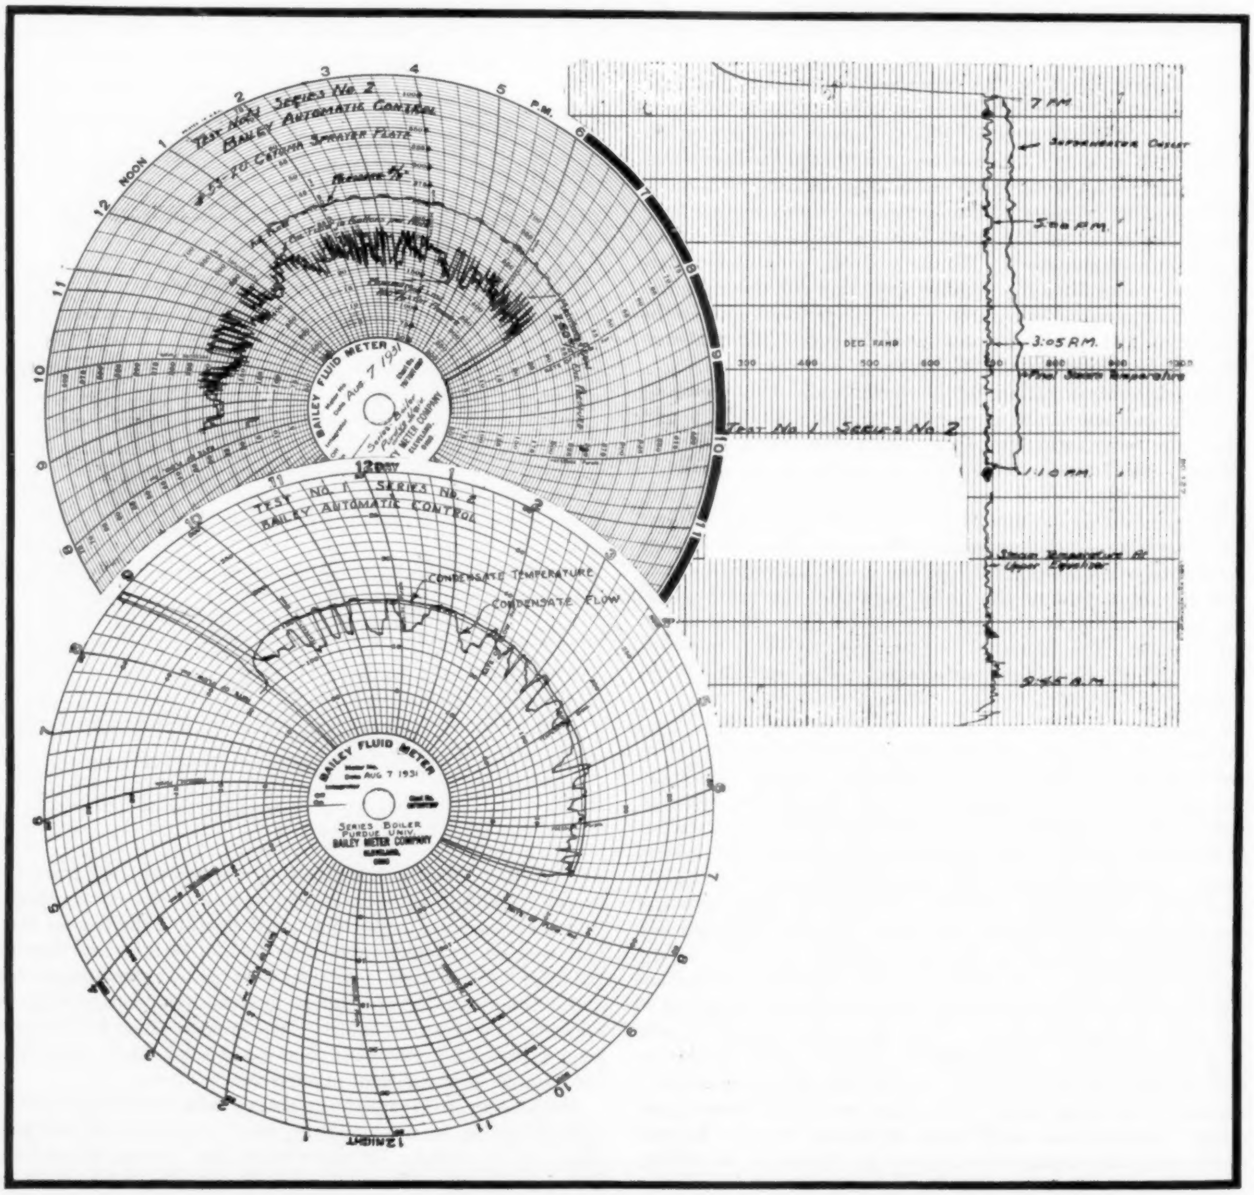

FIG. 15 PERFORMANCE OF BAILEY AUTOMATIC CONTROL WITH A SWINGING LOAD

volume of the steam. Some unbalance exists in the lower furnace-wall section at the highest final steam temperature. In the furnace-wall section there is a rapid rise in temperature, followed by a section in which the temperatures increase quite slowly and then a more rapid rise to the final temperature. If the steam tables are correct at these pressures, an isothermal process, which takes place with decreasing pressures, involves the absorption of considerable energy by the steam. Consequently, although the temperature is seen to increase throughout the length of the furnace-wall section, the absence of such a temperature rise might not indicate the presence of an evaporating zone.

Studies on heat transfer in the furnace-wall section have been handled as follows:

In Fig. 14, the curves of pressure and temperature relations for test 4 have been plotted against tube length. The enthalpy, or heat content, per pound of the liquid and of superheated steam has been calculated from these data, using Keenan's Steam Tables and the data on Compressed Liquid Water as published by Professor Keenan in *Mechanical Engineering* for February, 1931. The solid line labeled H was thus obtained. Two points were selected in the superheat region and one in the liquid region of the furnace-wall section, from which a quadratic equation of enthalpy was obtained, expressed as a function of the length of the circuit X. The first derivative of this equation, when multiplied by the steam flow in pounds per hour and a constant (3.819), gives, as a function of the tube length, the rate of heat transfer in B.t.u. per sq. ft. of (gas side) furnace-wall surface per hour. This equation has been called dQ/dX. The heat-transfer rate based on the projected area of the furnace-wall surface (dQ'/dX) is obtained by multiplying the equation by $\pi/2$. Both heat-transfer curves are plotted in Fig. 14. Heat-transfer equations were obtained in a similar manner for most of the tests reported in this paper, and are given in Table 3.

With 240 deg. fahr. feedwater, the water temperature at the entrance to the furnace-wall section is so high that the curve of enthalpy of the liquid is quite short. For this reason only one point was selected in the liquid region when determining the enthalpy equation as a function of the tube length. Additional data with lower feedwater temperatures may make it possible to develop a cubic equation instead of the present quadratic equation and with possibly more accurate results.

The information on heat-transfer rates secured in the tests reported in this paper does not include all of the variables which enter into this problem. Additional tests will be undertaken in the near future to cover this phase of the investigation.

The experience with the Bailey automatic control indicates that the system functions satisfactorily at any final steam pressure between 1500 and 3500 lb. per sq. in.; also at any final steam temperature ranging from a few degrees of superheat to 830 deg. fahr., which is considered the maximum temperature at which it is desirable to operate the unit.

In Fig. 15 is exhibited a set of meter records obtained with automatic control on a swinging load over a period of six hours. These charts show that it is practical to operate with instantaneous load changes of approximately 20 per cent of the maximum possible rating without abnormal variation in pressure and with small variations in final steam temperature.

It has not been possible to determine the maximum instantaneous load changes which can be handled by the control system because of limitations in the speed variation obtainable from the boiler-feed-pump motor, but this is now being corrected.

This investigation was made possible through the generous cooperation of the Babcock & Wilcox Company, the Bailey Meter Company, the Crane Company, the Commonwealth Edison Company, the Crosby Steam Gage and Valve Company, and the Fisher Regulator Company.

Discussion

D. Robert Yarnall.[4] The high-pressure boiler described in Dean Potter's paper is of great interest to steam engineers everywhere, not only because of its high pressure and temperature range, but also because of its unique design, which enables it to be operated for experimental purposes at a wide range of pressures. In this same connection perhaps it will be of interest to engineers to know that another high-pressure boiler has just been installed and placed in service in our new steam laboratory in Chestnut Hill, near Philadelphia, which has still other characteristics. This boiler has been designed for the purpose of developing apparatus for the power plant and for industrial plants. Its characteristics must be such as to provide a controllable water level at the highest pressures and temperatures likely to be met by such apparatus in the large steam-power stations now built and likely to be built in the next ten years.

The boiler for this research laboratory, built for us by the Superheater Company, is of an unusual design. To the best of our knowledge it is the only boiler built to date for 2500 lb. working steam pressure, depending only on thermal circulation for the protection of evaporating surface.

This boiler consists of a mud drum, evaporating surface, and a steam drum. The evaporating surface is in the form of an ascending multi-loop construction, the terminals of which are connected to the mud drum and steam drum. The evaporating surface is in the form of a multi-loop construction so as to eliminate any strain where the evaporating surface is connected to the mud drum and the steam drum, due to contraction and expansion. The downcomers from the steam drum to the mud drum for feeding this evaporating surface are located out of the gas pass, but inside of the setting, so as to insure against any steam generation at this point, thus eliminating any tendency for the changing of the direction of flow in the evaporating surface.

In the generation of steam at 2500 lb. pressure the steam bubbles are considerably smaller due to this pressure than at the lower pressures; therefore considerable care must be exercised in the design of a boiler of this high pressure in order that the metal temperature be kept within a safe operating range when taking into consideration the metal used. This protection of the metal is obtained by fabricating the surface, as mentioned, in ascending multi-loop construction. The water is compelled to circulate continuously in the same direction, and by doing this those parts of the heating system exposed to the greatest heat always have water present, and not until the gases have cooled down do they come in contact with the tube containing the mixture of steam and water. Thus a positive circulation is established.

The evaporating surface is joined to the mud drum by means of a rolled joint with handhole openings opposite, whereas the surface is joined to the steam drum by means of a special clamp construction, making a metal-to-metal joint and also eliminating the necessity of handhole openings for making this joint. This type of joint was used on the steam drum to cut down the number of joints necessary to avoid the difficulties which may develop due to the changes in temperature which may be expected on the steam drum, as it has been found by practice that joints under these conditions should be kept down to the minimum, especially so when working under such high pressures.

The design of the high-pressure metal parts in this boiler was so arranged as to make all joints on the outside of the gas pass accessible for inspection, as well as for maintenance, and at the same time making the complete boiler as simple as possible in construction.

---

[4] Vice-President, Yarnall-Waring Co., Philadelphia, Pa. Mem. A.S.M.E.

The steam drum, having outside length of 5 ft. 10 in., outside diameter 18 in., inside diameter 12 in., or 3 in. wall thickness, is made from a solid forging such as is used on most high-pressure boilers. The mud drum is also bored from a solid forging.

The safety valve, made for 2500 lb. relieving pressure, is of the conventional type used on present high-pressure boilers, but in this case for a series of tests at lower pressures, extra springs were provided for relieving pressures of 750, 1500, and 2000 lb.

The boiler is provided with a series of different types of forged-steel water columns and high-pressure flat and round glass water gages. The blowoff valves installed for test purposes are of the forged-steel seatless type, designed for these high pressures.

This boiler has been designed with 130 sq. ft. of heating surface for maximum working steam pressure of 2500 lb.; a furnace volume of 82 cu. ft. has been provided. The boiler is fired by city gas fuel, the rate of combustion being automatically controlled by the steam pressure for the particular test being made at the time, the steam pressure itself being controlled for each test by an adjustable regulator.

In view of the small bore of the tubes which form the heating surface of the boiler, elimination of scale is very important in the operation of this boiler. For this purpose an evaporator has been provided, the condensate from which is stored in a vertical tank, from which the triplex motor-operated feed pump provides the necessary boiler feed.

Later on we shall be glad to present the results of the year's research resulting from the operation of this high-pressure steam testing laboratory. We will be glad to have others who may desire to conduct tests on high-pressure steam make use of this steam laboratory for their own tests, provided of course such tests do not conflict with our own researches.

Discussion following was given jointly with the paper by H. J. Kerr)

A. G. Christie.[5] Mr. Kerr's boiler has seven parallel circuits for the water and steam between feed inlet to the boiler proper and the outlet manifold. He had considerable trouble with instability of flow under certain conditions with these multiple circuits. The Purdue boiler, on the other hand, had only two parallel circuits, and these were provided with equalizer connections at intervals. Profs. Potter and Solberg do not mention any instability difficulties with any feed temperature. Evidently if multiple circuits are desired—and these will be necessary if large outputs are to be obtained—numerous equalizer connections should be provided to remove the danger of instability and to keep temperatures within moderate limits in all circuits.

Mr. Kerr might give a more complete discussion of the derivation and use of the data presented in Figs. 7 and 8. Heat contents of 3000 B.t.u. per lb. of steam, as here indicated, would require temperatures of 4000 deg. fahr. or thereabouts. The analysis of and deductions from these curves are not clearly stated in the paper.

It is claimed for this type of boiler that no scale is formed in the tubes. If absolutely pure water were used at all times, this boiler would serve admirably. But condenser leakage, and the desirability of maintaining proper sulphate-alkalinity ratios in the feed, will lead to the introduction of some solids into the boiler. If these pass on with the steam, there will be deposits of such materials in turbines at those stages near the dew point. Such deposits close the blade passages and lower the capacity of the turbine. It is a difficult matter to remove such deposits, especially if silica is present. This trouble may be greater with the through type of boiler than with present designs.

Boiler-feed pumps of the plunger type have proved most economical for pressures over 3000 lb. With such pumps the power at light loads becomes of such magnitude as to consume a large portion of the gain from going to such higher pressures. The question of auxiliary power will be an important consideration with high pressures.

This boiler has demonstrated the workability and reliability of high-pressure equipment and has opened the way for commercial developments. With materials under development for high temperatures as well, it seems reasonable to expect plants to be built for, say, 2500 lb. pressure and 1000 deg. fahr. steam temperature, requiring only one stage of steam reheating.

N. Artsay.[6] The two papers supplement one another, and it is best to consider them together. Enough has been said on the general aspects of the problem of coil boilers, and it is desired to comment on some important details.

The instability of flow in parallel circuits has been mentioned in both papers. The word instability implies that in some of the parallel circuits the resistance in presence of evaporation tends to decrease in spite of an increase in the rate of flow. The writer has made a theoretical investigation of stability of flow in such conditions and has found that the real instability is utterly impossible unless water passes through some metastable phase. What actually happens is that the changes in resistance at changing rates of flow are substantially reduced by the opposite changes in specific volume of the mixture, and so a considerable variation in flow is necessary to balance a slight change in hydraulic resistance, hence large steam temperature differences at the outlets from uniformly heated parallel circuits. In a given circuit the resistance of water is proportional to the square of mass flow, and in presence of evaporation the resistance increases also in proportion to the increasing specific volume, the latter in turn varying in opposite direction as the mass flow. Thus in evaporating coils the resistance will vary as a power of mass flow lesser than two but always positive. Therefore the true instability is impossible, but quite a range of conditions exists for the *uneven distribution* of flow among the parallel circuits.

Diagrams for 2500 and 3200 lb. per sq. in. pressures (Figs. 7 and 8), given in Mr. Kerr's paper to show the inherent instability of flow in some conditions, are very difficult to understand if the coordinates and the caption are correct. The relation between the curves is not clear, because it is not stated what factor has been kept constant in drawing the curves. Enthalpies of 3000 B.t.u. per lb. shown on the diagrams mean steam temperatures of the order of 5000 deg. fahr., and the pressure drops are so low that one is tempted to refer them to a small stretch of coil.

The work done at Purdue University, presented by Messrs. Potter, Solberg, and Hawkins, is excellent material for studies of coil-boiler possibilities. It seems that the character of the work undertaken by the authors invites suggestions on lines of further experimentation. So as to avoid misunderstandings in this serious feature of coil boilers, the diagram should be thoroughly explained.

The traced position of the point at which all water is converted to steam is rather important, as bearing not only on the correctness of thermocouple readings in their actual setting, but also as a possible means to detect the presence of metastable states of water. Therefore it would be of interest to weld two nipples before and after the average position of said point for connecting Professor Donovan's electrical calorimeter recently developed and checking the calorimetric determinations of steam quality at the pressure against temperature readings. This ingenious calorimeter could be of great value also in other ranges of evaporation. Great variations of heat content at slight temperature changes are indicated around the critical point, and the calorimeter would serve to check them.

[5] Professor of Mechanical Engineering, Johns Hopkins University, Baltimore, Md. Mem. A.S.M.E.

[6] Principal Assistant Engineer of Geo. A. Orrok, Consulting Engineer, New York, N. Y. Mem. A.S.M.E.

Another line of experimentation is suggested. At some point, let us say about 80 per cent vaporization, the boiler should be tapped and a small fraction of the mixture of steam and water led into a steel test tube heated strongly by a gas or oil burner. Concentrated solutions of various salts could be injected into the test tube and the deposition of scale in various conditions studied. The effect of velocity, pressure temperature, and concentration on scale formation could be studied at a low expense and in the range of conditions so far almost unexplored. Operation of Benson boilers seems to indicate that troubles due to scale deposits are reduced to a great extent if the vapor phase is eliminated. On the other hand, operation of high-fluid-velocity coil boilers also indicates the reduction of scale deposition. Thus a very interesting field may be opened up by such an investigation.

R. M. Gates[7] and W. H. Armacost.[8] The experiences outlined in the two papers should be of considerable value to those interested in this field of development. Analyzing the data reported in these papers, there are several points which do not seem clear.

Referring to Fig. 9 in Mr. Kerr's paper, it appears that this type of boiler unit is very sensitive, due to the wide variation of steam conditions from the several different circuits. It would be interesting to know whether this was due to unit design features, furnace conditions, or the type of feed pump used. It has been demonstrated in the operation of cracking units, as well as oil-heater units, which had several parallel flows, that wide variations in temperature resulted. This was of a serious consequence, due to the coking of oil in some of the circuits from overheating. Therefore, in some instances, separate pumps were used for individual circuits to enable uniform outlet conditions to be maintained. However, due to the improvements in design of heat exchangers, it was possible to reduce the number of streams and revert to the use of a single pump, at the same time obtaining sufficiently uniform temperatures at the outlets of the circuits.

There is another factor to which all power engineers are giving a great amount of consideration, this being the effect of the tremendous work which the metal must do and the temperatures which it must stand in high-pressure, high-temperature power-plant apparatus. To make this problem still more difficult there are the different sources of heat to deal with—of radiation, convection, or a combination of the two.

The preliminary results which have been obtained and are given in the report on the boiler at Purdue lead to much speculation regarding certain characteristics of water and steam at the place of transformation from one to the other when located in the radiant-heat section of the boiler.

Referring to the paper by Messrs. Potter, Solberg, and Hawkins, upon the high-pressure series boiler installed at Purdue University, it will be noted that Fig. 4 shows the relative positions of the sections of convection and radiant-heat absorbing surfaces, as well as location of thermocouples and pressure connections. Also, test No. 4 (quantity readings), tabulated on the sixth page, together with the thermocouple readings on the ninth page, shows that a uniform temperature in the radiant section is obtained from thermocouple position 10 to thermocouple position 25, which apparently denotes the transformation sections where liquid is being changed into vapor. This section contains approximately 45.5 sq. ft. of furnace exposed surface. Assuming that the temperatures in this section correctly denote those of water and saturated steam at the corresponding pressures and that latent heat only is added at this point, the heat-transfer rate is approximately 15,300 B.t.u. per sq. ft. of furnace exposed surface.

Referring to test No. 8, it will be noted that practically the same square feet of surface is in the transformation section, the temperature varying from 707 to 701 deg., whereas the absorption per square foot of furnace exposed surface would be 7140 B.t.u. if based upon the steam tables. It appears this absorption should be considerably higher than in test No. 4, as approximately twice as much fuel is fired, also the gas temperature leaving the boiler is 50 per cent higher.

Therefore in checking through the recorded thermocouple readings in Table 2, it appears that these readings in the transformation section are not giving the true temperatures, since practically a uniform temperature is recorded over a considerable length of tubing. In analyzing this further, it appears that this might be due to the fact that the furnace structure has a circular cross-section, and with the water flowing at the rate of 7 to 15 ft. per sec. through the tubes, the water holds to the opposite wall of the tubes from the furnace, due to the centrifugal force set up, whereas the steam being liberated in the form of small bubbles would probably have a tendency to slide along the inner surface of the tubing next to the furnace, thus causing the steam and water to travel along a greater length of tube before a thorough mixture results and complete transformation has taken place. Due to this reasoning the furnace side of the tubing in the transformation section would be overheated and the growth in the tube diameter would be greater in this section over a period of time than in any other part of the equipment. It would be interesting to know whether the authors of these papers have experienced any unusual growth or failure of the tubing in this particular section of the equipment.

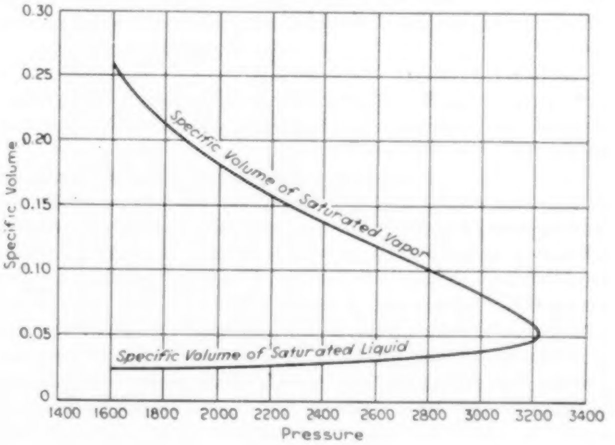

Fig. 16

Referring to Fig. 13, which shows that the temperature curves as plotted are practically a horizontal curve from 75 to 175 ft. on the furnace-wall section, it appears that this might be due to the foregoing reasoning, as the thermocouple readings are probably taken on the outside wall, where the water in the transformation section is always in contact with these thermocouples due to the centrifugal force resulting from the velocity of water. It would be interesting to know how all of these thermocouples were located in the tubing relative to the furnace.

[7] Vice-President, The Superheater Company, New York, N. Y. Mem. A.S.M.E.

[8] Engineer, Industrial Department, The Superheater Company, New York, N. Y. Assoc-Mem. A.S.M.E.

To substantiate this reasoning, it is only necessary to draw the curves showing the specific volume of saturated vapor and the specific volume of saturated liquid, using pressure and cubic feet per pound as abscissas and ordinates, respectively. By doing this the relatively small change in volume is readily visualized when saturated liquid changes to saturated vapor at these pressures. (See Fig. 16.)

Mr. Yarnall, in his discussion, has told that the particularly novel feature of his testing plant is the gravity circulation, or the fact that circulation was natural and not forced or positive in the boiler.

There are other features of design which are unique, but it must be borne in mind that the installation at the Yarnall-Waring plant was made for a specific condition, while the equipment for the Purdue plant was designed for capacity as well as for temperatures and pressures. It will be interesting to hear Mr. Yarnall's further remarks regarding the operation, not only of the boiler equipment, but also of the apparatus which will be tested.

It is encouraging to note the interest that manufacturers are taking in testing laboratories of their own. It is further interesting to note that there are facilities open at universities as well as at certain corporations where other manufacturers can have instruments and apparatus tested under conditions approaching those which will be attained in the field of operation.

The writers feel, however, that laboratory results will not give the entire answer and that we must still utilize the operating plants to give final results, but the laboratory work should eliminate much of the expense and time required to do all such work in the field.

The tests as reported are comprehensive and the equipment installed lends itself to very interesting tests as to absorption at high pressures by radiation as well as by convection. The authors are to be complimented on the great amount of test work accomplished and recorded in such a short interval of time.

Karl A. Mayr.[9] The systematic work done with the so-called once-through series boiler will be greatly appreciated by every one interested in steam generation.

Fig. 1 of Mr. Kerr's paper, showing over-all plant efficiencies at various steam pressures, is misleading. The efficiencies shown on this paper are obviously theoretical efficiencies based on the amount of heat available at straight adiabatic expansion down to a certain percentage of moisture, if steam of various pressures but of equal temperature is used.

When employing higher steam pressures, higher steam temperatures can be used effectively. If one would use, for instance, a steam temperature of 1000 deg. fahr. in connection with a steam pressure of only 300 or 400 lb. per sq. in., superheated steam would be blown into the condenser. A part of the valuable superheat could not be converted into power by any means and would be carried away by the condenser cooling water. If the temperature of 1000 deg. fahr. is used in connection with 1000 lb. per sq. in. steam pressure, a highly efficient cycle is obtained.

With higher steam pressures, more turbine bleeding and feedwater heating stages can be employed. Valuable heat can be transmitted to the boiler feedwater instead of carrying it to waste in the condenser cooling water.

The higher the steam pressure the more often or more extensively the steam can be resuperheated between prime-mover stages.

A paper by the writer was published in the April 1, 1930, issue of *Power*. The influence of steam pressure, steam temperature, the number of bleeder stages and the number and extent of reheater stages on the over-all plant efficiency was investigated in this paper. A turbine was taken as prime mover with very conservative efficiency figures for the individual stages. The influence of various efficiencies of the high-pressure turbine stages was also considered and of steam-heated reheaters versus reheaters in the gas path.

The investigation revealed that a plant with a steam flow of 100,000 lb. per hour at 2500 lb. per sq. in. pressure and 840 deg. fahr. temperature at the turbine admission valve, having a reheater in the gas path delivering steam at 240 lb. and 750 deg. fahr. to the lower pressure stage of the prime mover and having four feedwater heating stages, has an over-all efficiency of almost 34 per cent. This figure is based on an average stage efficiency of the high-pressure turbine stages between 570 and 2500 lb. per sq. in. pressure of only 70 per cent. Pressures in the neighborhood of 2500 lb. steam pressure and at least 800 deg. fahr. temperature, if used in connection with one reheater, give a decided advantage over cycles with lower initial pressures, also if such cycles use much higher initial temperatures. The use of pressures above 2500 lb. shows further improvements only if much higher initial temperatures are used or in the case of non-condensing plants.

Figs. 7 and 8 of Mr. Kerr's paper show that the disturbances caused by the evaporation process in tubes with a high rate of heat transmission disappear if the evaporating process is carried out over a larger part of the heat-absorbing tubes and when the flow resistance or the velocity is increased. They also disappear when the conversion of water to steam is carried out at the critical point. At this point no boiling takes place. If steam is generated at the critical point, it is 100 per cent dry. This is not assured if steam is generated in tubular once-through boilers at lower pressures and without special arrangements to separate the steam from the water.

These facts were realized by the Siemens-Schuckertwerke A.-G. in Germany in 1923, when they started to develop the forced-circulation boiler on a large scale. No unbalanced conditions need to be in the circuits of a boiler under forced circulation. The flow through the individual sections can be arranged in a way that most favorable heat absorption, velocity, and pressure-drop conditions are obtained. Conditions in every part of the generator are absolutely controlled. This is much in contradistinction to the thermo-syphon circulation boilers, where much is left to nature, and the distribution and velocity, particularly in the water walls of the combustion chambers, are almost the opposite of what they should be to assure equal and efficient heat-absorption work of all tubes and safe and controlled temperatures of the individual tubes.

The heat-transfer figures revealed in the paper by Messrs. Potter, Solberg, and Hawkins in combination with the respective gas and water or steam temperature give evidence that the heat transmission per square foot of heating surface and degree temperature difference to tubes containing water or a liquid is much higher than the heat transmission to tubes containing steam or water in a boiling state. The heat transfer from tube wall to the medium inside the tube depends roughly on the 1.2 power of the velocity of the medium. In a forced-circulation boiler, water and steam velocity can be considerably increased over that in natural-circulation boilers. If such a boiler is designed and operated so that the medium to be vaporized is as long as possible in a liquid state and under high velocity, the tubes are cooled very effectively. The maximum proportion of tubes containing water is in a boiler which generates steam at the critical point. Such a generator contains only water-heating and steam-superheating elements.

The design of the first forced-circulation critical-pressure steam generator of a capacity of 10,000 lb. of steam per hour was started in 1923. This boiler was in operation early in 1924.

---

[9] Chief Engineer, Siemens-Schuckertwerke A.-G., New York, N. Y. Assoc-Mem. A.S.M.E.

A pulverized-coal-fired boiler for 60,000 lb. of steam per hour was built in 1926. Another for twice this capacity followed two years later. A boiler which can be fired with gas, pulverized coal, or oil and of a capacity of up to 300,000 lb. of steam per hour has been in operation more than one year in Belgium. Rotary feed pumps are used in combination with the larger boilers.

An automatic control was developed in connection with these boilers which maintains the steam temperature within 3 per cent and the steam pressure within 2 per cent at load variations from 60 to 100 per cent. This temperature at the outlet of the generator is maintained high enough to secure sufficient superheat in the steam, so that no matter to what low pressure the steam might be reduced in the following superheating sections, there will be always 100 per cent dry steam in the superheater. A temperature of 760 deg. fahr. would be sufficient for this purpose according to the Mollier diagram. The boilers, however, are operated so that the steam temperature at this point is 800 to 850 deg. fahr.

In the ordinary boiler, the fuel supply, etc., must be adjusted to maintain a certain pressure in the boiler drum, and since the fireman can serve only one master, the steam temperature at the superheater outlet naturally cannot be steady at variable-load conditions. In boilers of the described type, fuel, air, and water supply are all adjusted for one purpose only—to obtain the desired steam pressure and temperature in the steam main at any output condition. A steady steam temperature, however, is most important in a high-pressure and high-temperature steam plant. Leaky joints and excessive stresses in the piping material occur only if the temperature changes.

The writer believes that the forced-circulation boilers will soon replace the boiler with natural circulation, at least where pressures above 500 lb. per sq. in. are used. The time is near when no one will leave nature such a free hand as she now has in the water walls and convection sections of a natural-circulation boiler, certainly not in equipments involving investments of hundreds of thousands of dollars.

Geo. A. Orrok.[10] It is very gratifying to see the presentation of the extremely interesting experimental results obtained in testing a series or coil boiler. This work has been delayed a full hundred years. When Jacob Perkins designed and built his high-pressure series boiler in 1828, only the lack of suitable instruments of measurement prevented him from proving to the world the great step he had made in the steam-generation problem. His engineering genius saw far ahead of his time. The work of Herreshoff in 1877, afterward in 1879, and Serpollet in 1880 showed that such designs were successful and could give good efficiency and real service. Much later, in 1897, DeLaval startled the forgetful engineering world by his high-pressure (2800 lb. per sq. in.) coil boiler and turbine at the Stockholm Exposition. A score or more of forgotten inventors have designed and built such devices, often very ingenious. The Siemens-Schuckert Company in Europe had had considerable success with the Benson boiler, while recently Doble in America has attained practical results in the automotive field.

In Mr. Kerr's paper the evolution of the steaming economizer into a coil boiler is well shown, and it would be very interesting to know the comparative operating difficulties for types shown by Fig. 2 and Fig. 4.

The next step was to build a plain coil boiler, and the engineering staff of the company should be congratulated on this enterprise. It seems that at last belated steps are being taken to investigate the problem of evaporation in a tube, the theoretical knowledge of which has lagged many years behind the study of other lines of development.

A year ago, in Chicago, the writer presented a paper entitled "The Boiler Room of the Future," in which he ventured the idea that the boilers of the future would be of the drumless coil type, cellular in their construction, absorbing the greater part of the heat as radiant heat, and fired with gas. Therefore, he doubly appreciates the present papers.

Let us hope that the able staff of Purdue University which has just given this exhaustive account of their first series of experiments on this boiler will carry the work much farther and investigate the processes of scale formation, corrosion, stability of tube materials, and effect of variable loads, so that the construction of the ultimate type of a high-pressure coil boiler will be soon a practical possibility.

The paper by Messrs. Potter, Solberg, and Hawkins contains a wealth of material for anybody desiring to study coil boilers. Sufficient observations of pressure drop in various sections of the boiler are given, to be a subject of a separate paper. So little is known about resistance of steam-water mixtures in tubes that the working out of this material is highly desirable.

The writer is not so sure about the seriousness of the question of instability in parallel circuits. He had the privilege of supervising several tests of the Benson boiler at the Siemens-Shuckert plant in Gartenfeld, Berlin, and the distribution of water among the twelve parallel circuits in that boiler was fairly good and never gave any trouble. We have a similar problem in low-pressure-drop superheaters, in reheaters, and in water walls, but these things have a way of straightening themselves out with the help of certain poorly understood principles which might be termed secondary effects.

There are of course many problems which must yet be solved before we have a really commercial coil boiler. The tube size should be large enough to allow turbining. The boiler must be adaptable for short banking periods and be able to stand rough handling with various fuels and various operating conditions. Automatic controls are necessary, as Mr. Kerr has pointed out. The operating man must forget the old shibboleths of "releasing surface," "water level," "steam storage space," and "water content," and go back to the principle laid down by Perkins of feeding the boiler when and as steam is required. The writer pointed out in an earlier paper that in high-pressure boilers the water content of the drum would not exceed 10 per cent of the total water contents. The coil boiler has cut out even this small proportion. It is believed that it will be found that high pressures, high temperatures, and large outputs can be secured with boilers of this type with the maximum of safety and at reasonable expense.

Arthur J. Herschmann.[11] Much in these two papers has been covered by able discussion. The over-all efficiency curve, Fig. 1 in Mr. Kerr's paper, shows, as can be verified by the Mollier chart, that there is little advantage in raising the steam pressure over 1900 lb. Operating engineers will be quick to appreciate the fact that while there is little to be gained in economy beyond 1900-lb. pressure there may be additional worry and anxiety. Mr. Kerr also states in regard to the once-through type of boiler that "whatever goes in must go out" and this must be especially well remembered where the tubes are so small in diameter and the pressure drop so great. The Loeffler boiler meets these conditions exceedingly well and gives besides, with great constancy, the highest superheat which tubes of reasonable cost permit. Loeffler boiler tubes are of carbon-steel with about 0.60 molybdenum. Mr. Moultrop, in his discussion of Mr. Kerr's paper, reminded us that highest superheat should receive as much attention as a reasonably high operating pressure. Loeffler boilers have now operated for some time without extraordinary difficulty being experienced, in units of 160,000 lb. of steam per hour, and we now build two boilers each for 330,000 lb. per hour. They always operate at 1900-lb. steam pressure with 932 deg. fahr. total temperature. Serious high-temperature trouble in Loeffler superheaters has never been experienced, and that without the use of expensive alloy steel, because we have always very ample cooling of these tubes by forced circulation. Even if the load should drop entirely, the temperature would rise but very little, because the steam which is circulated has little relation to the steam of the line. Only the pressure would rise for a short period.

[11] United States Agent, Vitkovice Steel Works, New York, N. Y. Mem. A.S.M.E.

James M. Taggart.[12] These two papers suggest the desirability of a simple, expressive, and uniform name for this class of steam generators. In addition to the titles given by the authors, boilers of the type described have been called flash, non-water line, and drumless boilers. One simple and expressive name appears to be "uniflow." This term, it is true, has been used to a limited extent and somewhat incorrectly for a form of fire-tube boiler with a special grouping of tubes. Accordingly where the designation must be specific the name could be extended to "uniflow water-tube boiler."

Small uniflow boilers similar to those described in the papers have been roughly tested and used with a fair degree of success for automobiles and some special installations. The pressures used have been from 300 to 500 lb. The principal objectives have been small size and freedom from danger of explosion. Larger sizes tried out have been either complete commercial failures or limited to special service. The reasons for failure have been the attempts to use them with contaminated feedwaters, faulty combustion, and flow controls, and in most cases with no provision for inspection, cleaning, or replacement of tubes.

The boilers described have avoided the use of contaminated feedwater and have proved the feasibility of combustion control. They do not, however, promise any improvement in respect to cleaning or easy replacement of tubes. It is true that if absolutely suitable feedwater is always used there would be no necessity of cleaning nor any damage. However, experience and the nature of the service prove that at times it will be necessary to operate on raw or contaminated water, even with the risk of burnt tubes. Where cleaning is possible, such operation over limited periods is feasible. With short tube lengths, easily removed, burnt spots would constitute only a minor maintenance charge.

Pressure drops through uniflow boilers require careful consideration. In the boilers described, as well as in most of the types of uniflow boilers formerly tried out, a constant area of flow is used. Apparently a better design relative to heat absorption and pressure drop over a wide load range would provide an increasing flow area over the steaming section.

The differential flowage encountered by Mr. Kerr in his tests is common to the type of equipment described. Where the length of parallel circuits is broken up by mixing headers, as would be required in an arrangement suitable for cleaning and easy replacement and also for providing an increasing flow area, the differential flow would cease to be accumulative. With proper design it could then be made a negligible factor.

The tests recorded are very interesting and provide new data relative to high-pressure steam generation. It is satisfactory to see that they check fairly well with the new steam tables. The results present some discrepancies, as is natural in a test of this character. The furnace temperature is shown as approximately constant for widely varying fire conditions. This would seem to be in error. Some heat-flow variances otherwise unaccountable may be due to this feature. In general, heat flow to water walls is above that shown by empirical and semi-theoretical calculations generally used for boiler furnaces. This probably indicates the importance of taking into careful consideration the shape and size of the furnace and the nature and location of the flame.

It is noteworthy that the heat flow in the steaming section was so much higher than for the superheating section. Making due allowance for the temperature difference, it is apparent that even with high densities dry steam has a much reduced heat-absorbing capacity.

The efficiency curve for varying steam pressures submitted by Mr. Kerr, like all similar general curves, is more deceptive than informative. Thus any increase in power-generating efficiency resulting from an increase in steam pressure depends quite largely on the increased range of regenerative effect resulting. Reheating and machine efficiency must also be considered.

After all, the real value of a commercial uniflow boiler consists in its safety from explosion, small size, and its low cost compared to any standard form of high-pressure boiler. When developed, it will open up a new field for high steam pressure in motive power and for certain industries where standard high-steam-pressure boilers are not now economical. It is probable that for central stations some drum effect will always be advisable.

Authors' Closure

The authors are particularly interested in the description by Mr. Yarnall of the 2500-lb.-pressure drum-type boiler which has been installed in the laboratory of the Yarnall-Waring Company by the Superheater Company of America. In the design of this boiler careful consideration has been given to the problem of natural circulation, which becomes serious at the higher pressures because of the increased density of the steam. It is hoped that Mr. Yarnall will investigate the circulation in this boiler under a number of pressures and steaming capacities.

Professor Christie states that it is reasonable to expect plants to be built in the future for 2500 lb. pressure and 1000 deg. fahr. steam temperature with one stage of steam reheating. The authors are in agreement with this prediction, and this fact has in part influenced their decision to carry on most of their testing at 2500 lb. pressure.

Mr. Artsay has apparently misunderstood the authors when he stated that the word "instability" had been used in their paper. No evidence of instability has been encountered during the operation of the Purdue University boiler. Some inequality of flow, or unbalance, exists in the two parallel circuits of the lower furnace-wall section due to unequal resistances in the circuits, but the outlet temperatures are stable at all times.

Messrs. Mayr and Taggart call attention to the greater heat-transfer rate in the furnace-wall tubes containing water than in the superheater tubes and attribute this to the better film coefficient of steel to water. In the opinion of the authors, the controlling factor of the heat-transfer rate is the arrangement of the surface with respect to the flame. The tubes in the lower furnace-wall section are in a better position to absorb the maximum amount of radiant energy.

Mr. Taggart states that "the furnace temperature is shown as approximately constant for widely varying firing conditions." He is probably referring to item 28 in Table 1, which the authors purposely called "furnace pyrometer reading," since they doubt the existence of a "furnace temperature" in a cavity in which combustion and heat transfer are proceeding simultaneously.

---

[12] Consulting Engineer, New York, N. Y. Assoc-Mem. A.S.M.E.

The pyrometer readings were obtained by sighting an optical pyrometer, through the inspection hole in the furnace door, on the flame at a point about 16 in. above the burner. Since the paper was prepared, experience on tests with variable excess air has indicated that this point is too near the burner, and as it is not convenient to change the opening in the furnace wall, these readings have been discontinued.

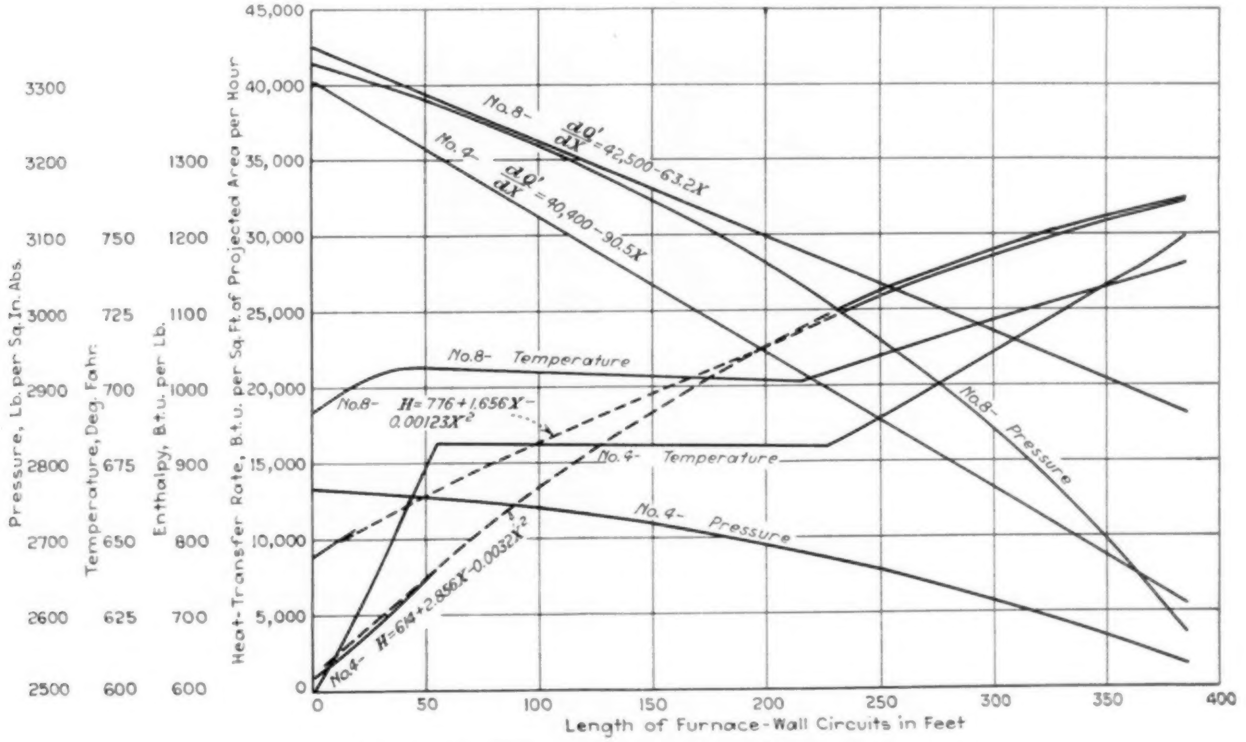

Fig. 17 Heat-Transfer Rates for Tests Nos. 4 and 8

Messrs. Gates and Armacost question the accuracy of thermocouple readings and state that, on this account, the heat-transfer rate in the evaporating zone in test No. 8 is only half of that in test No. 4, although the unit is operating at about double the rating. The authors have plotted the temperatures and pressures for these tests in Fig. 17 with the length of furnace-wall circuits in feet as the abscissa. The heat-transfer rates have been determined as outlined in the paper and plotted on the same abscissa. Apparently, Messrs. Gates and Armacost have made an error in their calculations. This is probably due to the fact that they had neglected to consider the effect of the pressures and of large pressure drops on the thermodynamic properties of compressed water and steam. In Test No. 8 the pressures pass through the critical point, and the specific heat of water is consequently very high. Furthermore, a plot of Keenan's data on compressed liquid water at temperatures between 680 deg. fahr. and the critical temperature will show not only big changes in enthalpy with either temperature or pressure variations, but an insufficient number of points to locate the curves accurately in this region. Consequently, large errors can be introduced by basing conclusions on one or two thermocouple readings in the region of the critical pressure.

If there is a marked tendency for centrifugal force to separate the water and steam and to prolong the apparent evaporating section, as suggested by Messrs. Gates and Armacost, such a condition should be noticed by a sudden rise in steam temperature immediately beyond the point where evaporation is complete. The method of calculating the heat-transfer rates should eliminate errors due to this factor, and should show at the same time the existence of such a condition. This possibility could not affect the curves of Fig. 13, as suggested by Messrs. Gates and Armacost, since the pressures are above the critical pressure at the points in question, and there is no evaporating zone. In this region the absorption of a large amount of energy can occur at nearly constant temperatures with decreasing pressures; this accounts for the shape of the curves in Fig. 13.

Messrs. Gates and Armacost raise the question of overheating of the furnace side of the tubes due to the possible separation of water and steam under the influence of centrifugal force. The furnace-wall tubes are clean internally and show no external evidence of overheating at any point. Thermocouples have been peened to the fire side of the tubes at a number of points and indicate a fire-side metal-surface temperature of from 40 to 80 deg. fahr. above the fluid in the tube.

In addition to the foregoing, the following may clear up questions which have been asked outside of the meeting:

Condition of Brickwork. An examination of Table 1 indicates that item 56 (radiation unaccounted for) is greatest during the first tests made in any one day. This is due to too little time having been allowed for the brickwork to be heated up to the proper temperature. While these tests are not intended primarily to check the efficiency of the unit, care is now being taken to reduce such errors to a minimum.

Air Supply. Table 3 shows considerable variation in the furnace heat-transfer rates. To check the effect of excess air supply upon heat-transfer rates in the furnace wall, a number of tests have been carried on to study the effect of varying the air supply. Briefly, the results indicate that variation in the maximum heat-transfer rates may be accounted for by changes in the air supplied. Complete details concerning these tests will be presented in the near future.

RP-54-2

Economic Life of Equipment

Derivation of Formulas for the Selection and Replacement of Manufacturing Equipment Which Depend Upon the Theory of Economic Utilization of Capital Resources

By H. O. VORLANDER[1] and F. E. RAYMOND,[2] CAMBRIDGE, MASS.

H. O. Vorlander

F. E. Raymond

The correct solution of the problems of how to select and when to replace equipment is vital to industry. In fact, it revolves about the larger problem of how to invest economically and profitably the capital resources of any enterprise. Many rule-of-thumb as well as a number of somewhat more exact methods are now being employed as a basis for determining equipment policies; however, no one of them is suitably adapted to the present needs of industrial executives, process engineers, plant managers, and sales executives. Accordingly the A.S.M.E. sponsored a research project to investigate thoroughly this subject and formulate the principles upon which any equipment policy should be based, and out of which practical technique can be evolved for the ordinary purposes of industry. As a result, this paper, which constitutes the formal report on the project, presents criteria for the economic or useful life of equipment, for the determination of depreciation policies, for the ultimate ability of equipment to produce earnings or profits, for protection from the hazard of impending obsolescence, and for the guidance of equipment manufacturers in the evolution of new designs and in anticipating the needs of industry. All of these criteria depend upon the relative economic superiority of some proposed type of equipment over some equivalent existing type or one chosen as a standard of comparison, and the evaluation of each can be achieved through formulas which are equally applicable to machine tools, jigs and fixtures, labor-saving or material-handling devices, process and power equipment, and even buildings or structures. Moreover, in the course of the investigations, many other important facts were discovered which relate to financial policies, accounting practice, the origin and proper methods of treating overhead, plant layout, maintenance, productivity and idle time, salvage and resale policies, machine design, and, in general, the earning power of the enterprise; all of which are discussed in detail.

SINCE the advent of the present era of widespread mechanization of industry, industrial executives have been continually confronted in the formulation of equipment policies with the questions: What type of equipment is it best to install to perform a given task or service? When should existing equipment be replaced? How can the capital resources of the enterprise be most profitably employed so that all productive fixed assets in the business can not only pay for themselves in the shortest possible time but also earn an adequate return on the investment—how to protect the enterprise from the hazards of obsolescence? In order that these executives may be provided with facts and a broader understanding of the issues at stake, this Society has instigated and sponsored an extended research project with the objective of investigating and revealing all aspects of the problem as well as formulating eventually practical techniques of approach.[3]

In its essence the whole problem resolves itself into the fact that those in industry who are entrusted with the expenditure of the funds of an enterprise must guard themselves against

---

[1] Research Assistant, Department of Business and Engineering Administration, Massachusetts Institute of Technology. Heinz Otto Vorlander was born in 1904 and received the degree of Diplom Ingenieur from the Technische Hochschule, Dresden, in 1928, for the completion of work mainly in the department of Mechanical Engineering, and comprising industrial management. He had had one year of practical work, one year as assistant at the College of Dresden, and one year of professional work as an industrial engineer before coming to the Massachusetts Institute of Technology to study for a Master's degree in Business and Engineering Administration as a German Exchange Student. He was awarded his degree in October, 1930, and from that time until last July was employed by the department as a research assistant, devoting his entire time to the study of the problem of selection and replacement of equipment.

[2] Associate Professor of Industrial Research, Department of Business and Engineering Administration, Massachusetts Institute of Technology. Assoc-Mem. A.S.M.E. Professor Raymond was graduated from Harvard University with the degree of A.B. in 1918, and in 1921 received the degree of S.B. from Massachusetts Institute of Technology. From that year until 1928 he was with the Crosby Steam Gage & Valve Co., of Boston, where he became works manager. Since 1928 he has been at M.I.T.

Formal report on a study of the problem of selection and replacement of equipment sponsored jointly by the A.S.M.E. Special Research Committee on Measures of Management and the Committee on Materials Handling Formulas of the Materials Handling Division. Contributed by the Management Division and presented at the Annual Meeting, New York, N. Y., Nov. 30 to Dec. 4, 1931, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[3] Now that the first portion of this research project has been completed and the resulting criteria, formulas, and techniques, in their fundamental form, have been presented to the membership of the Society, it is essential that the cooperation of a large number of corporations and their executives be obtained in order to carry out the second portion of the project relating to the evolution of individual formulas and techniques applicable to specific types of equipment such as all kinds of machine tools, jigs, and fixtures, material-handling and labor-saving devices, as well as power and process equipment and the like, which will be appropriately adapted to the current accounting procedure employed in any case. It is hoped that the value of this paper will be appreciated throughout industry to the extent that many executives will be willing to signify their desire to aid in the completion of this project by communicating directly with the secretary of the Main Research Committee of the A.S.M.E.

undue extravagance, as the greatest utility and satisfaction from their use can only be attained when such resources are adequately conserved and employed with economy. Accordingly if this is to be accomplished some fundamentally sound basis must be evolved which will permit the original selection of the most appropriate type of equipment for the performance of a given kind of service, and later its replacement by some more highly developed counterpart which can perform the same or even a more difficult service with sufficient additional economy of operation or maintenance to justify the cost of removing the existing equipment and the investment of the same or larger amounts of capital in that of the latest design. Obviously the foundation on which such a method of solution rests is the ability to obtain an economic balance between the costs of securing and carrying the proposed investment of capital and the anticipated economies of operation. It so happens that the actual amount of the capital investment is really of less consequence in the formulation of a policy for the installation or replacement of equipment, as the justifiable investment is controlled entirely by the economies which can be effected by their use. Therefore, since the fulfilment of all obligations of a financial or operating nature must be achieved within the serviceable life of the equipment, this measure of its ultimate economic utility will necessarily be a function of *time*.

Utility of Formulas in Evaluating Equipment Policies

Naturally, since the formulation of any equipment policy involves definite values of capital, costs, and quantities of production as well as time, the fundamental relations of these items in their various combinations can best be expressed in formulas, the resulting solution of which will yield the desired criteria for the guidance of industrial executives, or else they can be translated into a variety of practical techniques for use by plant managers, process engineers, or sales executives. If in this manner a means can be evolved for evaluating and rating the relative economic advantages of one type of equipment over another in the performance of a specific task or service, industrial executives will then be able to determine their equipment policies on a rational basis in terms of an economic utility which comprehends automatically all obligations arising from any given situation. Thus, they will be able to foretell when a piece of equipment has lost a sufficient amount of its original utility to make it worth while either to replan the methods of production or replace the machine with one of a radically new and more efficient type, to select the equipment with the highest economic utility, and to translate the sales arguments of the equipment manufacturer into terms of utility for the specific task involved. On the other hand, the equipment manufacturer can establish ratings of performance for each item or design in his catalog which will show clearly the relative economic advantage to be realized by the adoption of any one. Moreover the manufacturer can so schedule improvements in the design of equipment that he can stimulate the maximum uniform sales volume without discouraging his prospective customer by too frequent design change and an unreasonable sales policy of progressive obsolescence. In addition to the advantage gained by the process engineers through the aid such methods give them in their work of cost reduction, the facts thus derived will also permit the more rational distribution of earnings to the owners, workers, and consumers as well as to the enterprise itself in the form of a higher return on investment, more generous wage incentive systems, lower prices, or a greater margin for expansion or improvement, as each case may justly deserve.

Criteria for Determining an Equipment Policy

As a result of the present investigation it has been found that there are certain definite periods of time in the life of any equipment, when measured from the date of its original installation, whose completion marks the instant that certain primary obligations have been fulfilled. When such corresponding criteria for alternative types of equipment are compared with each other they provide a measure of the relative state of economic utility that the most efficient type has achieved over the other.

1 *The True Accounting Life* (H_t). The prime requisite in all equipment problems is the time within which a given type of equipment can pay for itself. This criterion can be evaluated by equating the summation of all costs, expenses, and obligations for the proposed equipment, whether of positive or negative characteristics, to a similar summation for some standard basis of comparison when making an initial installation, or to a similar summation for the existing equipment when there seems to be an advantageous opportunity to replace it. In making such a comparison it is assumed that the above criterion is satisfied when there are no excess savings or when all savings over and above the costs incurred by other obligations are devoted to the depreciation of the initial or gross investment in the proposed equipment. This condition has been commonly termed the "break-even point." Since in this case there can be no further savings achieved, the time that it will take to accumulate in a reserve fund the original capital outlay or investment in the proposed equipment from yearly payments or allocation of assigned savings in lieu of depreciation will be the minimum time for the equipment to pay for itself, and as such it has been termed the "true accounting life." Accordingly, this criterion should be employed as the basis for all rational depreciation policies.

2 *The True Economic Life* (H_r). In the ordinary course of business it can never be assumed that any type of equipment has achieved a full state of economic utility when it has been able through its operation over a period of years merely to pay for itself, because there is the implied obligation upon all productive capital assets that they must in some manner pay back to the investor of that capital, whomsoever he may be, an adequate return as a reward for assuming the risks of business through his investment. Thus, in only satisfying the first criterion this second consideration will have been omitted. Accordingly the ultimate criterion for any equipment policy demands that not only shall the original investment be returned to its owner together with the normal cost for its use, but also an adequate return must be earned as well. The amount of this return will vary in all cases, and depends upon the profitableness of the industry and the ability of the management. The minimum return for any single unit of equipment will be determined by the average earning power of every dollar invested in productive assets. Accordingly the *minimum utility life* (H_u) of equipment will be that period of time which is required for any single equipment to fulfil all direct and implied obligations as outlined above.

However, this situation does not account for that which ultimately involves the relative economic utility of alternative types of equipment. In this case it is of primary importance to ascertain whether the proposed type of equipment can achieve an earning power equal to that of the present or existing type within a reasonable length of time. Of course if the relative economic superiority of the proposed type is so low that it cannot become at least as profitable to operate as the existing type before impending obsolescence occurs, there is little relative advantage in actually installing new equipment of that type. Furthermore there may be reason to ascertain whether the proposed type can enhance the earning power already realized from the present type, when the performance of both is projected into the future, so that a desired increase in the return can be obtained after a certain number of years of operation from the present have elapsed, or so that these savings can be transferred from the owners of the business to its customers in the form of lowered prices. All of this can be determined through an inspection of the relative trends of the curves for the *functional rate of return* (r_H) for both types of equipment over the desired number of years. This functional rate of return is a yearly rate factor dependent upon the total net savings available, when computed for any definite number of years and averaged for the elapsed time, after all fixed and variable obligations have been met. Now the ultimate time criterion for the relative economic utility of alternative types of equipment for the same task is measured by the period of time (H_r) required for the functional rate of return for one equipment to equal that for the other. Hence this time when these conditions are satisfied is termed the *true economic life*.

3 *The Critical or Minimum Life* (H_s). In contrast with the utility life and comparable with the true accounting life, there is a period of time when only a single unit of equipment is considered, at the end of which the accumulated margin between all obligations and the net revenue from the sale of the products produced or processed by the equipment is just equal to the original outlay of capital invested in the equipment with no consideration for the return expected on the investment. In other words, the equipment unaided by any outside considerations can just pay for itself in this minimum amount of time. Hence, in an emergency the equipment can be replaced at this moment without leaving any fixed obligations to be borne by the superseding equipment, although all of its obligations to earn any return whatsoever on its investment must be carried over into the future. This instant of time has been designated as the *critical or minimum accounting life*.

4 *The Serviceable Life*. In opposition to the various time criteria just discussed, which depend upon the performance of the equipment, there is the *serviceable life*, which is governed by the occurrence of obsolescence. Obsolescence is in most cases an uncertain factor, but it may be largely influenced by a more rational control over design change, or by the development of better production methods and processes, except where the whim of the customer influences the utility of the product or service and in turn influences the utility of the equipment employed in its production or performance. When an arbitrary accounting life is set there is always the risk that impending obsolescence will occur before that life has expired. The case is the same with the true life, but if the true life is shorter than the arbitrary one, which it often is, there is no need of running an undue risk of impairing capital resources irreparably through the occurrence of obsolescence before the equipment has paid for itself on the arbitrary basis. The risk of impending obsolescence can be measured by the ability to forecast future conditions, or in this case the probable rapidity and intensity of design change, and its relation to the true life. If the true accounting life or even the true economic life exceeds the apparent serviceable life, then the proposed machine is not sufficiently highly developed to justify its installation; that is, the increment in the transfer of skill to the machine is not great enough to warrant replacing the present equipment with that which is under consideration on the basis of anticipated economy of operation. If the true life approaches the supposed time for the occurrence of obsolescence or the serviceable life, but does not surpass it, then the interval of time between these two points when related to the true accounting life is the measure of the risk. The severest test is that between the critical life and the useful life when compared with the anticipated serviceable life.

Thus, if equipment be classified according to design cycles and compared upon the basis of some standard task, the dividing line between partially obsolete and totally obsolete equipment can be determined by a comparison of the true accounting or minimum utility life for the most modern design with some basic criterion for the time in which a machine can pay for itself, probably some fraction of a year. In this way a measure of the relative utilities of the two designs can be obtained which depends upon the savings that accrue through the marked superiority of the most modern one. For the minimum condition just mentioned, the superiority of the latest design will be sufficiently great to warrant the complete obsolescence of the earlier design, with which it is being compared, and of course all previous models as well.

5 *The Physical Life* (H_p). Furthermore there is the *physical life* of the equipment, which depends upon the wear and tear from actual operation and deterioration of its substance. This life is the measure of the depletion of the physical characteristics and attributes of the equipment. Without maintenance the physical life may be short, so that maintenance in a sense is insurance against a too early depletion of the actual utility of service.

Criteria for Depreciation Policies

At this point it is advisable to digress for a moment to discuss depreciation policies, because the bases for such policies underlie also the whole theory of the economic utilization of capital resources and its measure, the economic life of equipment. Current accounting practice differs radically from the methods proposed in these pages for depreciation because normally an arbitrary rate of depreciation is set and then there is no actual accumulation of a reserve. In the determination of the *true accounting life* a fixed rate of depreciation cannot be employed, because then one automatically sets up an arbitrary time in which the equipment is supposed to pay for itself whether the conditions will permit it or not, and then there is no relation expressed between the savings, which can be legitimately diverted to depreciation, and actual depreciation. In such cases this estimated time is called the *arbitrary accounting life* (H_a) of the equipment. Furthermore current accounting practice rarely makes any provision for maintaining the original investment intact. Ordinarily, at any time in the normal life of the equipment its actual capital value is represented by the book value as it stands upon the records of the company, that is, the initial investment less depreciation allowance. But such a value at no time can represent the initial investment since depreciation takes no tangible form; for the most part it is only a writing down of asset values, with a corresponding adjustment on the balance sheet from earnings. One can never say that the savings which theoretically go to depreciation are available when the time comes for replacement as so much cash or its equivalent to be used in the purchase of new equipment. To be correct and maintain the original investment intact, depreciation payments should be made by setting aside periodically cash or securities in a reserve for replacement, so that for any item of equipment at any time the sum of those funds derived from depreciation plus the book value of the equipment will always equal the initial investment, with due credit for interest on the funds thus reserved. In passing, it should be stated that there is no definite obligation to set aside more funds for depreciation in lieu of increased future capital expenditures at the time of eventual replacement, because one need not provide for expansion or improvement in this manner if the return on the investment will be an ample inducement in securing additional capital when the appropriate time comes. This factor of a reserve for replacement demands immediate consideration by all industrial executives.

Other Criteria in the Problem of Selection and Replacement of Equipment

In addition to the foregoing criteria there are several others which are of importance in dealing with any problem of selection and replacement of equipment. The first is the determination of the *maximum justifiable investment* in any type of equipment which is suited to a specific task. This will depend upon the economies of operation which it is desired to obtain, assuming certain standard conditions. The second is the determination of the *minimum resale value* which it will be permissible to anticipate, and whether or not the equipment is so productive of economies that it will be permissible to scrap the equipment at the end of its useful life instead of having to depend somewhat on second-hand values to obtain within a reasonable time the full return of the initial capital investment. The third is the *critical total production* which will have to be effected before there will be sufficient total revenue out of which adequate funds for depreciation can be obtained. If prices fluctuate or the volume of business declines it is quite probable that, unless some unforeseen circumstance arises, the equipment will not be able to pay for itself in the appointed economic life. Furthermore it is advisable to learn the *minimum average yearly output* or capacity under which the equipment can operate and meet all obligations, or, in other words, *the maximum allowance for idle time.*

The Basis for an Equipment Policy

In the subsequent analysis from which these criteria have been derived, certain conclusions stand out as guiding principles to be followed in formulating an equipment policy and in evaluating the criteria which govern a particular situation. They are:

a The capital resources of the enterprise must at all times be conserved, and the initial investment must at no time be impaired, for any cause, even impending obsolescence.

b All equipment must be maintained in the most efficient state, and at least ready to operate.

c An adequate return must be earned on the investment over and above the cost of capital, not only as a reward for risk, but also to provide some opportunity for growth either through earnings put back into the business or through the ability to attract new sources of capital whenever such funds are required.

d Adequate provision must also be made for estimating and accounting for certain contingencies arising from the normal risks of doing business or the too sudden occurrence of obsolescence.

e In order to account properly for the nature, occurrence, and behavior of any and all direct or implied obligations, all comparisons and computations must be based upon the total of the entire group over some definite or indefinite period of time. The comparison of annual costs has failed to reveal all the vital complexities of the problem.

f Finally, since provision has been made in the original cost estimates for products to be produced or processed by the equipment, or established by the performance of equipment now in operation for the eventual fulfilment within a definite time of all obligations belonging to a specific type, all additional obligations must be paid for out of savings which can be achieved within the limits prescribed by these provisions and still within a reasonable time, as it is impossible to suppose that a reduction in the normal rate of return on the investment or an increase in selling prices will be permissible to offset any such increase in the total obligations incurred by a change in equipment.

Fundamental Considerations for the Evaluation of Equipment Policies

For practical purposes of comparison, out of all the formulas and methods proposed and employed heretofore, only two groups have been found worthy of attention. The first, which are recommended for use in determining policies for the selection and replacement of equipment, depend upon the total accumulated costs, expenses, and obligations for the entire anticipated life of both types under consideration. The second, which are applicable to the determination of the effect of an equipment policy upon the final cost of the product, depend upon the translation of all yearly costs to unit costs at the normal capacity of the equipment or some adjusted capacity equivalent to the current sales demand. The remainder of this paper will accordingly be devoted to the evolution of appropriate formulas and the development of practical techniques for daily use in industry. However, in order to avoid certain erroneous conclusions, the following injunctions must be observed.

a One must assume that all types of equipment are identical as far as the general problem is concerned, and that in making any application of the technique all possible combinations of factors may be encountered.

b To arrive at the correct solution of the problem, all comparisons employed must be fundamentally based upon equal amounts of service rendered by both types of equipment, with an additional provision for modifying this assumption only when the circumstances involve a change in the amount of service as well. If the comparison is made on the basis of unequal amounts of service, a false advantage is gained for one or the other piece of equipment which may or may not at some future time be realized.

c Similarly all obligations which are dependent upon or vary with time must be reduced to a common or equivalent basis. This will be necessary when there is some future obligation which will occur in its entirety at some one specific time in advance and for which a provision for its eventual payment must be made each year prior to the time when the full obligation becomes due, in order that the eventual burden which it will place upon the economy of operation may be recognized and accounted for among those obligations which are a constant burden upon the equipment at the present time.

d All comparisons of the cost characteristics of alternate types of equipment cannot be made to reveal the correct economic advantage of that type which is superior unless the resulting relationships are so formulated as to expose the differential between each individual cost characteristic for both types. Only in this way can the significant factors be exposed and those for which there is no relative advantage eliminated.

e It must be recognized that the introduction of a new item of equipment will require a readjustment of the burden rates commonly employed in the distribution of overhead, and that a new method of allocating the burden of these items must be devised so as not to be unfair to either piece of equipment involved in the exchange. Even though the total overhead may not be changed, especially if those items which relate to the equipment are treated separately, the burden rates will have to be corrected because the use of the old ones in connection with the evaluation of the obligations of the new machine may not under the changed conditions account for the entire burden of overhead which must be distributed in full.

f Depreciation must be based not on the gross initial investment but only on the out-of-pocket investment; that is, the difference between the gross investment and the net salvage value which it is possible to anticipate at the time when the economic life of the equipment comes to an end, with due allowance for removal costs and similar changes, including any unamortized investment left over from previous types of equipment because of their replacement prior to the expiration of their true accounting life.

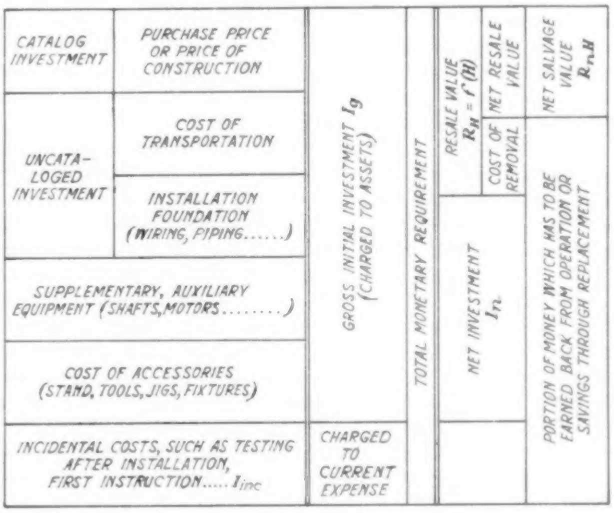
g Finally, simplification of the resulting formulas and techniques must and can be made only when all elements of the problem are thoroughly revealed and understood. Equipment will vary in accordance with the service for which it is designed, and in no case will all of the elements of the problem apply to the same degree. Hence eventually separate formulas must be evolved for machine tools, jigs, and fixtures, and labor-saving devices or material-handling equipment.

Application of the Theory of Economic Utilization of Capital Resources

With these considerations in mind let us turn for a moment and see what this whole problem of selection and replacement of equipment comprehends if a rational and workable solution is to be achieved. The problem itself is not a difficult one; in essence, the sole objective is to justify the expenditure of capital resources for some form of facility or equipment on the basis of the anticipated economic utility or superiority of the proposed type over the existing type or that which may have been adopted as a standard of comparison. Primarily it is a financial problem dealing with the investment of funds, the cost of capital, depreciation, the usual financial charges pertaining to taxes, insurance, and the like, income from reserve funds, return on the investment, and savings from operations or services performed. Thus the principles which have just been set forth are in reality applicable to problems of much larger scope than those found in industry alone, and hence when taken as a whole they constitute the *theory of economic utilization of capital resources* which normally appear in the form of facilities employed to promote our daily business activities. The economic superiority of one facility over another, whatever its nature may be, can then be demonstrated by a comparison between the magnitude of the financial obligations incurred by the installation and operation of any two facilities designed or appropriate for a specific purpose, and the relative ability of either one to pay for itself in the shortest possible time out of operating economies, with due regard for the quality of output or the service performed. Thus in industry the problem may become more than a financial one, because if the ultimate economic superiority of one form of a facility depends upon its operating costs, it must take into consideration as well all factors such as materials, labor, set-up or preparation costs, tools, maintenance, repairs, rent, power, indirect labor, and all overhead items, including supervision and service charges, which naturally pertain to industrial equipment. In fact, the problem revolves about the characteristic differences between alternate types of equipment for each item of financial and operating costs, especially those which vary with the quantity or magnitude of the service and the passage of time. Accordingly, if an adequate solution is to be attained it is essential that the elements of the problem be investigated, the nature of each contributing cost factor be ascertained, and its behavior and influence revealed.

Elements of Investment

Since interest is centered at this moment entirely upon the selection and replacement of manufacturing equipment, the investigation so far has been confined to a study of the industrial aspects of the problem, though it will require only slight adjustment in the conclusions to apply them to any facility, whatever its useful purpose may be. Before entering upon a consideration of the relationships which underlie and control any sound equipment policy, it is essential that a thorough understanding be obtained as to the precise interpretation of each factor relating to the problem. First of all are the investment factors. Normally, the original investment is regarded as the capital expended for the equipment either through purchase or through development and construction. Nevertheless in the final analysis this does not represent the entire investment as there must be added thereto transportation and installation costs as well as any investment of a similar nature for auxiliary equipment and accessories, and any expense that may be incurred through testing and perfecting the performance of the equipment when first placed in service. Of all these various forms of capital outlay some portions are characteristically an asset which will have to be depreciated over the life of the equipment, while others are in the nature of transitory expense which has no real, lasting value and which must be charged to the cost of operation and paid for out of the potential savings during the first year the equipment is in use before depreciation and realization of operating savings can be provided for. Furthermore, everything considered, it is not the actual investment for the proposed equipment which must be justified, but rather the obligation to maintain intact the total outlay of capital incurred either by the installation of the new equipment or by the present or previous equipment, in which case the obligation must be carried over and imposed upon the new equipment as an additional burden. In other words, it is the differential or out-of-pocket investment, the algebraic sign of which determines the nature of the obligation, because only that portion of the total obligation upon the new equipment needs to be depreciated which cannot be offset by the resale or scrap value for both the present and proposed equipment and any income on the replacement reserve.



CATALOG INVESTMENT

NET SALVAGE VALUE R_{nH}
PORTION OF MONEY WHICH HAS TO BE EARNED BACK FROM OPERATION OR SAVINGS THROUGH REPLACEMENT

Fig. 1 Elements of Prime Investment

The *prime investment* in a situation of replacement involves all cost from the time of the first consideration to the time of placing the equipment into useful operation. J. Chas. Fish in his "Engineering Economics"[4] defines prime investment as the sum of the costs of investigation, promotion (financing, organizing), and construction or purchase and installation.

The investment obligations due to the installation of any piece of equipment are defined by the *gross investment* (I_g) of capital, the sources and ultimate disposition of which can be demonstrated by the accompanying chart (Fig. 1).

Each situation rquires a different set-up for the elements of prime investment. Other items must be considered, as, for example, cost of removal, cost or expenses for temporary equipment during the installation of main equipment, the purchase of patents and rights if in the nature of assets, the interest cost on capital tied up during the time of investigation, promotion, or purchase (installation) of equipment, loss of net income due to interruptions during period of installation, cost of accidents to persons employed in the installation, cost of accidents to equipment during time of installation, and similar contingencies.

---

[4] **McGraw-Hill Book Co., 1915, p. 34.**

That portion of the total outlay of capital, herein designated as *incidental costs* (I_{inc}), which is expended in the testing of equipment and the training of the operator is not ordinarily considered a part of the gross investment because it is an intangible non-recurring item and should be written off as an element of current expense. All cost incidental to the installation of new equipment is usually charged to current expense or depreciated during the first year. Whatever the accounting method is in regard to such expenses, they should not be omitted in the equation for total accumulated cost (C_H) during the whole life. If such costs are debited to current or operating expense, they immediately lose their connection with the particular equipment under consideration; if they are charged off as depreciation during a shorter predetermined but arbitrary time, the result in the total-cost formula is an addition to the gross initial capital value. It is then obvious that the new equipment has to carry its own incidental expenses that must be earned back in some indeterminate time.

The main point is to know on just what portion of the prime investment interest and depreciation are to be paid, and upon which taxes are to be based. The second factor to determine is the sum of all capital costs incidental to the acquisition of the equipment. Owing to the prescribed basis for the computation of taxes, the ever-existing obligation to pay a cost for the use of capital resources and insure the equipment from all common hazards, the major purpose of depreciation in maintaining the original capital outlay intact and possibly the contractual obligation to pay royalties on patents which are specified on some arbitrary basis, there may be distinct differences in the items of investment employed in computing these various obligations. The cost of capital must be computed on that portion of the total outlay which is eventually to be capitalized as an asset and which normally is the gross investment I_g defined above. If, on the other hand, the incidental costs I_{inc} are not to be written off in the first year but depreciated along with the gross investment I_g, then the cost of capital must be computed upon the basis of $I_g + I_{inc}$. Since there are legally prescribed methods of computing taxes, the basis for yearly tax payments will be different from the gross investment or even the book value; however, by means of appropriate coefficients the actual basis for tax computations can be related to the gross investment, hence one must use $I_t = a \cdot I_g$. The basis for insurance will depend either upon the gross investment or the book value at the time of renewal of the policy, but it is conceivable that the actual premiums paid will not conform exactly to the payment of cost of capital. Here again an adjustment by means of coefficients will be required if the gross investment is to be employed as the actual basis for such computations. Since the funds set aside annually for a replacement reserve are only of such an amount as at the expiration of the economic life will equal the original outlay less funds received from resale (S_r) or salvage (S_v) plus any obligation (K) carried over from previous equipment, depreciation must be based on the summation of these investment factors which for any type of equipment will be expressed by $I_g + I_{inc} - S_v$ if the incidental costs are not written off in the first year. Finally, the payment of royalties may be based upon some arbitrary figure depending upon the particular advantage obtained from the use of patents or designs belonging to others; however, the basis of such payments can again be probably related to the gross investment by means of a suitable coefficient.

OTHER VALUES RELATING TO THE INVESTMENT

During the useful life of the equipment the value of the original investment is gradually altered through a natural process of exhaustion of its useful qualities until a time arrives when it is sold or discarded as junk. The various terms applied to designate the actual value at any one of these stages may be interpreted as follows:

a Book Value (I_b) is the arbitrary value assigned to any piece of equipment at any moment during its useful life, and may or may not correspond with the value derived from the gross investment less accumulated depreciation.

b "Wearing" Value[5] is an arbitrary term employed to designate the value remaining in any piece of equipment, as evaluated by appraisal of remaining utility through the difference between the net resale value and the scrap value at any time.

c Salvage Value (S_v) is that value which can be obtained in some manner for the equipment at the time of its removal or displacement. When the equipment is not sold the salvage value is computed upon the net factory *utility value*, or that value which, by appraisal, the equipment will retain and carry over to the new use to which it will be put in some other location in the plant.

d Net Resale Value (S_r) is that value which at any time can be realized by the sale of equipment in the second-hand market, and is greater than the scrap value of the equipment but approaches that value as its ultimate limit. Due allowance must be made, however, for the costs or expenses of removal, etc. Actually its real value at any instant of time is a function of the elapsed time from date of purchase.

e Scrap Value (S_c) is the minimum realizable value of the equipment expressed in terms of the "junk" value of the materials employed in its construction at the current market quotations for scrap-metal prices, after there ceases to be any utility value in the equipment as such for any purpose whatsoever.

f Unamortized Value (K) is that portion of the prime initial investment which remains at any time when a piece of equipment is replaced, as the difference between depreciated gross investment or true book value and the net proceeds received from salvage or transfer of the equipment to some other division or department of the enterprise with due allowance for costs of removal or transfer, and which could only be paid back were the equipment retained in operation throughout its full accounting life.

The unamortized value can be expressed mathematically as follows:

Let C_R = cost of removal or transfer of present equipment
I_b = book value of present equipment
S_v = salvage value of present equipment.

Then

$$\begin{aligned} K &= I_b - (S_v - C_R) \\ &= I_b + C_R - S_v \end{aligned}$$

If the sale of the present discarded equipment does not cover the book value I_b, the loss K is usually dealt with in three ways:

a It can be written off to profit and loss, either at once or in the course of two or more years. It can also be charged to special replacement reserves, if such are set aside from surplus.

b It can be included in overhead and charged to cost that way.

c It may be added to the cost of the new equipment and treated as an addition to the investment, eventually being charged to cost through depreciation.

The first two methods are commonly practiced in accounting for losses from replacing industrial equipment, while the third method is followed in the case of real estate and the buildings erected upon it. But whatever method is followed, one should not forget that charging the unamortized value to profit and loss or to overhead takes the burden away from the particular equipment that causes the loss, thus loading the whole business or all the facilities with the responsibility of carrying the loss. A replacement formula is independent of the accounting practice when it has to scrutinize the economic factors of the equipment charge. The relation of such a loss to the new equipment must be upheld by charging the full unamortized value of K to the new equipment. Then this loss is added to the capital value and depreciated along with it.

---

[5] J. C. L. Fish, "Engineering Economics," p. 47.

It is well to note at this point that the salvage value when the equipment is sold will be equal to the gross resale value, or when junked it will equal the scrap value.

CAPITAL VALUES EMPLOYED IN REPLACEMENT PROBLEMS

Owing to the fact that the formulation of a policy for the selection and replacement of equipment depends upon the differential relationship between the total obligations for both items of equipment over their entire lives, respectively, one will be required to draw eventual conclusions from certain capital values which express their relative characteristics, as follows: Whenever such differences are to be employed in the subsequent analysis, as may occur between some item relating to the present or existing equipment (indicated by subscript 2) and the same item for the new or proposed equipment (indicated by subscript 1), the symbol Δ will be prefixed to the symbol for the item itself to signify that a comparison of this nature is intended.

a Additional Capital is the increment in capital outlay between the gross investment for each type of equipment, and can be expressed as

$$I_{g1} - I_{g2} = -\Delta I_g$$

This value is of considerable importance because provision must be made to earn the normal expected return on this increment as well as on the original investment before the remaining savings from operations can be even applied to amortize the investment; otherwise the earning power of the corporation will be impaired.

b Differential Prime Investment is the measure of the relative basic investment obligations entering into any equipment problem, and can be expressed by

$$(I_{g1} + I_{\text{inc1}}) - (I_{g2} + I_{\text{inc2}}) = -\Delta(I_g + I_{\text{inc}})$$

c Out-of-Pocket Investment is that portion of the combined investment obligations for both types of equipment under consideration which remains after balancing the individual obligations for each, and can be represented by the relation

$$(I_{g1} + I_{\text{inc1}} - S_{v2}) = (I_{g1} + I_{\text{inc1}} - I_b + K)$$

d Invested Capital That Must Be Earned Back is that portion of the combined investment obligations which can only be replaced through depreciation in order to maintain the total outlay of capital unimpaired, and can be represented by

$$(I_{g1} + I_{\text{inc1}} - S_{v2}) - S_{v1} = \text{capital} - f(H)$$

This equation is set up upon the assumption that the out-of-pocket value on the day of replacement is to be reduced by the salvage value at any time. The knowledge of such a function of salvage value is therefore of great importance for the computation of the true accounting life during which the suggested equipment will pay for itself out of savings effected from replacement. Heretofore no attempt has been made to introduce this function into the problem. The present simplified solution deals with the scrap value (S_c) at the end of the useful life rather than with the functional salvage value,

$$(I_{\text{inc1}} + I_{g1} - S_{v2}) - S_{v1}$$

Thus the amount of capital to be earned back is in excess of the "wearing value," or the difference between salvage and scrap value. If the present equipment has reached its inherent scrap value $S_{c2} = S_{v2}$, then $S_{c2} = I_b - K$, and consequently the *refunding investment* becomes

$$(I_{\text{inc1}} + I_{g1} - S_{c1}) - (I_b - K)$$

or

$$(I_{\text{inc1}} + I_{g1} - S_{c1}) - \left[I_{g2}\left(1 - \frac{H_2}{H_{e2}}\right) + \frac{H_2}{H_{e2}} S_{c2} \right] + K$$

when time differences are accounted for and where

H = any period of time in the life of the equipment and,
H_e = an estimated life for the equipment.

ORIGIN AND NATURE OF COST FACTORS

Each equipment represents a unit of investment with all the obligations, financial, physical, and managerial, necessary to carry the equipment. Since the prime object is its useful operation, either for productive or other purposes, all items of cost as well as charges relevant to the invested capital must be taken into account. These obligations naturally divide themselves into three distinct classes.

The first, straight financial charges (F_I)—mainly interest taxes, insurance, and depreciation—are those connected with the maintenance of capital. They arise from the obligations incurred by the employment of capital in the form of facilities having physical shape or form, which are derived in turn from the necessity to maintain intact the original outlay of capital and the fact that all capital, no matter how it is employed, carries with it certain costs, not only that due lenders of capital but also those which are assessed upon it in the form of taxes, insurance, royalties, and the like. It is well to note that in the fulfilment of these obligations certain minor sources of income may develop which, along with the major items of expense, will produce positive and negative obligations.

The second class consists of operating expenses (F_o) which are understood to include only such items as maintain the equipment in an operating condition, as, for example, direct labor, power, direct lubrication, preparation, and set-up costs. Inasmuch as any equipment can be operated at the above-named costs without fulfilling its function, it is not necessarily productive and this involves in addition not only the cost of material, but also that for the lubrication of the tool.

The third class of expenses are usually referred to as overhead (F_B), the origin of which is not always clearly related to any particular equipment.

The combined annual financial, operative, and general costs are considered to be a characteristic for any equipment. They may be called *producing equipment cost* if connected with production, or in general, *operating equipment cost* (C_y).

DEPRECIATION

First in importance in the class pertaining to financial charges (F_i) is the yearly depreciation (D), as the whole problem of replacement revolves about the ability of the equipment to pay for itself in a reasonable period of time. Normally an arbitrarily specified amount is charged off from the original investment or the book value each year to account for a natural and gradual loss in utility. This amount represents in the eyes of executives that portion of the investment which the equipment is expected to earn back during any year. In any isolated case which does not involve replacement or a comparison between two similar types of equipment, the investment to be depreciated will of necessity be that portion of the original investment which cannot be regained through resale or which cannot be absorbed in the first year as a charge to operations. When a comparison is to be made, the differential investment value must be employed as previously defined. The magnitude (D_a) of the yearly depreciation is usually determined by dividing the out-of-pocket investment which must be written off with due consideration for salvage values by a predetermined number of years (H_a) in which it is expected that the equipment may be maintained in profitable operation. Hence in general

$$\frac{(I_g + I_{\text{inc}} - S_v)}{H_a} = D_a$$

$$D_a = I_d \cdot d_a$$

$$I_d = (I_g + I_{\text{inc}} - S_v)$$

and

$$d_a = \frac{1}{H} \text{ when } H = H_a$$

Now in the case where some new equipment supersedes some existing equipment, the depreciation of which has not already been fulfilled, it is insufficient to base the investment to be depreciated solely upon the out-of-pocket investment because the new equipment must in some way bear the burden of the undepreciated portion (K_1) of the existing equipment or any unamortized investment (K_2) which it is obliged to carry itself from its own time of installation on still earlier types of equipment. Accordingly the actual depreciation charge (D) for both types of equipment as used in eventual computations will be

$$D_1 = I_{d1} \cdot d_1 = \frac{I_{g1} + I_{\text{inc1}} - S_{v1} + K}{H_a} \quad \text{if } d_1 = \frac{1}{H_{a1}}$$

and

$$D_2 = I_{d2} \cdot d_2 = \frac{I_b - S_v + K_2}{H_{a2}} \quad \text{if } d_2 = \frac{1}{H_{a2}}$$

where $K = K_1 + K_2$. It is well to note that, in most of the equations which follow, K_2 will be disregarded and K will be assumed to be K_1.

This arbitrarily determined yearly depreciation on the basis of H_a has, however, no relation to the ability of the equipment to earn back the investment in this number of years, and gives no guarantee that the original investment will always remain unimpaired. Furthermore, unless funds are definitely set aside periodically equal to the amount of yearly depreciation, whatever it may be, there will be no money available to accomplish the replacement of the equipment when the appropriate time arrives. Hence a reserve fund for replacement is of the utmost importance if the equipment of a plant is to be maintained in a high state of efficiency. Otherwise how can the earnings of any equipment be accumulated so that in time its original investment will be actually returned to the owner and equivalent modern equipment be substituted for the present one when its utility has ceased to exist? The fact is that the ability of any equipment to pay for itself is dependent solely upon the savings which it can effect through economies in operation, except in such cases where it has been possible to reduce the aggregate of all yearly financial charges at the time of installation through careful purchasing and finance. Hence, as will be emphasized later, the time which it will thus take to earn back the out-of-pocket investment with due regard for all direct and contingent obligations will be the measure of the ability of the equipment to pay for itself, and as such it becomes the only rational basis for determining the annual depreciation rate (d). This time will hereafter be designated as the true accounting life (H_t), the evaluation of which is one of our major objectives.

INTEREST

The second important element among the financial charges is the cost of capital. It is universally accepted that the employment of capital in any manner implies a charge for the use of that capital at an annual rate of interest (i) as determined by current money-market operations. Thus, when capital is expended for equipment of any sort there is immediately created an obligation for that equipment to bear the cost of the capital invested in it, regardless of the source of the capital. The investment I_i upon which the cost of capital is to be computed will in general be that amount (I_g) of the prime investment in any equipment which has been capitalized as an asset and as such is carried on the books of the company. In the case of new equipment which supersedes some existing equipment, the asset value of which (K) has not been fully depreciated, the new type must also assume the burden of paying the cost of this capital until it has been fully amortized. Accordingly

$$I_{i1} = I_{g1} + K$$

where $K = K_1$ and K_2 is assumed equal to zero. Similarly if the present equipment is still carrying the burden of some equipment which it displaced, provision already exists for the fulfilment of this obligation, so that in special cases

$$I_{i2} = I_b + K_2$$

Ordinarily K_2 may be neglected in this case as well. Hence the interest charge, which in this case is computed on the principal alone and not compounded, may be expressed as

$$i \cdot I_{i1} = i_p(I_{g1} + K)$$

or

$$i \cdot I_{i2} = i_p(I_b + K_2)$$

where $i = i_p$ in both cases.

It so happens, however, that interest is not only payable but also receivable, because through the operations of an adequate depreciation policy a reserve fund is accumulated, the interest charge on which should be credited to the equipment for the time that the money is idle awaiting eventual reinvestment in some superseding equipment. Thus, in addition to the cost of capital, income from the reserve fund applicable to any single equipment must be accounted for in determining its accounting or economic life. Accordingly, if the estimated life of the equipment be H_e for depreciation purposes, the interest charges payable for any period H are

$$\sum_0^H (iI)_p = Hi_pI$$

and the interest charges receivable for the period H are[6]

$$\sum_0^H (iI)_r = H_e \frac{(H_e - 1)i_rD}{2} + (H - H_e)i_rI$$

$$= H_ii_rI - {}^1/_2\, i_rI - {}^1/_2\, H_ei_rI$$

---

[6] The derivation of these expressions depends on a time series which is developed in full in the original report on this research project on file at the Massachusetts Institute of Technology.

where $D = I_d/H_e$. The net difference or total effective interest charge for the period of H years then becomes

$$(iI)_e = \sum_{0}^{H} (iI)_p - \sum_{0}^{H} (iI)_r$$

$$= \frac{iI_i}{2}(H_e + 1)$$

assuming that the rates of interest payable and receivable are identical. Now if the time H_e within which the equipment is expected to pay for itself is made the variable as in the case of the determination of the true accounting life, $H_e = H$ and

$$(iI)_e = \frac{iI_i}{2}(H + 1)$$

The average net interest charge for any year within the period may now be computed for use in determining the yearly financial charges; whereupon

$$(iI)_{\text{avg}} = \frac{(iI)_e}{H} = \frac{i \cdot I_i}{2} + \frac{i \cdot I_i}{2H_e}$$

Since the second term in the equation decreases progressively as the numerical value of H increases it can be disregarded for practical purposes, so that the approximation

$$(iI)_{\text{avg}} = \frac{i \cdot I_i}{2}$$

will be acceptable for the moment.

Unfortunately no such simple expression can be employed in the determination of the net average yearly investment charge, because the capital values employed in computing interest payable and receivable are not identical and because in any comparison between two types of equipment the elements of investment differ, depending upon the extent to which depreciation of the present equipment has been achieved. Furthermore there are two means of computing the interest charges for the present equipment, one based on the original investment and the other on the book value with due regard for previously accumulated reserve fund. An analysis[7] of this situation shows that there is no difference whether interest is computed on a decreasing book value or as a constant on the original capital investment corrected by a credit from current depreciation provisions or with an average interest percentage rate, provided the interest and depreciation charges are accounted for in the proper time sequence. As a result of all derivations for interest the following two equations for the new and present equipment will be used in the later discussion:

$$H\,(iI)_{c1\text{avg}} = \frac{i(I_{g1} + K)}{2}(H + 1) + \frac{iS_{c1}}{2}(H - 1)$$

$$= \frac{i}{2}H\,(I_{g1} + S_{c1} + K) + \frac{i}{2}(I_{g1} - S_{c1} + K)$$

and

$$H\,(iI)_{c2\text{avg}} = \frac{i}{2}(H + 1)(I_b + S_{c2})$$

Total Financial Charges

Naturally in computing the total financial charges (F_1), items such as taxes and insurance must be included. However, all such items are independent of time in the determination of their annual amount since both of the above are derived from the application of a fixed rate upon a certain portion of the prime investment which is set arbitrarily by tax laws or insurance policies. Furthermore any rights relevant to the ownership of the equipment may justifiably be included in this category as well. They include royalties on patents, franchises, licenses, etc. The character of these charges has duly to be considered as either an additional cost to the original capital (prime investment) or as a yearly charge without specific time limitation, or as a charge proportional to the output of the equipment. Their treatment in the problem depends upon the characteristic of each item as established by prior agreement and the method of prorating each, either to the unit of production, on the basis of prime investment, or as an indeterminate charge over the life of the equipment. Accordingly this total accumulated value for any period of H years can be simply indicated by

$$F'' = H(tI_t + i_sI_s + \ldots.\ \text{etc.})$$

all of which can be accurately determined for any year from factory records and can be considered as a distinct group of *invariable charges.* Hence for any single equipment the *total financial charges* can be expressed as

$$HF_1 = HD + H(iI)_{c\text{avg}} + F''$$

Direct Labor, Materials, and Supplies

Turning now to the second class of obligations, relating to operating expenses (F_o), the cost of direct labor and materials will first be considered. In general these two factors need but slight treatment as their relation to the problem is obvious and their nature should be quite well understood.[8] Both factors when expressed as a yearly cost vary directly with the quantity produced (XN) and their total value for a period of H years is likewise a direct multiple.

Briefly, *material expense* is based on the required number of pieces at full capacity (N) passing through the equipment, and may be expressed as ($M + A$) in dollars per year where M represents the annual monetary equivalent of material actually needed for the finished product while A is the allowance for spoilage and waste material which normally accumulates during any year. If there is a change in the nature of the service performed, due to the introduction of a higher quality of material, the advantage thus gained will be evidenced by a reduction in waste or number of pieces failing to pass inspection, by the salvage costs as represented by the term A, or by the operating savings due in general to better methods of manufacture made possible in this manner. Otherwise the cost of materials will cancel out when making a comparison between two types of equipment.

Direct Labor Cost (L) equals the annual amount of dollars spent for direct labor on a given task at full capacity (N) during the year. If there is a gain due to the new equipment from a reduction of accidents or a lessening of workers' fatigue, it will show up eventually in the final operating savings as the general efficiency of human effort will be greater. *Direct supplies* (M_s) behave in a manner similar to either of the above items, and the same conclusions apply since only those items which are consumed in the course of production such as tool points, waste, cutting oils, lubricants, and other similar materials are to be considered a part of it. Its value for purposes of computation will be the summation of the normal yearly amount of each contributory item.

---

[7] Again the derivation of these expressions depends on a certain time series which is developed in full in the original report on this research project.

[8] See "Quantity and Economy in Manufacture," by F. E. Raymond, McGraw-Hill Book Co., 1931, for a more extended treatment of the composition of these two elements.

PREPARATION COSTS

The items of this group are distinct from direct production costs because they are independent of the quantity produced on any order and have a constant value for any lot being processed by the equipment. These costs include all charges relating to machine change over, tool preparation, order writing, production control, control laboratory, and technical engineering work pertaining only to the order or any other overhead items having similar characteristics. In the long run it cannot be said that the preparation costs (P_p) per order are entirely independent of quantity as their accumulation over a period of years depends upon the relation of the economic lot size to the average annual consumption (S_y) or demand for the product or products processed by the equipment. To account for these costs properly special formulas must be employed which have been specifically derived for the purpose.[9] Now if P' be allowed to represent the yearly accumulation of the preparation charges where P_p equals the constant cost per lot produced, differing for each product and each type of equipment, and f' and f'' are certain unit cost factors, it is possible to use the expression

$$P' = \sqrt{\frac{XNP_p}{f'}} \quad \text{for a large dollar value of inventories and storage costs}$$

or

$$P' = \sqrt{\frac{P_p}{f''}} \quad \text{for small inventories and a high work in process value}$$

where X = productivity factor, and
N = normal number of pieces produced per year at capacity, both of which will be explained more fully later on.

POWER COST

Even though the cost of power is usually treated as an item of overhead, it is in reality much more of a direct charge against production when an analysis of the cost structure is centered upon the equipment, and therefore in this case it must be considered on the latter basis as distinct in itself. Unlike the foregoing cost elements which are directly related to the quantity produced, the annual power charge (E) has two definite characteristics: one being the actual cost relating to the power consumed by the equipment, which varies directly with production; and the other the fixed capital charges relating to the power plant, transmission lines, supplementary control equipment, as well as line losses, all of which are of a general nature and do not vary with production. The first may be easily computed on the basis of the power required to perform a specific task and reduced to a unit charge as a function of time of operation or of quantity produced. The difficulty comes with the invariable charges as these are constant for the plant, department, or burden center, and have no relation to the specific equipment in any group. Thus when old equipment of one type is replaced by a more modern type there is naturally a change in the proportionate allocation to each unit of equipment in the new arrangement. If no change in the power plant or its equipment belonging to the factory is required because of new productive equipment, the influence of these invariable charges may be neglected, provided that their allocation through machine-burden rates is not unfair to all equipment individually in the group affected. On the other hand, if a change in the power equipment is necessitated by replacement or installation of new equipment in the factory, the latter must carry the burden of the increased invariable charges or else this increase must be prorated to all equipment thus affected by a change in burden rates. It is recommended that the annual invariable charges (V_i) be allocated on a basis of the rated horsepower of each unit of production equipment. Hence, if E equals the rated horsepower demand for the factory, the unit charge per rated horsepower will be

$$v = \frac{V_i}{E}$$

and then the annual demand charge for a piece of equipment having a horsepower rating of e_{eq} will become $W_i = v_i e_{eq}$ in dollars per year. The variable power charges (V_v) can then be allocated on the basis of hourly or yearly production if

v_v = power consumed per piece or
v_v' = power consumed per hour
NX = pieces produced per year
t_o = the time to process one piece in hours, and
XT_N = actual working hours per year
$= NXt_o$

Hence, the general power-consumption charge for any equipment will be

$$\left.\begin{aligned} W_c &= v_v XN \\ &= v_v' XT_N \end{aligned}\right\} \text{in dollars per year.}$$

UPKEEP EXPENSE

In ordinary accounting practice, upkeep expense is treated entirely as an overhead item; however, since the magnitude of this form of expense is completely controlled by the nature of the equipment, it must be given separate consideration. Upkeep is composed of three elements which incur expenses over a period of years in quite different ways. The first is that arising from the daily attention given to the machine by its operator or millwright in the form of lubrication, cleaning, adjustments, and the like, the annual cost of which is directly related to production. This element is naturally a function of quantity [$f(X)$]. The second is maintenance, which must be carried on regardless of the use of the machine in order to insure its being in a ready-to-run condition. Its cost over a period of years is a direct function of time [$f(H)$]. The third is repairs, which are necessary to replace worn out parts and to keep the equipment up as nearly as possible to its original state of efficiency, and consequently its cost may increase year by year as more and more parts have to be replaced. The cost of this element throughout the life of the equipment is undoubtedly a complex function of time [$f(H^\mu)$].

Accordingly, the yearly cost of maintenance becomes

$$M_y = m_1 + m_2 f(X) + m_3 f(H)$$

where m is any constant.

Then the total cumulative maintenance cost for H years is

$$\sum_0^H (M_y) = M_H$$

Now if the yearly increment of any element in maintenance cost for which m is the coefficient is a linear function ($M_y = mH$), then

$$\sum_0^H (M_y) = M_H = \frac{m}{2} H(H + 1)$$

---

[9] See "Quantity and Economy in Manufacture," by F. E. Raymond, p. 172 for generalized formulas, and p. 37 for their various derivatives for special cases, from which an evaluation of the factors f' and f'' can be obtained.

$$= \frac{m}{2} H^2 + \frac{m}{2} H$$

In this case the total accumulated charge is represented by the sum of all the rectangles for the reason that each one equals the yearly increment. Evidently (see Fig. 2) the area under the curve is smaller by $Hm/2$, bringing up the total to

$$M_H = \frac{m}{2} H^2 + \frac{m}{2} H$$

However, if the yearly cost of maintenance becomes a more complex function $[f(H)]$,

$$M_y = m \cdot f(H)$$

or, for example,

$$M_y = m_1 + m_2 X + m_3 H^{\mu}$$

where

$$\sum_{0}^{H} (M_y) = M_H$$

Here again the summation of M_y is not only the area under the curve but an additional summation of a series of triangles standing beyond the curve, so

$$M_H = H(m_1 + m_2 X) + m_3 \frac{H^{\mu} + 1}{\mu + 1} + \frac{m_3}{2} - H^{\mu}$$

In combination with a functional depreciation charge and its accumulation at any time H in accordance with the resale value of the equipment, it is well to note that such equations might lead to the determination of a minimum point of yearly cost at a future time. This investigation, however, was not intended to pursue all the characteristics of the individual equipment, but only those for alternative equipment with the view of comparing them.

SPACE CHARGES

Similarly this group of charges normally belongs in overhead, and is composed of rent items such as property taxes, insurance, interest, depreciation, upkeep, repairs on buildings and fixtures, and service items such as heat, light, ventilation, and the like. However, since it is common practice to allocate such items through machine-burden rates where the proportion of the whole borne by each unit of equipment is prorated on the basis of the floor area occupied by it, a change in equipment where greater or less floor space is utilized will seriously alter the distribution of this part of the overhead. Furthermore, if no cognizance of the importance of this item is taken, no opportunity will be provided for accounting for any savings which may arise through a reduction in the area devoted to production. This is important because in many instances processes may be consolidated by new equipment and other work may then be performed in space thus made available, with a marked saving in overhead and the possible avoidance of having to add to the factory buildings in the near future. Even though no immediate saving can be made in rental and space charges, unless the property is not owned outright and the contemplated changes are extensive, it seems illogical to penalize a product by continuing, as a part of its ultimate cost, charges which do not properly belong to it. With the new equipment, if less space is occupied, the burden of the remaining unoccupied space left over from the previous equipment should become a general charge against the management until such a time arrives that it can be properly utilized, so that the product affected by the change can derive its full share of the benefit. When greater space is required than formerly, there is a deduction from the general burden of unoccupied space borne by the particular department or burden center in which the equipment is located, and then a greater burden of space charges must be transmitted through the equipment to the product. Now if:

A_t = total space or area of a productive department in square feet
A_{eq} = total space occupied by equipment including space for its operator, work bench, raw and finished material, etc.
A_w = all space required for aisles and other general departmental purposes
A_u = all unoccupied space, and
b_s = summation of all space charges per year.

$$A_t = A_{eq} + A_w + A_u$$

and the unit space-charge factor becomes

$$s_p = \frac{b_s}{A_t} \text{ (dollars per year per square foot)}$$

Then if a_t = area occupied by the unit a_q plus that assigned to it, $a_w = a_q + a_w$, both in square feet, where $a_w = A_w a_q / A_{eq}$, the annual burden carried by any unit of equipment will be

$$B_s = s_p a_t + s_p A_u \frac{a_t}{A_{eq} + A_w}$$

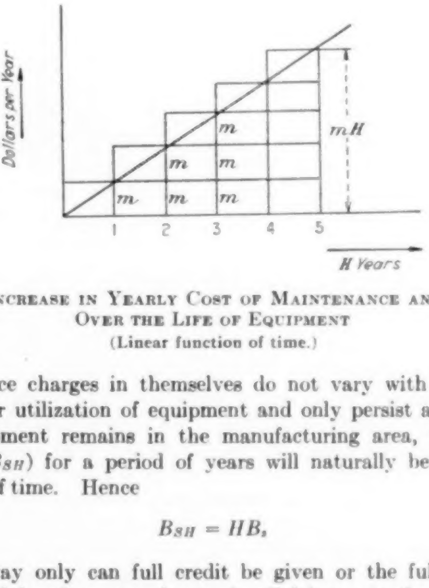

FIG. 2. INCREASE IN YEARLY COST OF MAINTENANCE AND REPAIR OVER THE LIFE OF EQUIPMENT
(Linear function of time.)

Since space charges in themselves do not vary with the production or utilization of equipment and only persist as long as the equipment remains in the manufacturing area, the total charge (B_{SH}) for a period of years will naturally be a direct function of time. Hence

$$B_{SH} = HB_s$$

In this way only can full credit be given or the full burden distributed for the space charges in all fairness to the product, and then it is up to the management to see that the second term in the expression for B_s is made to approach a value of zero by profitably utilizing the unoccupied space. If this is not done the burden of the space charges is increased upon all equipment within the department or production center.

OVERHEAD EXPENSES

The third and last class of obligations contain all expenses and charges which are normally considered a part of overhead (F_B), exclusive in this case of such items as have been previously given separate treatment because of the fact that their magnitude is largely dependent in some manner upon the specific type of equipment. In general those items which will now be considered under this classification will be those that are derived from some service supplementary or complementary to actual production, and whose origin is in no way connected with the direct operation of the equipment or the function it performs. Normally such items are budgeted for the year and allocated to departments, production centers, productive units, or the product itself, and distributed through burden rates computed either on man-hours or machine-hours according to their association either with the product or the equipment and their individual origin or behavior. Those which vary with production will be combined into a man-hour burden rate and those which continue irrespective of production will be combined into a machine-hour rate in the sense that they accumulate as long as the plant is in a ready-to-run condition. Thus an accounting can be made of the cost of idleness. The all-important point in the computation of the natural obligations which are incurred in the course of manufacture or performance of a service is that every element of expense must be accounted for and related eventually to the product in some manner characteristic of its particular behavior at the point in the production sequence nearest to that where the expense originated. Normally such refinement in accounting practice is unessential; however, in the determination of an equipment policy where one picks out and studies a particular operation and the facilities employed to perform the task, all of the obligations must be recognized and properly related if the economic advantage of one type of equipment over some other is to be ascertained.

The great weakness of burden charges made in the formulations by several authors and in the formula of The American Society of Mechanical Engineers is that they all contemplate charging the burden at a percentage rate on some direct cost related to the amount of work done. As a matter of fact, various kinds of equipment in operation call for widely varying investment charges, operating expenses, and all the remaining items making up burden as well. This fact is entirely disregarded if a uniform burden rate per hour, or a percentage of the labor cost, is added to the strictly financial and prime operating expense. The essential object of the new equipment being to reduce either labor cost or production time, the old methods of applying overhead are apt to charge a smaller amount of burden to the superior equipment, although this equipment might in reality be the source of higher general expenses. Furthermore there is the danger of duplicating costs which have already been accounted for separately. This use of such an ideal cost-accounting scheme is possible, as will be shown later through the introduction of "Differential Costs." Thus automatically from all productive overheads, general burden, or even administrative burden, only those are selected which in any way originate or disappear by virtue of the adoption of a new type of equipment.

The allocation of all items of overhead expense must be given very careful consideration in this particular problem as there is a serious element of danger connected with the use of ordinary burden rates, because, if they be employed without regard to the origin or nature of the specific expense items relating to the new equipment on an equal basis with the old, the changes in relative performance between the two types may make it impossible to adequately distribute the total burden of overhead which should rightly apply in each case. Some overhead items apply directly to the product, while others apply only to the machine. Furthermore some items accumulate on the basis of space or operating time, while others accumulate on the basis of the time the machine is actually installed, whether in use or not, the horse power rating, the number of machines under one operator, the lot size, the quantity produced, or the capacity of the machine in pieces per hour. Moreover, overhead may accrue to the machine or the product not only from the use of the equipment but also from the allocation of general or departmental expenses which apply to all machines in the department. Charges of this nature are derived from general administration expense, cost of control, time keeping and records, supervision, service, supplies consumed in the course of departmental operations, transportation, indirect labor, and helpers. These items may each have specific characteristics of its own as described above, or if not they can be treated as a lump-sum item of general overhead. At all events, in figuring the obligations of this nature which must be borne by a new piece of equipment, the treatment of overhead must be so worked out that the summation of all obligations prorated to each equipment item in a department after any proposed change will equal the summation of all obligations before the change or the total obligations for the department in either case. For instance, a change in machine capacity may require the readjustment of existing burden rates for all items accumulating on time and independent of the quantity produced, even if there is no change in the total departmental overhead burden due to the change in equipment. In the computation of burden rates for use in problems relating to equipment policies it is recommended that the total annual expense for any overhead item be divided into its variable and invariable items and reduced to two hourly rates as follows:

(*a*)

$$\frac{\text{Total fixed charges}}{\text{Year}} \times \frac{1}{\text{Total rated capacity}} = \frac{\text{Unit demand rate}}{\text{Year}}$$

$$\frac{\text{Unit demand charge}}{\text{Year}} \times \frac{\text{Year}}{\text{Standard Working Hours}} = \frac{\text{Unit demand rate}}{\text{Hour}}$$

(*b*)

$$\frac{\text{Total Variable charges}}{\text{Year}} \times \frac{\text{Year}}{\text{Total production}} = \text{Unit consumption rate}$$

(*c*)

$$\frac{\text{Unit consumption rate}}{\text{Hours}} + \frac{\text{Unit demand rate}}{\text{Hours}} = \text{Total hourly service rate}$$

(*d*)

$$\text{Man-hour rate} + \text{machine-hour rate} = \text{Total burden rate}$$

or

$$b_{mn} + b_{egn} = b_r$$

Accordingly, if T_x equals the actual operating man-hours per year and T_N the normal available working hours per year, the yearly variable burden related to any piece of equipment will be

$$O_x = b_m T_x = b_m X T_n$$

and the yearly invariable burden born by the equipment will be

$$O_f = b_{eg} T_N$$

Elements of the Annual Equipment Cost

The foregoing analysis of all cost elements which are directly or indirectly incurred by the introduction of equipment of any sort to facilitate production or the performance of some service, is of utmost importance if correct conclusions as to the true economic utility of any single piece of equipment are to be determined. Only in rare cases will each item discussed above be required in its entirety, and in the solution of any problem only those elements or that portion of their mathematical expression need be used which the circumstances demand. In the further development of this subject little attention need be paid to these individual elements as long as their specific characteristics are recognized, so that when application of any resulting formulas is desired, simple substitutions of values in the correct locations can be made. In the case of operating expense (F_o), it will be seen that certain yearly costs vary directly with production $f(X)$, and all such items will be collected into a group to be known as *Quantitative Costs in Direct Proportion* (XC_q), where X stands as the factor of productivity. If N equals the standard number of pieces to be produced in a year or the capacity of the equipment and N_z the actual production in a year to meet the normal sales demand (S_{yz}),

$$X = \frac{N_z}{N}$$

Hence

$$XC_q = X(M + A + L + M_s + W_c + O_z + m_2 + \ldots\text{etc.})$$

A similar group which varies in a more complex manner with production will be termed *Quantitative Costs in Functional Proportion* [$f(X)C_p$]. Typical of these is the preparation cost P', so that

$$f(X)C_p = \sqrt{\frac{XNP_p}{f'}} + \ldots\ldots\ldots\ldots \text{ etc.}$$

A third group under this classification are those which can be designated as *Time-Related Costs in Functional Proportion* [$f(H)C_t$], which for the most part are characterized by repairs under upkeep costs (M_y) when they increase from year to year. Hence

$$f(H)C_t = \frac{m_3}{H}\,\frac{H^\mu + 1}{\mu + 1} + \frac{m_3}{2}\,H^{\mu - 1}$$

The other portions of upkeep such as regular attendance (m_2x) and regular maintenance (m_1) naturally will fall under other groups. If repairs be uniform over the life of the equipment, the average yearly cost can be included directly with the maintenance expense.

A fourth grouping may also be established that will comprise all annual charges or expenses which do not vary from year to year, and this will be composed of certain cost elements contained in each of the three classes of obligations. This group will be known as *Invariable Costs* (C_f), and its value may be computed from the expression

$$C_f = F_I + O_s + W_i + m_1 + B_s + \text{etc.}$$

Now the total yearly operating or *Producing-Equipment Cost* (C_y) can be expressed by

$$C_y = C_f + XC_q + f(X)C_p + f(H)C_t$$

and evaluated when the correct expressions and their equivalent numerical values are introduced, as this equation contains every element of the direct obligations which are incurred through the use of equipment. If annual depreciation and any other similar obligations be deducted from the total yearly financial charges (F_I), they can be combined into a fifth group, the elements of which will have the characteristic of being *constants throughout the entire life of the equipment.*

PREVIOUS TYPES OF SOLUTION

Since an expression can be obtained through which the entire obligations may be appropriately accounted for with regard to any specific type of equipment, it now becomes possible to compare various types of equipment which are adapted to the performance of certain tasks and determine which is the most suitable in terms of its economic utility. Most often in the mind of the industrial executive the criterion for judging the utility of any type of equipment is expressed by the ability of the equipment to perform a certain task as to quality at least as well as the present equipment or one that is taken as a standard of comparison, to effect certain economies in operation, and to pay for itself in the shortest possible time. The question now arises as to the best manner in which to determine that this criterion can be satisfied by one type of equipment more satisfactorily than by any other. Numerous attempts have been made to derive a formula for this purpose, but none of them have proved entirely suitable to the problem, and in no case was any one universal in application. To summarize the existing formulas, they can be classified according to methods of solution as follows:

a Based on yearly cost of service[10]
b Based on capitalized cost of service[11]
c Based on unit cost of service[12]
d Based on capitalized unit cost of service[13]
e Miscellaneous.[14]

The fact is that all of these formulas fail in some respect to meet the criteria for an appropriate solution of the problem as set forth at the beginning of this paper, although each formula arrives at an approximate value for the *true accounting life.*[15]

THEORY OF DIFFERENTIAL COSTS

Accordingly a new basis of comparing the economic utility of alternative types of equipment was evolved upon the theory that only through the relation of the total obligations incurred by any two types of equipment over an indefinite number of years such that at some time the obligations of both would become equal could the economic superiority of one type be established. Hence the elapsed time or period (determined by the solution of this relation) required for one type to pay back to its owner all obligations incurred by him in its original purchase and expected of it while in operation, becomes one measure of the economic utility of that equipment for the specified task, and as such it has been termed the *True Accounting Life* (H_t).

[15] For the analysis of previous types of solution see "A Study of Formulas for the Selection and Replacement of Manufacturing Equipment," by H. O. Vorlander, Graduate Thesis 1930, Course XV, Department of Business and Engineering Administration, Massachusetts Institute of Technology, or the official report on this research project.

In such a comparison it is assumed that a new type of equipment is to be compared with some type now in use or with some standard type chosen as representative of a desired standard of performance. Now to express mathematically, so as to obtain the desired solution, and measure this relationship the concept of *differential costs* was introduced. By this is meant the difference between the total obligations (C_{H2}) of the present or existing equipment over the period of time ($H = H_t$) and the total obligations (C_{H1}) for the new or proposed equipment over the same period of time. Thus if the symbol ΔC_H be employed to indicate the differential cost it may be evaluated by the expression

$$\Delta C_H = C_{H2} - C_{H1}$$

As a result of this relationship differential costs will appear among all the elemental cost items, so that hereafter a standard notation will be employed where, for instance, in the case of material costs

$$\Delta(M + A) = (M_2 - M_1) + (A_2 - A_1)$$

or

$$-\Delta(M + A) = (M_1 - M_2) + (A_1 - A_2)$$

or

$$\Delta M - (-\Delta A) = (M_2 - M_1) - (A_1 - A_2)$$

as might be the case if $A_1 > A_2$.

The Break-Even Point and the Reward for Risk

Thus to satisfy the foregoing criteria for the true accounting life as the measure of the economic utility of some proposed type of equipment, it becomes obvious that the total obligations incurred by both types over the period H_t must be equal and that $\Delta C_H = 0$. This condition will be designated as the *break-even point.* Naturally if either type of equipment be continued in operation beyond the time H_t where this situation occurs, that type having the lower operating and overhead costs will have a distinct economic advantage over the other type with higher costs. This is, of course, due to the fact that the savings in such costs are sufficient to pay back to the investor or owner of the equipment all charges incurred through the adoption and installation of the higher priced equipment in the time H_t, including the original outlay of capital. Therefore it would seem that if all financial operating and overhead costs are contained in the value of the yearly producing-equipment costs for the existing type (C_{y2}) and for the proposed type (C_{y1}), the break-even point, and hence the true accounting life, could be computed from the fact that

$$\Delta C_y = C_{y2} - C_{y1} = 0$$

However, there is one more obligation which, though of an implied nature, is very real, and that is the necessity for maintaining unimpaired the earning power of the capital facilities employed. This is due to the fact that all capital invested in manufacturing or productive operations must return to its owner not only the cost for its use but also a reward for the risks involved in its investment. This reward for risk when it has accumulated eventually appears as that portion of the dividends paid over and above that equal to the cost of capital at the current market rate. Hence if the investment in equipment for the performance of some task or service is increased so as to reduce the operating and overhead costs through better production methods, an equal return or reward must be earned upon the added capital invested in the new equipment. Accordingly, if the current rate of return on all capital invested in the productive assets of the enterprise be r_a, the extra reward for the risk of investing this additional capital will become

$$H\,\Delta C_r = r_a(I_{g2} - I_{g1})H$$

and then the total direct and implied obligations for both types of equipment will be

$$C_{H1} = HC_{y1} + r_a I_{g1} H$$

and

$$C_{H2} = HC_{y2} + r_a I_{g2} H$$

The true break-even point (see Fig. 3) can now be expressed as

$$\Delta C_H = H(\Delta C_y + \Delta C_r) = H\,[(C_{y2} - C_{y1}) + (C_{r2} - C_{r1})] = 0$$

Evaluation of the True Accounting Life

Since the time in which some proposed type of equipment can pay for the increased financial obligations out of operating economies is the means of justifying in the eyes of individual executives the adoption of this new type over some existing type, the true accounting life (H_t) will be the time in which full depreciation of the original capitalized investment (I_g) plus any write-off of incidental installation charges (I_{inc}) less any legitimately anticipated salvage value (S_v) can be achieved. Hence the time H_t will be the logical basis for establishing a sound depreciation policy and the annual rate of depreciation, such that $d = 1/H_t$. In later portions of this study this value will be recommended as that for the depreciation rate in place of an arbitrary accounting rate d_a which has no relation to the existing obligations. Accordingly, with these facts in mind, the time H_t can be determined from the following equation, if the two financial items for interest and depreciation be written out in full and the appropriate expression for any case be introduced for the remaining items. If

$$C_{H1} = H\left[\frac{(I_{g1} + I_{\text{inc1}} - S_{e1} + K)}{H} + \frac{i}{2}(I_{g1} + S_{e1} + K) + \frac{i}{2H}(I_{g1} - S_{e1} + K) + C_{y1}'' + C_{r1}\right]$$

where $C_{y1}'' = C'_{f1} + X_1 C_{q1} + f(X_1)C_{p1} + f(H)\,C_{t1}$ and

$$C'_{f1} = C_{f1} - D_1 - (iI)_{\text{cavg1}}$$

and if

$$C_{H2} = H\left[\frac{I_b - S_{e2}}{H} + \frac{i}{2H}(H + 1)(I_b + S_{e2}) + C_{y2}'' + C_{r2}\right]$$

where $C_{y2}'' = C'_{f2} + X_2 C_{q2} + f(X_2)C_{p2} + f(H)C_{t2}$ and

$$C'_{f2} = C_{f2} - D_2 - (iI)_{\text{cavg2}}$$

and since for the break-even point $C_{H1} = C_{H2}$,

$$H = H_t = \frac{I_{g1} + I_{\text{inc}} - I_b + K + (S_{e2} - S_{e1}) + \frac{i}{2}[(I_{g1} - I_b + K) - (S_{e2} - S_{e1})]}{(C''_{y2} - C''_{y1}) + (C_{r2} - C_{r1}) - \frac{i}{2}[(I_{g1} - I_b + K) - (S_{e2} - S_{e1})]}$$

In order to avoid compound functions of time $f(H)$, which would greatly complicate the use of this equation in ordinary practice, the salvage value S_v for either type of equipment has been taken as the ultimate scrap value S_e instead of $S_v = f(H)$ as is actually the case when the situation $H = H_t$ depends upon the break-even point. Similarly, the group of cost items which, if they existed, would appear in the item of time-related costs in functional proportion $[C_t f(H)]$, have been disregarded, assuming that in ordinary cases these items would be directly proportional to time and would be included under the group of invariable yearly charges C_f. Of course, if a true mathematical picture is to be obtained of the actual situation as governed by known events where, for instance, the annual sales curve could be projected accurately into the future $[S_{yH} = f(H)]$, it would be necessary not only to insert these functional values for S_y and C_t but also to relate all quantitative costs $[XC_{qH} + f(X)C_{pH}]$ for the entire period (H) to time through the expression

$$[XC_{qH} + f(X)C_{pH}] = HXC_q + f(HX)C_p$$

where

$$HX = \frac{\sum_0^H N_s}{N} = \frac{\int_0^H S_y f(H)dH}{N}$$

and the total sales for the period H is $S_{yH} = S_y f(H)$. However, if these relations be introduced into the equation $C_{H1} = C_{H2}$ and solved for H, the resulting value for H_t will only have a theoretically useful value. Fig. 3 will assist the reader in visualizing the relationship of all obligations or cost elements and the reason that there exists a point H_t where these obligations for alternative types of equipment become equal and are satisfied.

BASIS FOR DETERMINING THE TRUE ECONOMIC LIFE

In specifying the criteria for the true accounting life within which any proposed equipment can return its original cost and pay for all obligations out of operating economies, no consideration was given to the fact that normally the installation of new equipment implies that these operating economies should be sufficiently adequate to permit cost reduction, the realization of a larger earning power, and eventually price reductions to customers. This situation changes quite radically the aspect of the problem. Now the criterion becomes the time H_r, the true economic life within which all obligations can be met, including depreciation plus an accumulation of savings equivalent over a period of years H to the total cost reduction or extra profits desired on all items produced or services performed by the equipment in the same period. This entails a complete analysis of the entire price-cost structure of each of these products or services, and the introduction of the sales price or its equivalent. The total annual revenue from the sale of any one of these may be expressed by

$$pS_y = \Sigma R_{eq} + R_w + C_b + \Sigma C_y$$

where p = unit net average sales price
S_y = average annual consumption or sales demand
ΣR_{eq} = total annual return on the investment in all equipment employed in a specific process
R_w = total annual return on the investment in inventories and work in process for a specific product
C_B = total annual portion of the cost of doing business allotted to a specific product (general financial, sales, and administrative expense), and
ΣC_y = total annual cost of operation for all operations and equipment employed in that process. (Previously described and defined.)

As developed in another study,[16] the total revenue from any product or service can be broken down into its elements and an equivalent piece price (p') established for the product at any point in the process sequence, so that

$$p'S_y = R_{eq} + C_y$$

When multiple products are handled by a given unit of equipment a summation in this equation of identical elements for each product can be made in order to obtain the total equivalent yearly revenue. This whole development is made possible by the fact that the total profit from annual sales of a product can be expressed as so many dollars of return on each dollar of capital invested productively in either equipment of all kinds, work in process, or inventories. Accordingly if $(\Sigma I_{eq} + I_w)$ dollars are invested in the production of an article or the performance of a service, there will be a uniform rate of return r_a on that capital so that if

$$\Sigma R_{eq} + R_w = pS_y - C_B - \Sigma C_y$$

$$r_a = \frac{\Sigma R_{eq} + R_w}{\Sigma I_{eq} + I_w} = \frac{pS_y - C_B - \Sigma C_y}{\Sigma I_{eq} + I_w}$$

or for any equipment in the process sequence,

$$R = R_{eq} = r_a I_g = p'S_y - C_y$$

THE EARNING POWER THROUGHOUT LIFE OF ANY EQUIPMENT

Since it has been established that all equations for determining the economic utility of equipment must be based on relations involving all obligations, now of any sort, upon their accumulated totals over an indefinite period of H years, it can be stated that

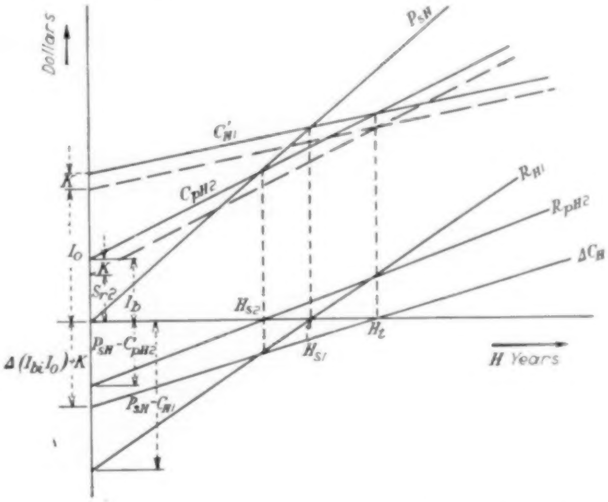

FIG. 3 RELATION OF ALL OBLIGATIONS AT THE BREAK-EVEN POINT FOR DETERMINING THE TRUE ACCOUNTING LIFE (H_t)

$$P_{SH} = Hp'S_y = [r_a I_g + D_a + C_y']H$$

when for convenience $D_a = I_d/H_a$ and $C'_y = (iI)_c + C''_y$, where C''_y has been already defined, have been inserted. The value to be used for H_a in computations may be either an arbitrarily established accounting time for depreciation to become completed or the mathematically correct time H_t just previously derived. Hence if provision for the financial obligations of depreciation and reward for risks of doing business is to be made within the period H,

$$HR + D_a = P_{SH} - C'_y H$$

or in any average year

$$R + D_a = p'S_y - C'_y$$

Now if the portion R_H of the total revenue for the period H above all accumulated current yearly charges or obligations contained in HC'_y normally available for depreciation and a return on the investment is

---

[16] See "Quantity and Economy in Manufacture," by F. E. Raymond, McGraw-Hill Book Co., 1931, chapters X, XI, and XII.

$$R_H = H(R + D_a) - (I_o + K)$$

because if $R_H = P_{SH} - C_H$ by definition, $R_H = (HR + HD_a + HC'_y) - (I_o + K + HC'_y)$ where $I_d = I_g + I_{\text{inc}} - S_v + K$ in general, and $I_o = (I_g + I_{\text{inc}} - S_v)$ in the original expression for C_H, then for the proposed or new equipment,

$$R_{H1} = H(R_1 + D_{a1}) - (I_{o1} + K_1)$$
$$= H(p'_1S_{y1} - C_y'_1) - (I_{o1} + K_1)$$

and for the existing or present equipment

$$R_{H2} = H(R_2 + D_{a2}) - (I_{o2} + K_2)$$
$$= H(p'_2S_{y2} - C'_{y2}) - (I_{o2} + K_2)$$

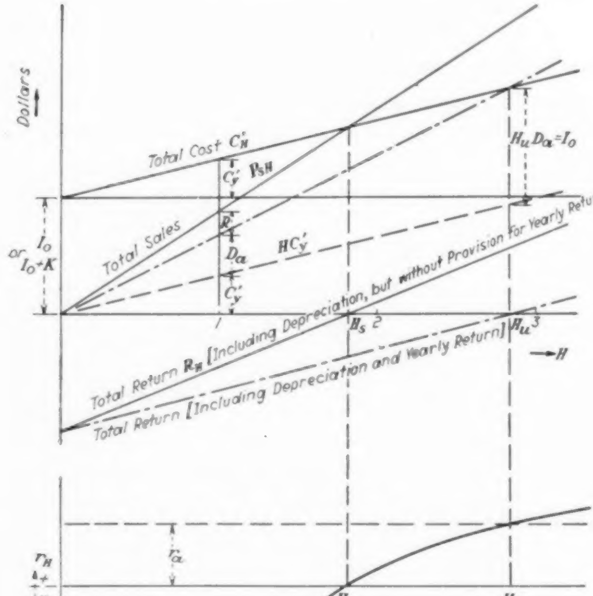

FIG. 4 RELATIONSHIP OF TOTAL SALES REVENUE AND ALL DIRECT AND IMPLIED OBLIGATIONS FOR THE DETERMINATION OF THE FUNCTIONAL RATE OF RETURN (r_H), THE CRITICAL LIFE (H_s), AND THE UTILITY LIFE (H_u) FOR ANY SINGLE UNIT OF EQUIPMENT

However, since this last expression R_{H2} refers to the time the existing equipment was installed and inasmuch as a definite time H_r has elapsed since then, it is advisable also to express R_{H2} at the present time at which the replacement policy is being determined. Accordingly if the investment in the existing machine now has only a depreciable value of $I_b - S_{c2}$ remaining due to an accumulation of $d_{a2}(I_{g2} + I_{\text{inc}2} - S_{r2} + K_2)H_r$ dollars in a reserve fund over this elapsed time,

$$R_{H2} = H(R_2 + D_{a2}) - (I_b - S_{c2})$$

TIME CRITERIA OF EARNING POWER

Now with these facts in hand it will be possible to penetrate into the situation still farther, as it is well to know what takes place with regard to the economic status of any equipment whether it has been in use a short or relatively long time. In the course of business a situation might arise where it was essential that the equipment policy be revised, and it would be necessary to determine the immediate economic status of some particular single unit actually in use. In other words, has it been possible in the elapsed time for the equipment to have earned enough money to pay for itself, assuming that all savings over cost are devoted to this purpose? From the equation for R_{H1} it is evident under these conditions that if the elapsed time $H = H_r = H_s$, the critical life for the equipment will be expressed by

$$H_s = \frac{I_o + K}{R + D_a} = \frac{I_g + I_{\text{inc}} - S_r + K}{R + D_a}$$

In this case original cost besides all obligations will be paid, except that no return on the investment can be earned.

On the other hand, if the elapsed time $H = H_r = H_u$, where

$$H_u = \frac{I_o + K}{D_a} = \frac{I_g + I_{\text{inc}} - S_r + K}{D_a}$$

the normally anticipated return on the investment at a rate r_a can be earned besides the payment of all financial and operating expenses. This time H_u, the *utility life*, will coincide with the time H_t, the true accounting life, only in the special case where $d_a = d = 1/H_t$. Fig. 4 will aid in visualizing these conditions. In all such determinations it must be assumed that the actual value of the term $H(R + D_a) > (I_o + K)$ and that $P_{sy} > C_y'$ if any valid interpretation of the solution of any problem is to be obtained.

THE FUNCTIONAL RATE OF RETURN

Now if, in the latter case especially the total accumulated return on the investment be analyzed year by year from the time of the original installation of the equipment forward, it will be found that the rate r_H, obtained by dividing the annual average R_H/H of the total profits applicable to a return on the investment up to a given date by the capitalized gross investment I_g on which the return is to be earned, will vary (see Fig. 4) from minus infinity ($-\infty$) at the start to zero at the time $H_r = H_s$, and will reach a value of $r_H = r_a$ at the time $H_r = H_u$. Below the point H_s the value of r_H is negative, because some of the revenue normally applicable to a return on the investment is really devoted to depreciation. Above this point the value of r_H is positive. Now this *functional rate of return* is of much significance in the whole problem of the selection and replacement of equipment, as it is the measure of the potential earning power of any type of equipment performing any task or service at any instant of time throughout its actual serviceable life. If, for instance, the actual functional-rate curve for a given equipment is known, and it is advisable to ascertain whether a certain earning power (r_{des}) can be achieved after a given period of operation, one can trace along the curve until the ordinate representing the rate desired (r_{des}) is reached, and then read off from the corresponding abscissa the time required to attain it. If the time thus found is equal to or less than that in mind, the situation is satisfactory. Furthermore, if it is important that a reduction in price be brought about, a similar procedure may be employed to ascertain whether the functional rate of return will permit the revision without lowering the value of $r_{H'}$ below that of r_{des}, or whether it will so alter the position of the curve, its general shape remaining the same, that the rate r_{des} or at least the rate r_a can be still attained in a given time without the danger of equipment obsolescence interfering with the new price policy. Accordingly, if such information can be obtained from the functional rate of return its value at any time H can be determined for

$$r_H = \frac{H(R + D_a) - (I_o + K)}{HI_g}$$

$$= \frac{R + D_a}{I_g} + \frac{(I_o + K)}{HI_g}$$

$$= \frac{p'S_y - C'_y}{I_g} - \frac{I_o + K}{HI_g}$$

As a corollary to this situation the time H_{des} at which any desired total accumulation of the return on investment as expressed by the functional rate r_{des} can be attained may be determined from

$$H_{des} = \frac{I_o + K}{(p'S_y - C'_y) - r_{des}I_g}$$

$$= \frac{I_o + K}{R + D_a - r_{des}I_g}$$

Furthermore, in order to connect this portion of the subject with that devoted to the determination of the true accounting life, it can be shown[17] that $\Delta R_H = -\Delta C_y$.

Relative Earning Power of Equipment

Now when it comes to the comparison of alternative types of equipment especially adapted to the performance of a certain task to determine which has the greatest economic utility, the relation of the functional rate of return for each type under the prescribed conditions has its most valuable application. Through a comparison of the two functional rate curves (see Fig. 5) it will be possible to determine at exactly what time (H_r) the overall performance of one type in terms of economic criteria will become identical with that of the other and beyond which the first equipment will excel, not only in having met its greater obligations in a shorter time and at a lower production cost, but also with a greater cumulative return even on a larger investment, or the same cumulative return at least from a lower price level. In making such a comparison the concept of relating the total accumulated obligations respectively incurred by the two types of equipment over their entire serviceable life is most essential in order that accurate conclusions may be arrived at. Otherwise unfulfilled obligations of one type of equipment cannot be properly transferred to the type which supersedes it and appropriately accounted for. To obtain an adequate picture of the circumstances which surround the problem, Fig. 5 should be referred to.

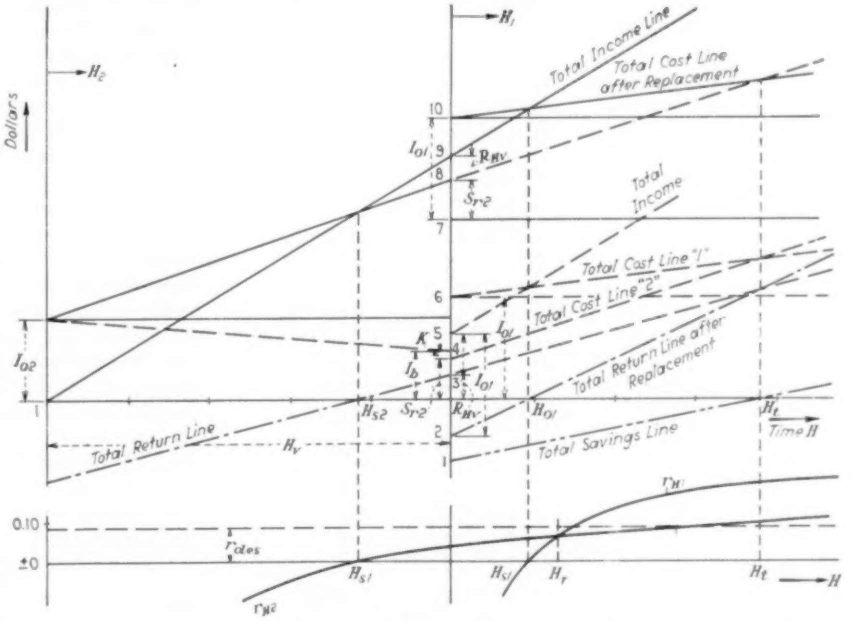

FIG. 5 RELATIONSHIP OF TOTAL SALES REVENUE AND ALL DIRECT AND IMPLIED OBLIGATIONS FROM THE TIME OF INSTALLATION OF THE ORIGINAL EQUIPMENT FOR THE DETERMINATION OF THE TRUE ECONOMIC LIFE (H_r) WHEN ALTERNATIVE TYPES ARE INVOLVED

TRANSFERENCE OF OBLIGATIONS FROM THE PAST, PRESENT, OR FUTURE

In approaching the problem care should be exercised to differentiate as well as to properly translate the various obligations of either equipment from the time at which they occur, either past, present, or future, to the time at which the comparison is being made. In so doing it must first be recognized that over the period H_v during which the existing equipment has been in service, the excess of revenue over all obligations applicable as a total return on the investment has accumulated to R_{Hv}, whereupon the functional rate of return after H_v years of operation is

$$r_{Hv} = \frac{R_{Hv}}{H_v I_{g2}}$$

In the second place, when the existing equipment is replaced the salvage value (S_v), whether in the form of net resale value S_r or scrap value (S_e), must be added to the net income over the time H_v, which will automatically enhance the net remainder between revenue and total obligations so that

$$r'_{Hv} = \frac{R_{Hv} + S_r^2}{H_v I_g^2}$$

In the third place, if a deficiency exists in the attainment of a desired average rate (r_{ydes}) of return on the investment in the old equipment over the period of H_v years, or in the fulfilment of depreciation, it must be transferred to the new equipment just as any credits due to an excess in return can be used to help justify the new type. Accordingly, if L be used to designate the total deficiency necessary to increase $r_a I_{g2}$ to $r_{ydes} I_{g2}$, the new functional rate will become[18]

$$r''_{Hv} = \frac{R_{Hv} + S_{r2} + L}{H_v I_{g2}}$$

where

$$R_{Hv} = H_v(R_2 + D_{a2}) - (I_{o2} + K_2)$$

and

$$L = I_{inc2} + K_2 + K_1 - S_{r2} + C_R + (r_{ydes} - r_a)I_{g2}H_v$$

TIME CRITERIA FOR THE NEW EQUIPMENT REFERRED TO ORIGINAL DATE

Now turning to the new or proposed equipment the economic utility of which is to be justified, these new considerations pertaining to the transfer of unfulfilled obligations will necessitate a revision of the time criteria H_s and H_u already evaluated under the simplest conditions. Out of these, three alternative criteria appear, each dependent upon the nature of the obligations transferred. First, if an excess R_{Hv} of revenue over all obligations has accumulated over H_v years from the old or present equipment, a deduction can be made in the total obligations of the new equipment throughout its life. Second, if only a certain salvage value is received upon the disposal of the old equipment, a smaller sum will have to be credited instead. Third, if a deficiency has occurred, then these unfulfilled obligations of the old equipment will appear as a debit against the anticipated performance of the new equipment. Hence it will be necessary to rewrite the expressions for H_{s1} and H_{u1} as follows, where, for the critical life,

---

[17] For definite proof of this statement see official report on this research project (Part II, p. 59), on file at the Massachusetts Institute of Technology.

[18] For derivation of the appropriate expression, as given below, see official report on this research project part II, pages 65–66.

$$H_{s1} = \frac{I_{o1} - S_{v2} - R_{Hv}}{R_1 + D_{a1}}$$

$$H'_{s1} = \frac{I_{o1} - S_{v1}}{R_1 + D_{a1}}$$

$$H''_{s1} = \frac{I_{o1} - S_{v1} + L}{R_1 + D_{a1}}$$

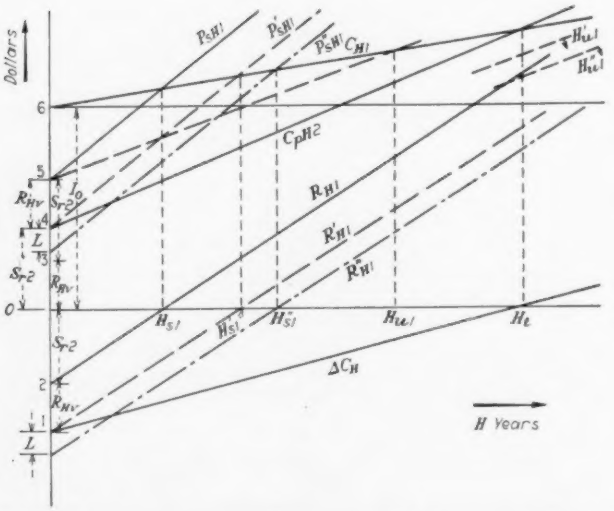

FIG. 6 INFLUENCE OF AN EXCESS OR DEFICIENCY IN TOTAL REVENUE OVER THE LIFE OF THE EXISTING EQUIPMENT UPON THE TOTAL RETURN ON INVESTMENT (R_{H2}) AND THE OBLIGATIONS (L) TO BE TRANSFERRED TO SOME PROPOSED TYPE OF EQUIPMENT

Similarly for the utility life,

$$H_{u1} = \frac{I_{o1} - S_{v2} - R_{Hv}}{D_{a1}}$$

$$H'_{u1} = \frac{I_{o1} - S_{v2}}{D_{a1}}$$

and

$$H''_{u1} = \frac{I_{o1} - S_{v2} + L}{D_{a1}}$$

It will be noticed in Fig. 6 that the effect of imposing these credits and debits on the new equipment is either to raise or depress the curve R_H representing the actual accumulation of excess revenue over all obligations available for a return on the investment. Thus when the functional rate r_{H1} for the new equipment is to be determined for any time H, it represents the composite situation for the entire serviceable life $H_v + H$ of both equipments combined.

EVALUATION OF THE TRUE ECONOMIC LIFE

At the beginning of this section on the relative earning power of alternative types of equipment it was stated that the particular type having the greatest overall economic utility would be that one which could achieve in the time $H = H_r$ an earning power, as measured by the functional rate of return r_{Hr1} at that moment, which would equal the functional rate r_{Hr2} that would have been attained by the original or existing equipment if continued in operation up to the same moment, $H_v + H_r$ years from its installation, with due consideration of the logical transfer of all unfulfilled obligations at the time H_v of actual replacement. Therefore it is important for all interested in replacement problems to know the exact time H_r when this situation occurs as it is the ultimate criterion, even superseding that of the true accounting life H_t. Because of this fact, the elapsed time H_r is designated as the *true economic life.* Accordingly, the basis for evaluating H_r is derived from the fact that, as seen in Fig. 5, the above criterion is satisfied only when the functional-rate curves for both types of equipment intersect. Nevertheless, before an equation can be established for the true economic life, a correction will have to be made in the general expression for R_{H1} to account for the transfer of obligations from the old to the new equipment. Hence if $+L$ equals all debit items (see L above) and $-L$ all credit items (see R_{Hv} above) exclusive of the salvage value S_{v2}, and the total accumulated revenue from the new equipment be corrected for these adjustments such that

$$P''_{SH1} = H(R_1 + D_{a1} + C'_{y1}) + (S_{v2} \pm L)$$

and

$$R''_{H1} = P''_{SH1} - C_{y1}$$

or

$$= H(R_1 + D_{a1}) - (I_{o1} - S_{v2} + L)$$

then

$$r''_{H1} = \frac{R_1 + D_{a1}}{I_{g1}} - \frac{I_{o1} - S_{v2} \pm L}{HI_{g1}}$$

or, disregarding L,

$$r'_{H1} = \frac{R_1 + D_{a1}}{I_{g1}} - \frac{I_{o1} - S_{v2}}{HI_{g1}}$$

Now if

$$r_{H2} = \frac{R_2 + D_{a2}}{I_{g2}} - \frac{I_{o2} + K_2}{(H_v + H)I_{g2}}$$

and $r_{Hr} = r_{H2} = r_{H1}$, for $H = H_r$,

$$H_r = \frac{I_{g1}(I_{o2} + K) - I_{g1}(I_{o1} - S_{v2}) - H_v I_{g2} I_{g1}}{2I_{g1}I_{g2}\Delta\alpha}$$

$$\pm \sqrt{\left[\frac{H_v I_{g1} I_{g2} - I_{g1}(I_{o2} + K_2) + I_{g2}(I_{o1} - S_{v2})}{2I_{g1} I_{g2}\,\Delta\alpha}\right]^2 - \frac{(I_{o1} - S_{v2})H_v}{I_{g1}\Delta\alpha}}$$

where

$$\Delta\alpha = \frac{R_2 + D_{a2}}{I_{g2}} - \frac{R_1 + D_{a1}}{I_{g1}}$$

$$= \Delta r_a + \Delta d$$

$$d = \frac{1}{H}$$

$H = H_t$ when depreciation is based on the true accounting life

H = H_a when depreciation is based on an arbitrary accounting life

r_a = rate of return on the gross capitalized investment in any single equipment as determined by the profit from the sale of products processed over it.

INFLUENCE OF OBSOLESCENCE UPON THE USEFUL LIFE OF EQUIPMENT

Since definite stages of economic utility for any type of equipment can be established in accordance with certain criteria, it now becomes possible to show what effect the occurrence of obsolescence within one of these stages will have on the utility with regard to the obligations and anticipated earning power which have yet to be fulfilled. The fact is that the hazard of impending obsolescence, whether it arises from design change or economic conditions, introduces an element of risk that obsolescence may occur at some time when all obligations incurred by the installation of new equipment cannot be completely fulfilled. If it occurs before the accounting life H_t has expired, the original capital outlay will be impaired, causing a loss in investment to the owners of the enterprise. If it occurs before the equipment has been able to earn an adequate return on the investment and thereby increase the earning power through realization of the actual economies of operation, the anticipated gain through a reduction in costs cannot be achieved, and on the basis of this obligation as well the equipment has not been able to fulfil its purpose. Furthermore, if depreciation is based upon an arbitrary accounting life H_a, the occurrence of obsolescence will again make it impossible for the machine to pay for itself in the appointed time. Accordingly, the intensity of the risk of impending obsolescence can be measured by the ratio of the time H_s, the critical life, and H_u, the utility life, at which the investment is earned back through depreciation and yields a satisfactory return, to any assumed time of obsolescence H_{ob}, at which all reasonable estimates of the ability to forecast show that obsolescence will in all probability occur.

$$\text{then } \rho_a = \frac{H_u - H_s}{H_u\left(1 - \dfrac{H_s}{H_{ob}}\right)}$$

The basis for constructing such a ratio measure becomes evident when we consider that each equipment passes through these various life-time stages, and that the chance of loss from obsolescence is diminished for two reasons: one being the capability of the equipment to attain H_s within a minimum of time, and the other its capability under the circumstances of so improving the functional rate of return between H_s and H_u that the time H_u comes as close as possible to H_s. Whenever time of impending obsolescence may occur, the ratios H_s/H_{ob} and H_s/H_u must become a minimum in order to avert the risk of obsolescence. If, as an example, $H_s = 1$, and if obsolescence is not likely to occur before ten years, the risk factor depends upon the time H_u. The factor ρ_a for H_s/H_{ob} = const., then increases when H_u comes nearer to H_{ob}, and decreases when H_u approaches H_s. The limiting values are (see Fig. 7)

$$\begin{array}{ll} H_u = H_s & \rho_a = 0 \\ H_u = H_{ob} & \rho_a = \dfrac{H_u - H_s}{H_{ob} - H_s} = 1 \\ H_s = H_{ob} & \\ & \rho_a = \infty \end{array}$$

As a result it becomes evident that any equipment, the design of which is susceptible to rapid changes or improvements, should have as short a critical life H_s as possible. Furthermore, since any equipment is also obligated to return over a period of years an appropriate profit on the investment, it is essential that the utility life H_u, at which point the return is measured by the normal anticipated rate of return r_a, should approach the time H_s as closely as possible. In fact, the new equipment should be able to attain a designated earning power at a time as much as possible in advance of the time when the existing equipment would achieve the same earning power. Thus the ratio ρ_{ob} provides a measure of the ability of any type of equipment to meet all of its direct and implied obligations before obsolescence occurs. It should be noted that this ratio is in no way a measure of design obsolescence itself, as such a factor[19] depends upon the degree to which additional entities of designers' and workers' skill have been transferred and embodied into the mechanism of the equipment.

SECONDARY CRITERIA FOR THE SELECTION AND REPLACEMENT OF EQUIPMENT

Now that definite time criteria have been established for the guidance of industrial executives in formulating an equipment policy when the specifications for two alternative types of equipment are known as well as for the tasks or services which the equipment is to perform, there are a number of other criteria, in some instances of equal importance, which can be derived from the major ones just developed.

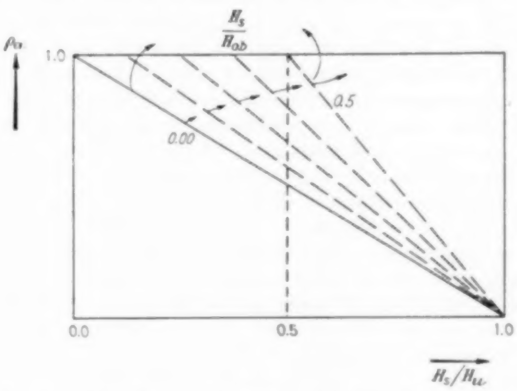

FIG. 7 CHART FOR COMPUTING THE RISK FACTOR (ρ_a) OF IMPENDING OBSOLESCENCE

1 *The Critical Sales Volume for the Economic Life.* Since the volume of business may fluctuate during the expected life of the equipment and if it should, as a result, not amount to the total volume which was anticipated as being necessary to provide the gross revenue from which adequate funds for meeting the obligations incurred by the adoption of the new equipment can be obtained, it is essential that some means of detecting any changes in the original economic situation shall be devised. Accordingly, if the total output required to meet all obligations be computed on the basis of the normal yearly capacity N_s, a figure can be obtained which, when compared with cumulative sales from year to year, will indicate whether the conditions underlying the true accounting life will be met. Hence the total economic or critical quantity to be produced during H_t years at a cost of C_{Ht} will be $S_{yHt} = N_s H_t$.

2 *Maximum Justifiable Investment.* In making the selection of equipment it is often important to know the maximum outlay of capital which the anticipated savings from operations or other sources will justify, because if there be any excess savings in favor of one particular type of equipment, a better type even

---

[19] The development of such a factor is still in a preliminary stage. See Graduate Theses (1931) of C. A. Bartells and T. R. Wigglesworth, Course XV, Department of Business and Engineering Administration, Massachusetts Institute of Technology.

than that might still be justifiable provided the opportunity for its adoption could have been foreseen in some manner. Now, if after computing the value of H_t for what appears to be the most suitable equipment available not exceeding certain limits of capital outlay, it may be found that the time H_t could within reason be extended to an estimated life H_e without incurring any danger from obsolescence and thereby permit the purchase of a more expensive type which otherwise could not have been justified. Accordingly, since the excess savings ΔC_{He}, which could be obtained from the type of equipment first selected if continued in service up to H_e after all ordinary obligations have been satisfied, will be dependent upon the relation of H_e to H_t, and since any obligations incurred by an additional investment will have to be paid for out of these savings, the maximum justifiable investment is

$$(I_{g1} + I_{\text{incl}} + K - I_b)_{\max} = \frac{H_e}{H_t}(I_{g1} + I_{\text{incl}} + K - I_b)$$

3 *Minimum Permissible Resale Value.* On the other hand, if circumstances similar to those in the previous case exist, except that it is definitely decided to purchase a certain type of equipment for an investment of $I_{g1} + I_{\text{incl}}$ at some time, and if it be advisable to postpone the purchase for the moment provided that the same price and installation costs will hold in the future, the postponement will be justifiable for such time as the second-hand resale value of the equipment to be replaced remains above a certain fixed minimum. Of course the determination of this exact time is in all probability indeterminate unless there is a rather well-recognized resale curve for the specific type of equipment. Nevertheless, if a limiting minimum resale value can be determined, it can be used through a comparison with periodic second-hand price quotations to ascertain when the replacement should be made so that the resale value actually received will not be less than this predetermined minimum. Accordingly, on the assumption that $K = I_b - S_{r2}$ and that the excess savings ΔC_{He} can be earned in the estimated time H_e, the minimum resale value for the equipment to be discarded can be determined from the expression

$$(S_{r2})_{\min} = (I_1 + I_{\text{incl}})\left(\frac{H_e}{H_t} - 1\right) - \frac{H_e}{H_t}(I_b - K)$$

Furthermore, it might be mentioned that another equation could be developed, though possibly more complicated, to express the situation where part of the savings ΔC_{He} are employed to increase the justifiable investment and the other part to reduce the minimum permissible resale value at the same time.

4 *Minimum Productivity.* It often happens in establishing a policy of equipment replacement that a new machine can be obtained and operated at a considerable economic advantage, and yet there is the danger that over protracted periods it cannot be operated at capacity N or even at a normal annual rate of productivity $N_s = S_y$. However, if the equipment can pay for itself in a comparatively short time H_t, and if there is reason to believe that it will not become obsolete before some estimated time H_e, it may be advisable to find out what minimum rate of productivity X_m will be permissible in order to properly compensate for the cost of idle time so that the equipment can still pay for itself in a reasonable period. From an analysis of the total obligations C_{yH} for any period H, it becomes evident that the portion of these obligations which continue regardless of production, namely, those elements which drop out while $X = 0$, will constitute the cost of idle time (C_{LH}). Then the yearly cost when $X = X_m$ will be

$$C_{Ly} = \left(\frac{I_d}{H} + C_f'\right)(1 - X_m)$$

From this situation it is possible to develop an expression for the minimum productivity permissible for the proposed equipment on the basis of a comparison between its performance (X_m) under these conditions and that (X_s) for the existing equipment under standard conditions, whereupon

$$X_m = \left(\frac{C_p}{C_q + \beta}\right)^2 + (X_s C_q + \sqrt{X_s} C_p)$$

$$\pm \frac{C_p}{(C_q + \beta)}\sqrt{\left[\frac{C_p}{4(C_q + \beta)}\right]^2 + (X_s C_q + \sqrt{X_s} C_p)}$$

where

$$\beta = \frac{I_d}{\dfrac{H_t}{2} \pm \sqrt{\dfrac{H_t^2}{4} - \dfrac{I_d}{C_f'(C'_{ye} - C'_{yn})}}}$$

and the yearly obligations less depreciation under standard conditions are

C'_{ye} for the existing equipment

and

C'_{yn} for the proposed equipment

if H_t = true accounting life for the proposed equipment at normal productivity X_n.

Furthermore the time H_{tXm} which it will take to complete full depreciation at minimum productivity can be computed from the equation for H_t when X_m is substituted for X.

UNIT-COST COMPARISONS

In many instances the ultimate economic utility may have a greater significance to industrial executives when the circumstances which surround any equipment problem have been translated into terms of unit costs rather than retained in their original form as derived directly from a consideration of the relative overall economic advantages of alternative types of equipment over a period of H years. Accordingly, to permit this transformation the total annual operating equipment cost C_y must be reduced to the unit equipment cost c_x, where

$$c_x = \frac{C_y}{N_x} = \frac{u_f}{X} + u_q + u_n f'(X) + f'(H)\frac{u_t}{X}$$

For simplicity in the following analysis it will be permissible to neglect the term $u_n f'(X)$ as its value when reduced to a unit basis ordinarily becomes relatively insignificant, if N_x is reasonably large, and to assume that the cost elements in the term $f'(H)u_t/X$ are constant for any year and therefore can be combined with those belonging to the term u_f/X. As a result the following deductions can be made.

1 *Savings From Changes in Unit Cost Based on Equal Amounts of Service* (see Fig. 8).

Case A. Neither equipment is fully employed:

$$\Delta C_y = N_{xa}(c_{x2} - c_{x1}) = N_{xa}\Delta c_x$$

Case B. Present equipment is fully employed:

$$\Delta C_y = N_2(u_{\min 2} - c_{x1})$$

Case C. Suggested equipment is fully employed while present equipment is overloaded:

$$\Delta C_y = N_1(c_{x2} - u_{\min 1})$$

Case D. Capacity of suggested equipment can be fully utilized, while the required amount of output necessitates additions to the present equipment.

$$\Delta C_y = N_1(c_{x2a} - u_{\min 1})$$

No attempt has as yet been made to study the cost curves of additional equipment, and there remains as well the question regarding the influence of utilizing the equipment in excess of normal capacity. The unit cost curves in Fig. 8 are plotted on the assumption that the equipment remains idle for the remainder of the allotted time. Only when the equipment is adapted to other tasks can the savings per unit of service be computed on a minimum unit cost basis which neglects the unit cost of idleness.

2 *The Number of Pieces to Maintain Same Unit Cost* that must be obtained per year from the proposed equipment can be computed as follows (see Fig. 9):

$$N_{x2}c_{x2} = N_{x1}c_{x1}$$

$$N_{x1} = N_{x2}\frac{c_{x2}}{c_{x1}} \text{ and}$$

$$X_1 = \frac{N_{x2}c_{x2}}{N_1 \ c_{x1}}$$

For any required number of pieces N_{x2} there is a corresponding number of pieces (and an equivalent time) for the suggested equipment to operate at the same unit cost.

TABLE 1 TABLE FOR THE COLLECTION OF DATA—YEARLY COST C'_y

(All in dollars per year)

Cost items	Machine tools		Jigs and fixtures		Handling equipment	
	Present	New	Present	New	Present	New
F^s						
Taxes	x	x	x	x	x	x
Insurance	x	x	x	x	x	x

Organization	x	x	..	..	..	..
Supervision	x	x	..	..	..	..
Power	x	x	..	..	x	x
Transportation and storage	x	x	..	..	..	..
Space (assigned space charge)	x	x	..	..	..	..

3 *Capacity of New Equipment Required to Obtain Equal Unit Cost at the Break-Even Point:*

$$N_b = \frac{u_{f1}N_1 - u_{f2}N_2}{\Delta u_q}$$

also

$$X_{b1} = \frac{N_b}{N_1}$$

This number of pieces is the critical or minimum number in order to obtain an economic advantage from the suggested equipment.

4 *Minimum Time* on proposed equipment to turn out the minimum number of pieces:

$$T_{\min} = \frac{N_b T_n}{N_1} = X_{\min} T_n \text{ (hours per year)}$$

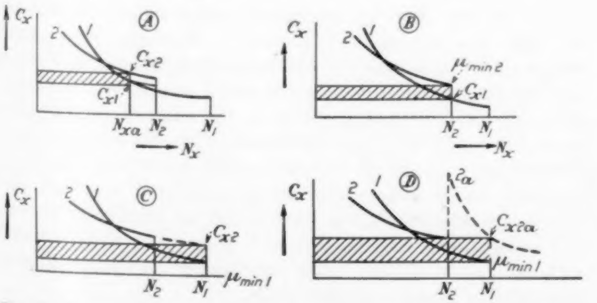

FIG. 8 SAVINGS FROM CHANGES IN UNIT COST DUE TO THE REPLACEMENT OF EQUIPMENT BASED ON EQUAL AMOUNTS OF SERVICE

where T_n equals the normal working hours per year at capacity.

5 *Yearly Cost of Idle Equipment.* If equipment is operated only a portion of the available time at a normal rate of operation but with resulting idleness during the rest of the year,

$$C_{is} = u_f(N_{x1} - N)$$

where N_x is the reduced output and N the normal amount thereof. This item, however, cannot be an absolute figure unless the unit cost of invariable charges (u_f) comprehends all original expenses.

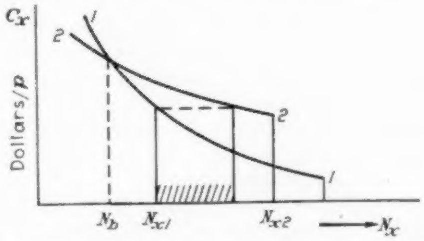

FIG. 9 RELATIONSHIP OF UNIT COSTS FOR THE DETERMINATION OF THE PRODUCTIVITY OF THE PROPOSED EQUIPMENT SUCH THAT UNIT COSTS ARE UNALTERED

6 *Technical Sales Arguments.* The information derived from the foregoing analysis and comparisons of relative operating proficiency for alternative types of equipment will be of value to the manufacturers of equipment because the technical advantages of each type can be presented in terms of the unit cost of the product which are familiar to the prospective purchaser as a user of equipment. Thus, a technique can be developed for use in the sale of any particular type from these relationships, by means of which a rapid comparison can be obtained between existing and proposed types, on a standard basis of comparison, without involving any of the intricacies of the users' accounting system or discrepancies which might exist between two dissimilar methods.

APPLICATION OF FORMULAS TO VARIOUS TYPES OF EQUIPMENT PROBLEMS

Much emphasis has been laid throughout the foregoing discussion upon the necessity of knowing what factors required by a general solution of the problem are essential in the determination of a suitable equipment policy for some specific type. Naturally when any of the formulas evolved in this study are to be applied to machine tools or process equipment, jigs and fixtures, and labor-saving devices or material-handling equipment, specific attention must be paid to the origin and behavior of the cost elements and financial obligations incurred in each case, as no two situations will require identically the same elements. For this reason much space has been devoted to a consideration of the nature of all obligations and costs so that their relation to time and quantity could be thoroughly understood. Furthermore, it is essential that the distribution of overhead be carefully analyzed so as to separate that portion which may be affected by changes in equipment from that which is invariable with such changes. It was pointed out that there is considerable danger in the treatment of these fixed overhead items if their basis of distribution be altered by a change, as in no case is it permissible to show a reduction in the total burden placed on any equipment when, for instance, the new equipment can achieve a reduction in operating time but when the total annual burden of this sort for the specific equipment remains unaltered by the change. The point is that the difference between a reduction in such burden per unit of product and the invariable total annual burden placed upon the equipment must be recognized. Accordingly, as a result of a preliminary survey of a number of cooperating industrial enterprises, it has been shown that the elements which are indicated by a cross (x) in Table 1, must be considered when formulating an equipment policy for any of the general types specified at the top of the columns.

Discussion

Harold V. Coes.[20] It would be very illuminating if the authors were to secure the necessary basic information from some well-established company or companies, and apply the data to their formulas by comparing what actually was done by a given company in its replacement of equipment over a period of years, as compared with what might have been done under a more scientific basis as developed by the authors, and then compare what might have been done with the business cycles that prevailed at that time.

In other words, the writer is anxious to see whether it is possible to so utilize this scientific selection of equipment as to be able to place orders for equipment in off years or on the low side of the business cycle. He is thinking of long-range planning and the application of the process of scientific selection of equipment to long-range planning and the adaptation of these plans to business cycles. We have just opened the door to this type of thinking and planning in the papers that have been presented.

W. H. Rastall.[21] The writer would like to see the committee, in connection with its further work, go into some of the collateral phases of the problems it has been attacking.

In various parts of the report the authors use the expression "depreciation policy." It is suggested that they change this and attack the problem from the point of view of a broad "equipment policy."

American industry appears to be very much in need of an adequate equipment policy which, obviously, should cover depreciation, as has so long been discussed. It also should cover obsolescence, which is a somewhat newer phase of the old problem.

As yet the committee in its reports does not appear to have taken up the matter of calculating these factors on the basis of "replacement value," a point which was emphasized by Mr. Du Brul, and which the writer endeavored to second, because from our privileged position here we can see quite clearly that, in certain foreign countries particularly, this matter seems to be overlooked, with disastrous consequences. For example, quite recently Britain has abandoned gold and taken up sterling, yet British manufacturers still seem to be quoting the same old sterling prices, which is another way of saying that overhead costs have not been increased. Unconsciously they are giving their products away at less than cost. When a similar situation developed in Germany some years ago and the value of the mark collapsed, manufacturers there made the same mistake, and prominent Germans will today confess that they are not at all proud of the volume of export business Germany secured during those months. American manufacturers drifted into the same error during the period 1914 to 1920, when the purchasing value of the dollar was practically cut in two, and any manufacturer figuring his overhead costs simply in dollars unconsciously fritters away the assets of his enterprise.

It is true that certain able business men contend that we should not calculate these items on the basis of replacement values, for they contend that by using the present value of a 20-in. by 10-ft. lathe where the actual machine they might be employing was purchased, say in 1915, we are really using an entirely different thing as a basis for our calculations because of the progress in machine-tool design during the interval; that is to say, we are setting up a standard that is definitely higher than the one from which we started. Undoubtedly there is a certain validity in this argument, and the extreme case could probably be found in the experience of the telephone company, which finds it necessary to attract millions or hundred of millions of new capital annually in order to keep equipment down to date and to render the best possible service.

However, the typical small enterprise finds itself in a very different position from the telephone company, and if it fails to cover in its costs and accounting methods allowances that will enable it to maintain its factory equipment in an up-to-date condition, the enterprise will probably drift from a position of leadership into one of secondary standing. For this reason it is the writer's personal impression that an adequate equipment policy not only should require that depreciation and obsolescence be calculated on replacement values, but also should allow for the progress of the art in order that a position of leadership may be maintained.

An adequate study of equipment policy should also have to do with the second-hand problem. Obviously management suffers a great temptation in this connection and wishes to secure the highest possible price for discarded equipment. However, it is quite easy by such methods to encourage the development of an undesirable form of competition which serves to demoralize the industry. A recent experience that came to my attention covers a transaction where an inexperienced workman purchased second-hand knitting machinery at practically no cost, and consequently felt he was in a position to make sweaters without any overhead costs whatsoever—obviously a most demoralizing influence in that trade.

As is well known, the British textile industry is today suffering seriously from the same thing because of the export of second-hand textile machinery from Lancashire to those who compete in the markets of India and China. An adequate equipment policy would also seem to need to include allowances for the influence of the business cycle. Experience shows that the equipment industries suffer more from these fluctuations than do industries in general. The chart (see Fig. 10) illustrates this point. When industrial production as a whole rose, say, 20 per cent, in 1919 and 1920, machine-tool orders rose 200 per cent, and a somewhat similar condition existed in 1928 and 1929. Conversely, following collapse, there is a paralysis of buying, and in 1921 and 1931 it simply was not possible to sell machine tools. The conditions in 1919 and 1929 can only be described as equipment anarchy, a buying orgy, and conditions in 1921 and 1931 as a paralysis of buying, representing the absence of any adequate policy. At any rate, there was no continuity of policy, but merely a drift into a situation, but which resulted in the creation of a condition that greatly aggravated the distress resulting from unemployment. Certainly it would be difficult to justify the purchase of factory equipment under conditions existing as they did in 1919 and 1929, and if we are to claim a continuity of policy, it would be difficult to justify the paralysis of 1921 and 1931.

[20] Consulting Management Engineer, Ford, Bacon & Davis, Inc., New York, N. Y. Mem. A.S.M.E.

[21] Chief, Industrial Machinery Division, Bureau of Foreign and Domestic Commerce, Department of Commerce, Washington, D. C.

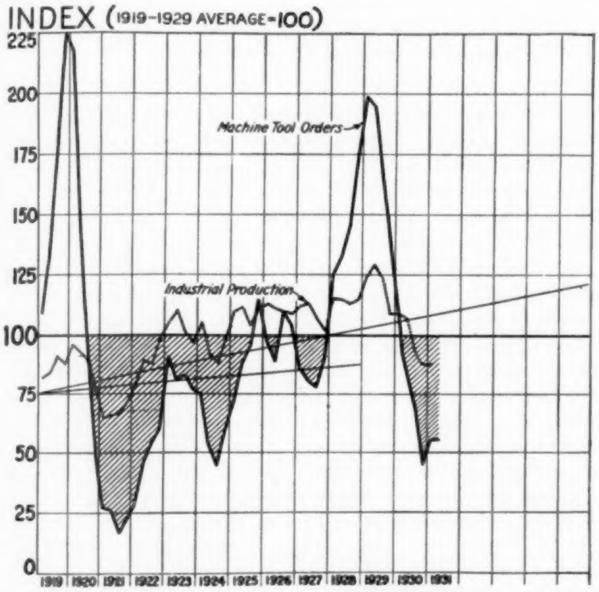

Fig. 10 Post-War Fluctuations of Machine Tools Compared With General Industry

All of the foregoing is based on the assumption that the committee will find it possible to continue its work which is indicated in the reports submitted at New York, and also on the assumption that they are in a position to broaden their discussion and include these aspects of an equipment policy, in addition to the previous discussion, which seems to have been confined to the factors related to depreciation and obsolescence in their simpler forms.

Authors' Closure

In the light of the foregoing discussions, the authors wish to emphasize that, in undertaking a research project which deals with a subject of so large a scope, they have recognized the magnitude of their problem and that they are not merely confining it to a consideration of depreciation or any other single factor, but are in fact taking up in sequence each phase of the problem in order to develop fundamentally sound principles upon which adequate "equipment policies" for industry can be formulated. There has been much confusion of thought over depreciation and amortization of the investment in plant and equipment which must be explained and eliminated before the problem of formulating true equipment policies can be reliably approached. Furthermore, the authors thoroughly appreciate that obsolescence is a major factor in all equipment policies, and it was their purpose in the presentation of this subject to show that whatever the accounting or economic life of some equipment may be according to the conditions under which the equipment is used, no proposed equipment could be justified if obsolescence should occur in the extreme case before the true accounting life had expired or in the normal case before the true economic life had expired. The fact is that the serviceable life based on the occurrence of obsolescence and the useful life based upon the economic utility of any type of equipment are inseparable and mutually dependent.

Similarly, the authors anticipate to extend their present work to include a study of resale values and second-hand markets, replacement values, the influence of steadily increasing cost of repairs with the passage of time; in fact, every risk of doing business which may arise from the use of equipment by industry. On the basis of such facts gained from an intimate knowledge of the equipment problems, not only of the user of equipment, but also of the manufacturer of and dealer in equipment, it is hoped that it will be possible to reveal the correct principles and methods of determining an equipment policy for industry. To accomplish this result, the authors wish to reiterate their desire that industry and particularly all members of this Society will cooperate with them in carrying forward this research project to a successful conclusion by presenting to them every equipment problem with which each executive or industry is faced.

RP-54-3

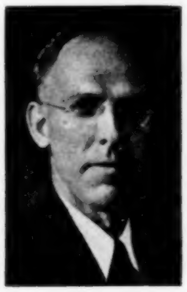
A Study of Primary Metering Elements in 3-In. Pipe

By S. R. BEITLER,[1] PAUL BUCHER,[2] and T. C. BARNES, JR.,[3] COLUMBUS, OHIO

This paper presents part of the results of a study of the performance of a complete series of primary metering devices in a 3-in. pipe line. The devices tested were as follows: Three types of orifices (concentric, eccentric, and segmental) with diameter ratios varying from 20 to 90 per cent; flow nozzles with diameter ratios varying from 30 to 88 per cent; also two venturi tubes with three throat sections each, with diameter ratios varying from 33 to 50 per cent. Discharge coefficients are given for these elements, using water as the metered fluid, with a wide range of differential heads. Coefficients are given also on some of the elements where superheated steam at various temperatures was the metered fluid. The effect of sharpness of orifice edge, of roughness of approach pipe, and of surface finish of flow nozzle on water coefficients is shown. The effect of temperature upon the diameter of the primary device and upon the coefficient of discharge for steam is also given.

THE work covered by this paper represents the continuation of the studies on the flow of fluids past metering elements in pipes, the results of which were presented in a paper by the authors at the 1929 Annual Meeting and published later in the Transactions of the Hydraulic Division.

S. R. Beitler



Paul Bucher

T. C. Barnes, Jr.

This first paper covered the work done on metering elements in a 6-in. pipe. Since the relatively small size of the condensing equipment made it impossible to secure high velocities in the pipes, it was decided to carry on the investigation in a 3-in. pipe line. With this line it was possible to get flows far beyond the values used at present in commercial practice and to cover more completely the range in use at present.

This work has been carried out as a project of the Engineering Experiment Station of the Ohio State University in cooperation with the Bailey Meter Company and has been financed jointly by the two organizations. The actual taking of the data on 3-in. pipe was started late in the summer of 1929 and continued until about the first of April, 1931. During the early part of the work R. L. Galley, Junior Engineer of the Bailey Meter Company, was in charge of the taking of data, while after December, 1930, Mr. Barnes took over this work and carried it to completion. All metering elements used, excepting the venturi tubes, were furnished by the Bailey Meter Company. The venturi tubes were furnished by the Builders Iron Foundry.

The authors wish to express their appreciation for the services of Mr. Galley, the help and advice of R. E. Sprenkle and J. C. Albright of the Bailey Meter Company, and of Profs. F. W. Marquis and Horace Judd of the Department of Mechanical Engineering of the Ohio State University, also to Ed. S. Smith, Jr., of the Builders Iron Foundry, for his cooperation, and to Dean E. A. Hitchcock and J. M. Weed of the Engineering Experiment Station of the university, and R. S. Coffin of the Bailey Meter Company, whose cooperation made it possible to finance this work.

Scope of the Work

When the work was first planned, it was decided to attempt to make it cover as far as possible all the usual metering elements and conditions that might be obtained in practice. This was carried out as far as possible. Data were taken with orifices, flow nozzles, and venturi tubes, using steam and water, and within the limits of the apparatus everything was varied which might influence the flow and which might vary in practice.

The metering elements tested were as follows:

(1) Three sets of concentric orifices with the ratio of orifice diameter to pipe diameter ranging from 20 to 80 per cent.

(2) One set of eccentric orifices with diameter ratios varying from 70 to 88 per cent.

(3) One set of segmental orifices with equivalent diameter ratios varying from 70 to 90 per cent.

(4) One set of steel flow nozzles, cadmium plated, with diameter ratios varying from 65 to 88 per cent.

(5) One set of bronze flow nozzles with diameter ratios of from 30 to 73 per cent.

---

[1] Assistant Professor in Mechanical Engineering, Ohio State University. Jun. A.S.M.E. Mr. Beitler received the degree of Bachelor of Mechanical Engineering at Ohio State in 1920. In 1920–1921 he served as apprentice engineer with the Whiting Corporation of Harvey, Ill. From 1921 he has been at Ohio State University as Assistant and Instructor in Mechanical Engineering. From February, 1927, to date he has been Consulting Research Engineer for the Bailey Meter Company, Cleveland, Ohio.

[2] Associate Professor of Steam Engineering, Ohio State University. Assoc-Mem. A.S.M.E. Mr. Bucher received the B.M.E. degree from Ohio State in 1918. He spent three months as assistant superintendent of power for the Kimberley-Clarke Paper Company, Neenah, Wis. From 1918 he has served as Instructor and Associate Professor at Ohio State. He has also, during vacation periods, served as test engineer for the Appalachian Power Company at Glen Lyn, Va., and from February, 1927, to date has served as Consulting Research Engineer for the Bailey Meter Company, Cleveland, Ohio.

[3] With S. R. Beitler, Ohio State University. Jun. A.S.M.E. Mr. Barnes received the M.E. degree in 1929 from Rensselaer Polytechnic Institute. He has been employed since 1929 as Junior Research Engineer by the Bailey Meter Company, Cleveland, Ohio, in experimental work on metering elements and in general engineering work on fluid meters.

Contributed by the A.S.M.E. Special Research Committee on Fluid Meters and presented at the Annual Meeting, New York, N. Y., Nov. 30 to Dec. 4, 1931, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

(6) One set of steel flow nozzles unplated with diameter ratios varying from 35 to 88 per cent.

(7) Two venturi tubes, with three throats each, with diameter ratios varying from 35 to 50 per cent.

(8) In the foregoing were several sets of three or four "similar" orifices of the same diameter ratio.

All were tested at various differential heads, and the coefficient of discharge was determined, using water as the calibrating fluid. Tests were made with differential heads as low as 0.05 ft. of water and as high as 49 ft. of water.

They were also tested using steam as the calibrating fluid. They were tested at two upstream pressures, 85 lb. per sq. in. absolute and at 20 lb. per sq. in. absolute. Each element was tested at various pressure drops at each pressure condition.

Certain elements were tested also at varying steam temperatures.

Tests were made also to determine the effect of sharpness of the edge of an orifice and of the roughness of the upstream pipe and of the effect of roughness on the inner surface of a nozzle.

All of these results have not yet been completely analyzed, and so in this paper it will be possible to present and discuss only a few of the results. These will be the values of the coefficients for water, the effects of orifice edge, pipe roughness, nozzle roughness, and the effect of temperature on coefficient and element size.

FIG. 2 CROSS-SECTIONS OF FLOW NOZZLES

mental orifices were made of plate 0.038 in. thick. This plate was corrugated with five concentric corrugations around the outside of the plate. The purpose of these corrugations was to enable the plate to be used without, or rather in place of, a gasket between two flanges. In all there were seven segmental and six eccentric orifices.

There were three series of concentric orifices used. The first series was made up of nine orifices of two types of construction. The first four orifices of diameter ratios 50 per cent and below (diameter of 50 per cent = 1.515 in.) were of $^1/_{16}$-in. plate with the edge of the orifice on the downstream sides beveled so that the thickness was $^1/_{32}$ in. at the edge. The other five orifices of 50 per cent diameter ratios and above were made of the 0.038-in. plate corrugated, as were the eccentric and segmental plates.

FIG. 4 DETAIL OF PIPE AT ORIFICE FLANGE

The second series was quite similar to the first except that all plates were of $^1/_{16}$-in. metal with the orifice edges beveled to $^1/_{32}$ in. There were six orifices in this series. All of the orifices in these two series were made by fastening the plate on a face plate and boring the orifice hole with an ordinary lathe tool and then polishing with some very fine emery cloth.

The third series was made of $^1/_{16}$-in. plate, as was the second, with the edges beveled, but the holes instead of being just bored, were bored and then honed to give a smooth finish and a smooth, sharp edge.

One concentric orifice plate was made of sheet brass, $^1/_{16}$ in. thick and beveled as were the others. This orifice was bored, but not honed.

All orifices were centered in the pipe by means of four pins riveted into the plate. A stamped "ear" showing the orifice number and other data was fastened to each orifice plate on the edge of the plate which was to be placed toward the pressure taps.[4]

Fig. 2 shows longitudinal sections of the various nozzles tested. These nozzles were made of steel, fabricated by flanging and welding, or were bronze castings. They were carefully bored to size and were finished very smooth. When first tested, the first five nozzles with diameter ratios above 65 per cent were cadmium plated. This plating was later removed by heating, and all nozzles were used with a smooth surface. All nozzles were carefully measured and inspected in order to have the throat section as nearly as possible a true cylinder. No nozzles were used which were out of round more than 0.0032 in. nor which had any divergence in the throat section from entry to exit.

Fig. 3 shows the general shape of the venturi tubes tested. These are approximate only, as no attempt was made to determine accurately the curvature at the throat and entry of the tube. There were two similar sets of tubes. They were cast-iron tubes with bronze inserts, as shown in the figure.

The orifices and nozzles were mounted between the flanges of two special sections of pipe which are shown in detail in Fig. 4. The upstream section consisted of a piece of seamless-steel tube $3^1/_2$ in. outside diameter and 3 ft. 6 in. long. Standard flanges were screwed on this tube, pressure connections and thermometer wells were welded in place, and then the tube was bored to an inside diameter of 3.027 in., which was the diameter of the pipe preceding the special sections. The tube was then cadmium plated to resist corrosion. It was thought this would keep the upstream pipe section the same at all times and thus eliminate

---

[4] NOTE: There were 13 tables accompanying the paper, which may be consulted by any one so desiring who may wish to obtain data without working directly from the curves.

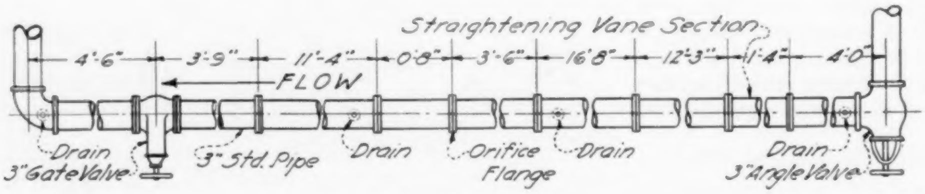

Fig. 5 Layout of Test Line

rusting or corrosion which might affect the orifice flow. However, the high-temperature steam used melted the cadmium, and for the last set of tests the pipe was not protected. This loss of plating, however, made no appreciable change in the diameter of the pipe.

The pressure taps used are shown in detail in Fig. 9. In this pipe two were used, both at a distance of one pipe diameter upstream from the orifice face—one for a determination of the differential head and one for the static pressure in the line. The thermometer well used in determining steam temperature was placed in the pipe at five pipe diameters upstream. This well could be withdrawn from the pipe, leaving no disturbance to flow when taking readings of differential head. The well used was the standard A.S.M.E. finned-wall type. It was in most cases filled with mercury to assure rapid heat transfer to the thermometer bulb. For some of the tests, however, cylinder oil was used as a fluid while for the highest temperatures solder was used. The thermometer used in determining the temperature of the water flowing through the line was located in a well five pipe diameters downstream.

The downstream section of pipe directly below the orifice flange was made of a piece of 3-in. extra-heavy pipe 9 in. long. This also had welded pressure connections and screwed flanges and was bored to 3.027 in. inside and cadmium plated to match the upstream section. The pressure taps were placed at each 0.1 pipe diameter from 0.3 to 0.8 diameter downstream from the orifice face. These connections were placed around the pipe at angles of 45 deg. to each other.

The flanges of the two special sections of pipe were then drilled with eight holes, the two sections lined up on a mandrel, the various pressure taps lined up along the pipe, and the flanges doweled. With this arrangement it was possible always to have the two pieces of pipe in line and also to have any downstream pressure taps lined up with the upstream taps. When the venturi tubes were being tested, the entry section was bolted to the flange of the upstream section of pipe.

The location and general arrangement of these sections is shown in Fig. 5. This arrangement gave approximately 32 ft. 5 in., or 130 diameters of straight pipe upstream from the orifice. In the 16 in. preceding this straight section there were straightening vanes consisting of pieces of $^3/_8$-in. pipe 14-in. long welded into the 16-in. section of 3-in. pipe.

A pressure tap and thermometer well were located at a point five pipe diameters below the orifice in the discharge pipe. These were for the purpose of measuring the temperature drop and restoration of pressure. The thermometer well was placed about one diameter below the pressure connection.

When water was being used as the calibrating fluid, the upstream flange in the section of pipe containing the straightening vanes was bolted directly to a 3-in. elbow, and this was connected through a valve to the laboratory service line. Water for calibration purposes was supplied by means of a 6-in. centrifugal pump having a capacity of about 1500 g.p.m. at 100 lb. per sq. in. discharge pressure. This pump was driven by a steam turbine, the speed of which was controlled by means of a fairly sensitive governor which gave a relatively constant pressure for any capacity, so that for any test run the flow was fairly constant during the whole run. The quantity of water flowing was controlled by the discharge valve of the pump.

When steam was used, the inlet flange of the first section of pipe was connected to a 3-in. angle valve through a 4-ft. length of pipe, giving the flow a chance to straighten out somewhat before striking the straightening vanes. This valve was connected to the laboratory superheated-steam header. Steam was supplied to this header at a pressure of 140 to 150 lb. per sq. in. gage and with quality varying from about 98 per cent dry to about 100 deg. of superheat. The steam was piped through a gas-fired superheater and then into the header. There was one pressure-reducing valve between the boilers and this line. This arrangement made it possible to secure a fairly constant pressure and temperature at the metering element for any one run, and to vary either the pressure or temperature within the limits of the apparatus.

For steam, the entire pipe line with the exception of the flanges and the section downstream from the measuring section was lagged with 85 per cent magnesia pipe covering of standard thickness.

The quantity of water flowing was determined either by weighing or by volumetric measurement. For weighing, the water was piped through a deflector pipe into either of two weighing tanks on platform scales. These tanks were of about 1200 lb. capacity and were fitted with quick-opening valves for dumping. This method was used for measuring quantities up to about 0.2 cu. ft. per sec.

For quantities above 0.2 cu. ft. per sec., the volumetric method of measurement was used. For measurement, one of the cisterns or bays of the laboratory was used. These bays are concrete tanks set below the floor of the laboratory. They are connected to $^3/_4$-in. gage glasses in a central measuring pit in the center of the laboratory by 2-in. pipes, so that the level of the water in the bay can be read on a scale placed behind the gage glass. Thermometers were placed in these gage glasses at about 4-ft. intervals in order to correct for difference in density between the water in the bay and that in the glass. The volume present in the bay for any gage reading was determined by calibration, and was read from a calibration chart.

When the measuring bays were used, the discharge from the test line was piped to a point directly over the wall between two of the bays and a suitable deflector pipe arranged to enable the water to be discharged into either bay. One bay could then be used as a spill and supply bay and the other as a measuring bay.

The pressure in the pipe was in all cases regulated by means of a 3-in. valve placed near the discharge end of the test line.

When steam was being used as the calibrating fluid, the quantity was determined by condensing the exhaust and weighing the condensate. To do this the exhaust line was piped to a surface condenser. This pipe was valved to control the pressure in the test line. The condenser used was an Admiralty type of surface condenser with a cooling surface of approximately 465 sq. ft. It was fitted with a wet vacuum pump and a circulating pump of the reciprocating type driven by a central steam cylinder. The cooling water was obtained from an outdoor reservoir and was returned to the reservoir for cooling. The water from the condensate pump was discharged into an open overhead tank for the elimination of air. This tank was fitted with a gage glass, to show the water level in the tank

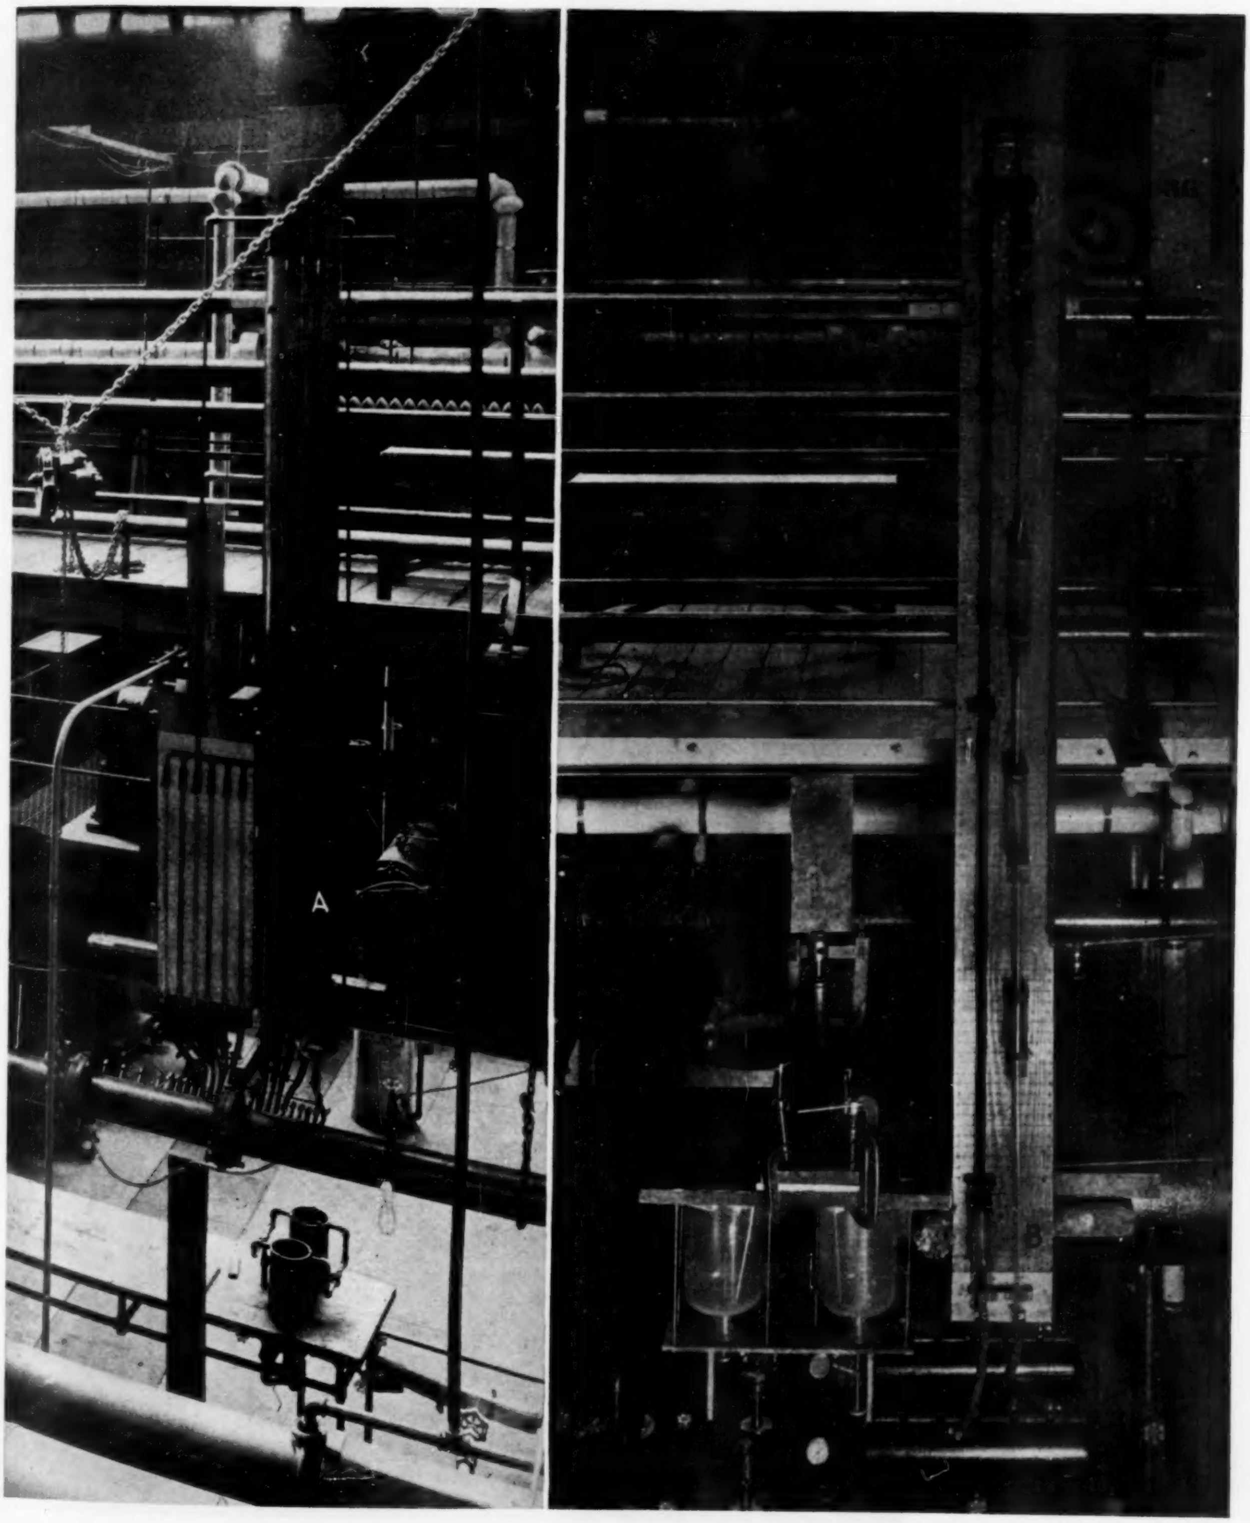

Fig. 6 Manometers for Water

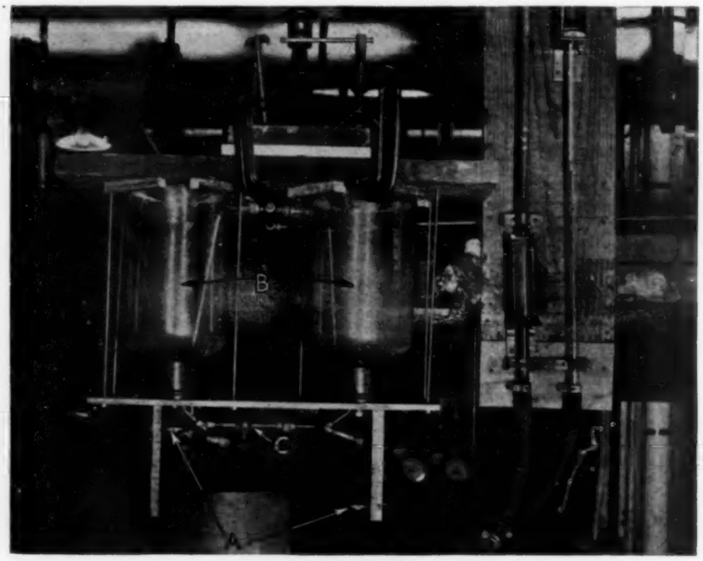

FIG. 7 DIFFERENTIAL HOOK GAGE

and the condensate was carried away through a pipe tapped into the side about 1 ft. from the bottom of the tank. The condensate then flowed by gravity through a suitable deflector pipe to one of two tanks of about 1200 lb. capacity set on calibrated platform scales.

For the water tests, two sets of manometers were used for measuring the differential pressure across the metering element. These manometers are shown in Figs. 6 and 7. The one first used was similar to the one shown at *A* in Fig. 6. This was a multiple inverted water manometer. It was made of one 10 ft. length of $^5/_8$-in. o.d. glass tubing connected to the upstream pressure tap and six $2^1/_2$-ft. lengths connected to the downstream pressure taps. The tops of the short tubes were manifolded and connected to the top of the long tube with $^3/_8$-in. pipe. A $^1/_4$-in. air line was piped into this line at the top of the long tube for supplying air under sufficient pressure to balance the water pressure in the manometer. The valves in this line were located at a convenient height and were arranged so that the air pressure could be varied as desired, and thus the level of the water in the two sets of tubes could be set at any convenient position for observation. This manometer was used for measuring pressure differences of from 1 to 10 ft. of water.

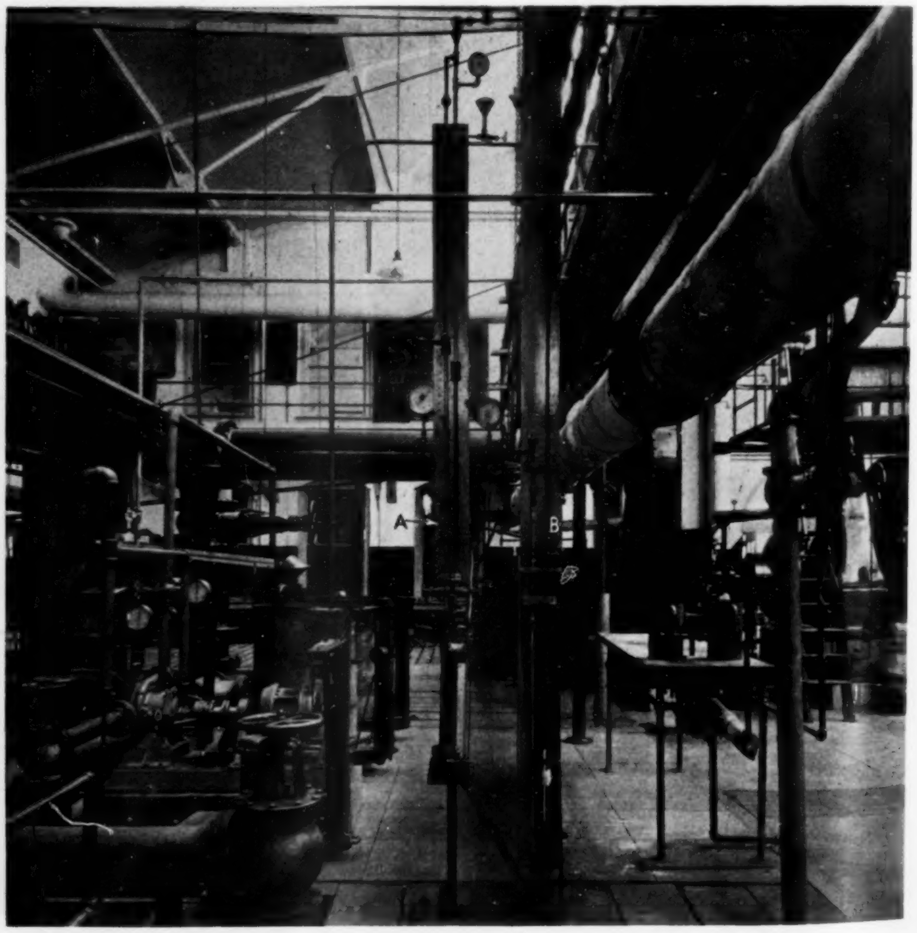

FIG. 8 MANOMETERS USED FOR DIFFERENTIAL AND STATIC PRESSURES FOR STEAM

For the later tests the manometer shown at *B* in Fig. 6 was substituted for the one at *A*. The difference in the two was the addition of the 2-in.-diameter glass tubes as shown at the zero level on the downstream side and at the 2-ft., 4-ft., 6-ft., and 9-ft. levels on the upstream tubes. The purpose of these volumes was to absorb the small pulsations in manometer readings and so make throttling unnecessary.

The scales for both of these manometers were laid off directly on the board behind the tubes, and the boards were carefully shellacked to protect them from moisture. They were graduated in feet and hundredths, and the zeros were carefully leveled. Thermometers were placed in the tubes of both manometers to determine the density of the water in the tubes. These were arranged at heights of 2, 4, 6, and 9 ft. in the upstream tube and at zero in the downstream tubes.

For measuring differential pressures of greater than 10 ft. of water an ordinary 50-in. mercury manometer was substituted for the water manometer and piped up with the necessary vents.

For differential pressures of 1 ft. or less the double differential hook gage shown in Fig. 7 was used. This was made of two glass aspirator bottles about 10 in. in diameter and 15 in. high. They were inverted and connected together at the top, while the bottoms were connected to the pressure taps. A special hook gage was mounted at the bottom of each bottle with micrometer scale *A* reading directly in 0.001 in. The hook *B* consisted of a straight piece of rod sharpened on the end. By using a light behind the bottle it was possible to read this as accurately as the scale could be read. A valved bypass *C* was provided between the two pressure connections for checking the zero reading of the two gages, and an air connection was made to the top connecting pipe to make it possible to balance the pipe-line static pressure.

A mercury manometer was also used to measure the difference in pressure between one pipe diameter upstream and five diameters downstream to determine the pressure loss across the metering elements.

Fig. 8 shows some manometers similar to the ones used for measuring differential head and static pressure when steam was being used.

The manometer shown at *A* was the one used for measuring differential heads. It was a 10-ft. inverted water manometer. It was made from gage glass and piping as shown in the figure. The top of the manometer was connected to a high-pressure air line so that it was possible to adjust the pressure in the manometer to approximately the same pressure as that within the pipe before the manometer valves were opened. A gage was used to indicate the pressure at the top of the manometer. The manometer scale was laid off on the oak supporting board, and the board was shellacked to prevent any change in the scale length due to atmospheric conditions. The bottom of the manometer was connected to the pressure taps in the pipe with $^1/_2$-in. copper tubing and radiators, which will be described later. The face of the manometer was covered with non-shatterable glass during the tests, so that the observers would be protected in case of tube failure.

Fig. 9 shows the arrangement of the bull's eye and radiator reservoir as connected to the pressure tap. The manometer legs were connected to the radiators by $^1/_2$-in. copper tubing and compression fittings.

The radiators were standard high-pressure radiator condensers used by the Bailey Meter Company. They are built of welded steel and are arranged as shown in the figure. The reservoir serves to hold a sufficient quantity of water to fill the tubes during any slight change of head, while the fins on the steel tube serve to condense enough steam to keep the reservoir filled with water. A vent is provided in the top of each reservoir to permit the venting of air. They were operated manually while warming up the apparatus. A special offset gate valve was placed at the end of the reservoir and was connected to the pressure tap on the pipe, through a special fitting. This fitting was made with two flat glass bull's eyes in the sides so that the level of water in the pressure tap could be observed. Care was taken always to have the reservoirs level with each other and also horizontal.

The static-pressure tap was taken off from the opposite side of the pipe, as shown in Fig. 4. This pressure tap was connected through a radiator reservoir and offset gate valve to two of three manometers. One of these, a 15-in. high-pressure mercury manometer, was connected also to a point five diameters downstream from the orifice flange and was used to measure the head loss through the metering element. One of the other manometers was used to measure the static pressure in the pipe. If this pressure was less than 20 lb. per sq. in., a standard 50-in. mercury manometer was used. Most of the runs were made at higher pressures, and for these the special manometer shown at *B*, Fig. 8, was used. This was a two-leg mercury manometer with two operating ranges, one from 6 ft. to 11.4 ft. of mercury, corresponding to pressures of 37 lb. per sq. in. to 68 lb. per sq. in., and the other from about 14.5 ft. to 19.9 ft. of mercury, corresponding to pressures of 86 lb. per sq. in. to 117 lb. per sq. in. It could be used for either range by changing the amount of mercury used. This manometer was made of three sections of $^1/_4$-in. glass tubing connected by $^1/_8$-in. pipe and fittings. A mercury reservoir made of $^1/_2$-in. pipe was mounted on the high-pressure side to prevent mercury from running into the pipe, and a trap was mounted at the top of the atmospheric leg to prevent any high pressure blowing out the mercury. The piping and tube packing glands were mounted on 1-in. by 6-in. boards fastened to an angle-iron frame, and the manometer scale was laid out directly on this board. The boards were well coated with shellac.

Since the low side of this manometer was higher than the center of the pipe line, it was necessary to pipe up to it from the radiator reservoir and to provide a vent at the highest point, which was at the top of the short leg of the manometer.

A pressure gage was placed on the pipe about ten pipe diameters above the pressure taps and was used for determining the upstream pressure when water was flowing and for adjusting only for steam flow.

METHOD OF TAKING DATA

The method of taking the data was quite similar in all cases. For the volumetric tests with water, it was as follows: With the orifices or nozzle properly centered and bolted between flanges, the pumps were started and flow was established at a rate to give the desired pressure drop across the metering element. This water was passed through the deflector pipe to the suction bay until a steady flow had been established and all of the air eliminated from the apparatus. The level of water in the measuring bay was then read. After all of the conditions were satisfactory, at a definite time the deflector pipe was snapped to a position discharging into the measuring bay. Readings of heads and temperatures were taken at the desired intervals throughout the run. The heads were read by two observers reading simultaneously. The test run was ended by deflecting the stream of water again into the suction bay at the time decided upon for the end of the run. After a sufficient length of time had elapsed for surging to cease in the measuring bay, a final reading of elevation of water in the bay was taken. All readings of the bay elevation were checked by two observers. The length of the test was controlled by several factors. First, in order to get accuracy, the minimum quantity of water in the bay was limited to a depth of 4 ft. If the level of water in the bay increased more than 4 ft. in a half hour, the run was limited to 30 min. in duration. Otherwise the test ended when the measuring bay was completely filled. Observations were taken so that the minimum number of head readings was 20, while the maximum time between readings was 2 min. Temperature readings and static-pressure readings in the test line were ordinarily taken at the beginning and ending of each run.

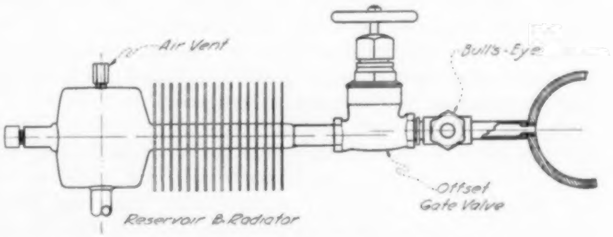

FIG. 9 DETAIL OF PRESSURE TAP AND CONNECTIONS

For the weighed-water test, the procedure in testing was similar to the displacement tests except that the water was run into one of the weighing tanks. At the beginning of a run the discharge was shifted into the other tank, and the two tanks were alternately filled, weighed, and emptied in the usual manner throughout the duration of the test. A calibrated stop watch was used to check the length of these runs, as some of them were of relatively short duration.

When steam was used, the condenser and superheater were started, and steam was turned into the line usually three or four hours before the beginning of a test. When the line was thoroughly warmed, the flow was adjusted to give approximately the desired pressure drop across the metering element, and the pressure in the pipe was adjusted to the approximate static pressure desired, and the apparatus was allowed to run at this rate for sufficient time to allow all temperatures to come to a point where they would remain practically constant. While this was going on the discharge from the condensate pump was allowed to flow into the waste-water trench; and while the line was warming, care was taken to eliminate all air and steam pockets from the manometer connections, and the water in the manometer tubes was allowed to cool approximately to room temperature. When the temperatures were constant, the test was started by throwing the deflector pipe to discharge the condensate into one of the weighing tanks, and the time of start was noted on a reliable chronometer.

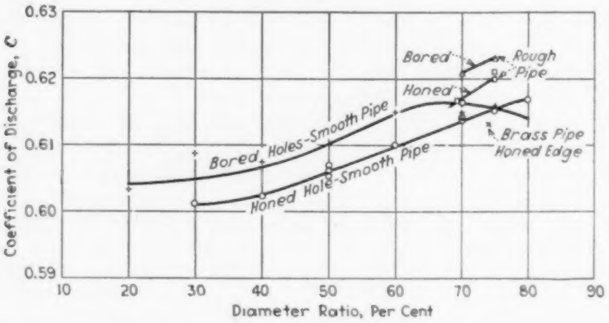

FIG. 10 VARIATION OF AVERAGE COEFFICIENTS WITH DIAMETER RATIOS FOR CONCENTRIC ORIFICES

Readings of the differential and static heads, temperatures, and pressures were taken at the desired intervals throughout the run. The differential and static-head readings were made by two observers reading simultaneously. The test was ended at a certain time by shifting the condensate discharge into the waste trench. The relative elevation of the water in the bulls' eyes at the pressure connections was recorded for each run. During the runs the cans were alternately filled, weighed, and emptied as with the weighed-water runs. Each run was made of sufficient length to get at least two tanks of water, the minimum amount in a tank being about 225 lb. The maximum length of run was 90 min., and the minimum was 30 min. Readings were taken of all pressures and temperatures at such intervals that the minimum number of readings was 20, and the maximum time between readings was 2 min.

CALIBRATION OF INSTRUMENTS

All instruments used were calibrated carefully. The platform scales were calibrated before and after using, over the entire range, by means of standard weights. These weights were then checked by the Ohio State Sealer of Weights and Measures, and found to be accurate within $^3/_4$ oz. in 100 lb., and the errors were found to be practically compensating.

The scales could be read to about $^1/_4$ lb., and were found to be so accurate that no correction was necessary. Care was taken at all times to keep the knife edges clean and to keep dirt and water from all working parts of the scales.

The measuring bay was calibrated by filling it with water. The water was weighed as it was put in, the height of the water in the bay gage glass noted, and the temperature of the water taken. The weight of water was found by using tanks on calibrated platform scales. A reading of the height of water in the bay was taken at increments of approximately 2000 lb. of water. A curve was then plotted showing the amount of water present in the bay for any gage height.

All thermometers were calibrated, the low-reading ones against a standard thermometer, and the high-reading ones by being placed in a well similar to the one in which they were used, and checked against temperatures corresponding to observed saturated-steam pressures.

The Bourdon gages used were checked against a dead-weight gage tester.

All manometer scales were checked periodically against a steel tape or a steel scale, while the zeros of the inverted water manometer were checked with a level at the same time. All manometers were checked for perpendicularity at frequent intervals. The mercury manometer was calibrated by comparison with a water column. The stop watches used were checked at intervals against a reliable chronometer, which in turn was checked against Western Union time.

The orifice and nozzle diameters were measured carefully with inside micrometers. The diameters were measured at four places, and the average considered as the average diameter of the opening. The nozzle diameter was measured at the outlet and also near the entry to the cylindrical portion. The diameter of the pipe was measured at the upstream pressure tap, and at a point about one-half pipe diameter downstream.

The condenser and measuring bays were checked for leakage at regular intervals.

DISCUSSION OF RESULTS

Water Coefficients. The results for runs using water as the calibrating fluid are shown graphically in Figs. 10 to 21, inclusive.

An attempt was made to secure at all times as great accuracy as possible in obtaining the data. All metering elements were installed with great care and inspected at regular intervals. When any change was made from one head or quantity measuring device to another, overlapping runs were made with both devices to insure that no errors due to equipment were affecting the results.

The usual practice was to make four runs on each primary element at differential pressures of approximately 2, 4, 6, and 9 ft. of water. The values of the coefficients for these runs were averaged, and this average was used for comparison with the coefficients for other orifices.

Fig. 10 shows these average coefficients plotted against orifice diameter for the concentric orifices, while Fig. 12 shows the same thing for all orifices, and on this curve are plotted the curves for concentric and eccentric orifices in 6-in. pipe as published in the 1929 Transactions of the A.S.M.E. Hydraulic Division.

The orifices calibrated being of two different finishes, gave two different curves, as shown in Fig. 10. The original orifices were made by boring the orifice holes with an ordinary lathe tool and then polishing the edges of the hole with fine emery paper. This did not give a uniform edge to the various orifices, leaving the upstream edge slightly rounded. This rounding was invisible to the naked eye, but could be detected under the microscope. This amount of rounding varied with different orifices, being the greatest on orifice No. 25,176, 30 per cent diameter ratio, and being very much smaller on the 75 per cent to 80 per cent diameter ratios.

In an attempt to secure more uniform results another set of orifices was made with the holes finished by honing instead of using emery cloth. This method of finishing gave sharp, smooth edges with no apparent rounding even under the microscope. When calibrated, these orifices gave the ratio-coefficient curve marked "honed hole." This curve is about $^2/_3$ of 1 per cent lower than that for the rounded-edge orifices up to about 65 per cent diameter ratio, and then the two curves cross at about 75 per cent diameter ratio, and the "honed hole" coefficient is about $^1/_2$ of 1 per cent higher at 80 per cent diameter ratio. The lower parts of these curves are about parallel to each other and to the curve for 6-in. concentric orifices, while the curve for the "bored holes" parallels the 6-in. curve throughout. The curve for the bored orifices is slightly above the 6-in. curve, while that for the "honed holes" is below it except beyond the 70 per cent diameter ratio.

The curve for the "bored holes" has about the relative shape and location with respect to the 6 in. as would be expected from the previously published work of Spitzglass.[5]

The lower portion of the curve for the "honed holes" is also as would be expected, as the sharper edge should give greater contraction and so a smaller coefficient. However, the upper portion of this curve is not at all as expected. No reason for this divergence from previous results was found, and apparently more data must be secured before any reasons can be found for this divergence. In an attempt to discover if rounding was the only thing affecting this, some of the honed orifices were chucked in a lathe and the edges rounded by holding fine emery cloth in the orifice while it was revolving. One 80 per cent and one 50 per cent orifice treated in this way were then calibrated, and in both cases the coefficient raised about $^1/_2$ of 1 per cent. The dulling caused by this treatment could not be detected by the naked eye.

During the latter part of the calibration the effect of scale in the upstream pipe was also investigated. The earlier tests were made with this pipe cadmium plated, and there was no rust or scale formed, but while running the steam tests the cadmium plate melted. While making some check runs later it was found that the coefficient for some of the orifices was from $^1/_2$ to 1 per cent higher than on previous calibrations. Cleaning the upstream tube to as nearly as possible the original finish, however, restored the coefficient to the original value. The two short curves marked "rough pipe" show the values of the average coefficients for the 70 per cent and 75 per cent ratio orifices with rough pipe.

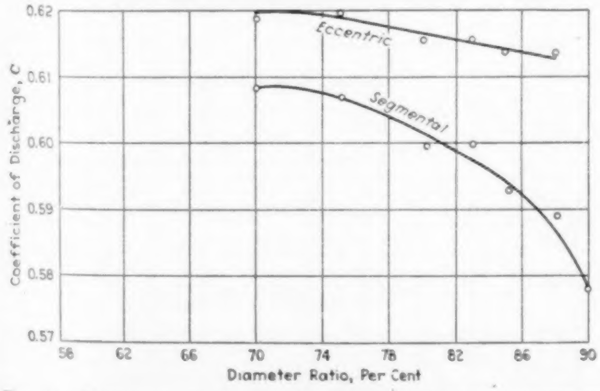

FIG. 11 VARIATION OF AVERAGE COEFFICIENTS WITH DIAMETER RATIOS FOR DIFFERENT ORIFICES

Fig. 11 shows the variation of average coefficient of discharge with orifice ratio for eccentric and segmental orifices. These are ordinary bored orifices and are subject to the variation in rounding of hole which accounts for the relative irregularity of the points on these curves. The curve for the eccentric orifices is higher and the values of R do not drop as rapidly with increase in diameter ratio as do those for the segmental orifices. This is probably due to the fact that the holes in the eccentric orifices are round and therefore similar, while those in the segmental orifices are not similar.

When plotted in Fig. 12, together with the curves for the concentric orifices and the curves for the 6-in. pipe, two things were apparent concerning the curve for the eccentric orifices. First, the curve for eccentric orifices seems to be about parallel and 0.2 per cent below that for the concentric orifices of the same type of hole finish, and, second, that there is no apparent similarity between the curves for the 6-in. eccentric orifices and those of the 3-in. The curve for the 6-in. eccentric orifices is above the curve for the 6-in. concentric orifices at all times, and instead of being parallel, the curvature is in exactly the opposite direction. Of these two curves the 3-in. appears to be much more logical. This would tend to throw some doubt on the accuracy of the determination of the eccentric orifice coefficients for the 6-in. pipe. The only apparent difference in the taking of data for the two different sizes of pipe was that, for the 6-in. pipe, the arrangement of the piping was such that the upstream and downstream pressure taps were not exactly in line along the pipe and this would probably affect the coefficient for an eccentric orifice.

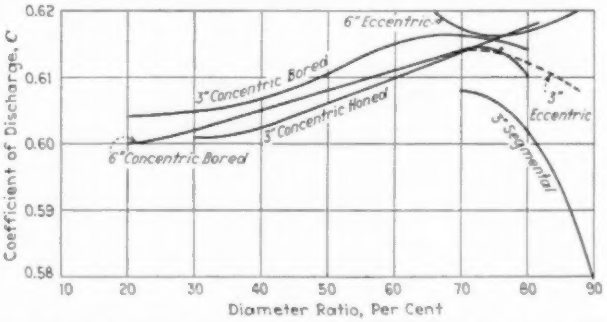

FIG. 12 VARIATION OF AVERAGE COEFFICIENT WITH DIAMETER RATIOS FOR ALL ORIFICES

Since no segmental orifices were calibrated in the 6-in. pipe, there is nothing with which to compare the curve for the 3-in. pipe; however, the values seem to have a logical relation to those for concentric and eccentric orifices.

Fig. 13 shows the values of the coefficient plotted against differential head for the various concentric orifices. A study of this figure shows that, for the 24 concentric orifices tested, the lower ratios showed a practically flat curve above a differential head of 1 ft., but below this head the coefficient of discharge rises very rapidly. As the diameter ratio of the orifice increases, this tendency of the coefficient to increase seems to start at a higher head; however, this is just a tendency, as not all do this—notably the coefficients for the 80 per cent honed orifice are almost the same down to 0.5-ft. differential head.

The 70 per cent orifice was tested up to 50 ft. of water differential head, and the results are plotted in Fig. 14. This curve shows practically no variation in the coefficient beyond the range shown for the rest of the orifices.

Figs. 15 and 16 show the variation of coefficient with head for the eccentric and segmental orifices. These curves are very similar to those for concentric orifices in that they are flat except for a sharp rise in coefficient for heads of less than 1 ft.

Fig. 17 shows the variation of the vena contracta and pressure

---

[5] Trans. A.S.M.E., vol. 45, 1922.

tap downstream from the orifice with orifice ratio. These values were determined previously to these tests, using data on other sizes of pipe, since the arrangement of downstream pressure connections made it impossible to get simultaneous readings of pressure drop at more than three points downstream for the concentric orifices or more than one point for the others. This curve shows the advantage of the eccentric and segmental orifices in throwing the vena contracta and therefore the pressure tap farther downstream.

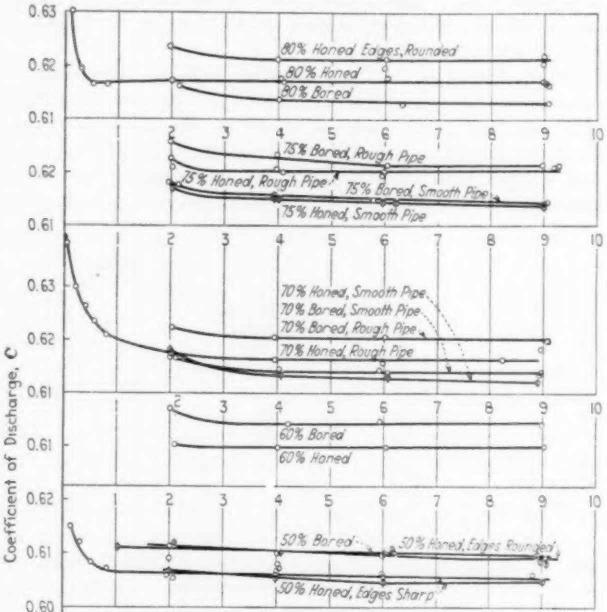

FIG. 13 VARIATION OF COEFFICIENT OF DISCHARGE WITH DIFFERENTIAL HEAD FOR CONCENTRIC ORIFICES IN 3-IN. PIPE

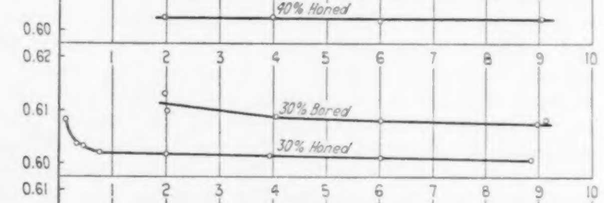

FIG. 14 VARIATION OF COEFFICIENT OF DISCHARGE WITH DIFFERENTIAL HEAD FOR CONCENTRIC ORIFICES

Fig. 18 shows the variation of average coefficient with ratio for the flow nozzles and venturi tubes. There are two curves for the flow nozzles—one for the cadmium-plated nozzles and one for the unplated nozzles. The difference in the two types of nozzles was only in the finish, as the same nozzles were used, first plated, and then with the plating removed. The plating gave the nozzle a somewhat rougher surface than the plain steel finish. These rough nozzles had a higher coefficient of discharge than did the smooth ones.

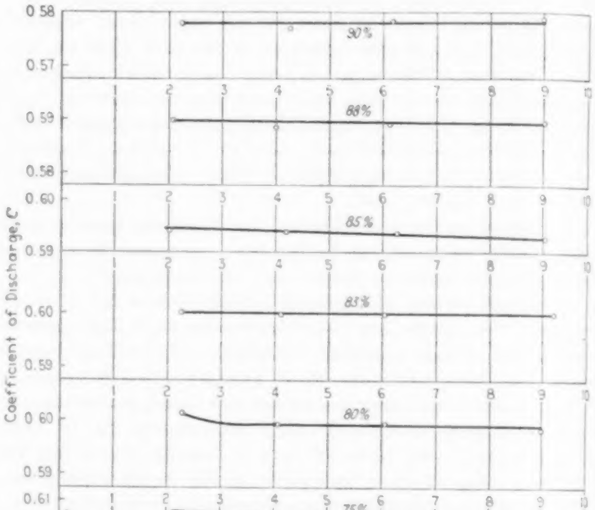

FIG. 15 VARIATION OF COEFFICIENT OF DISCHARGE WITH DIFFERENTIAL HEAD FOR SEGMENTAL ORIFICES

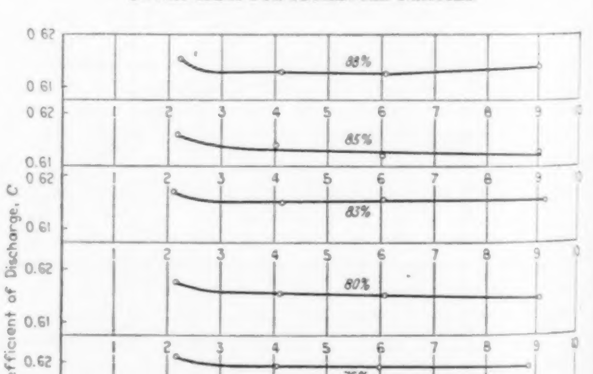

FIG. 16 VARIATION OF COEFFICIENT OF DISCHARGE WITH DIFFERENTIAL HEAD FOR ECCENTRIC ORIFICES

The points on the flow-nozzle curves do not line up as well as do those for the sharp-edged orifices. In fact, the variation from the line drawn is in the neighborhood of $^1/_2$ of 1 per cent plus or minus for the nozzles, while the maximum variation for the orifices was $^1/_2$ of 1 per cent for one point, and no other points were more than $^1/_4$ of 1 per cent off. This wide variation is probably due to differences in the approach curvature of the various nozzles. An examination of Fig. 2 shows that no two of these nozzles had exactly the same relative approach contour in respect to their throat diameter, and apparently that this contour has some effect on the magnitude of the coefficient.

For this reason the values of the coefficients given in this curve cannot be compared with the values published in the A.S.M.E. Fluid Meters Committee Report, part No. 1, as the contours of the nozzles whose coefficients are plotted there are not given.

One thing which is very apparent is the very rapid dropping of the coefficient with ratio for ratios greater than 75 per cent.

The curve for the venturi tubes is comparatively short, as only three tubes with different ratios were tested (33 to 50 per cent ratio). For this range the curve is apparently a straight line sloping at a somewhat greater angle than the curve for flow nozzles and slightly above it. Of the six throats tested only one showed values of coefficient off this line more than 0.05 per cent, and this one was so far off (0.65 per cent) that it appears to be due to some error of installation rather than any inherent difference in coefficient.

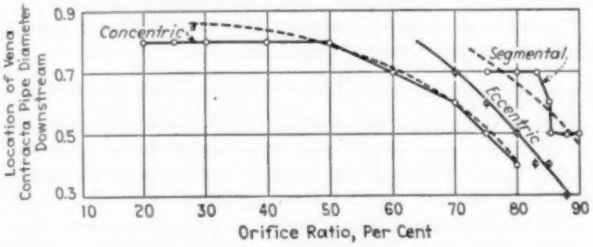

FIG. 17 LOCATION OF VENA CONTRACTA WITH REFERENCE TO PIPE DIAMETER AND ORIFICE RATIO

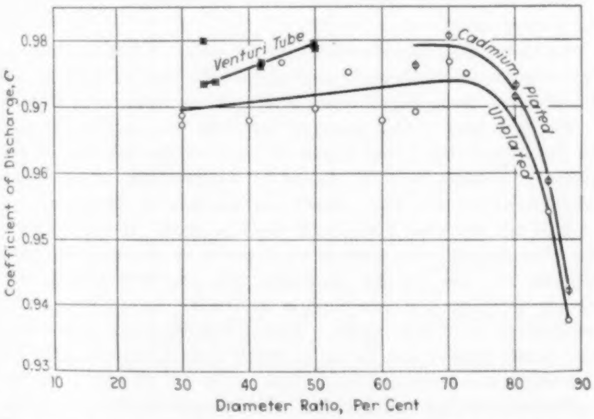

FIG. 18 VARIATION OF AVERAGE COEFFICIENTS WITH DIAMETER RATIOS FOR FLOW NOZZLES AND VENTURI TUBE

The curves, Fig. 19, giving the variation of coefficient with head for the flow nozzles, show an entirely different slope than do the similar curves for the orifices. In general they are not as flat as the orifice curves, but show a decreasing coefficient for decreasing head over the whole range of heads used, with the rate of change in coefficient increasing very rapidly for low differential heads.

Certain curves on Fig. 19 call for further explanation. The two curves for the 30 per cent nozzle show the effect of roughness

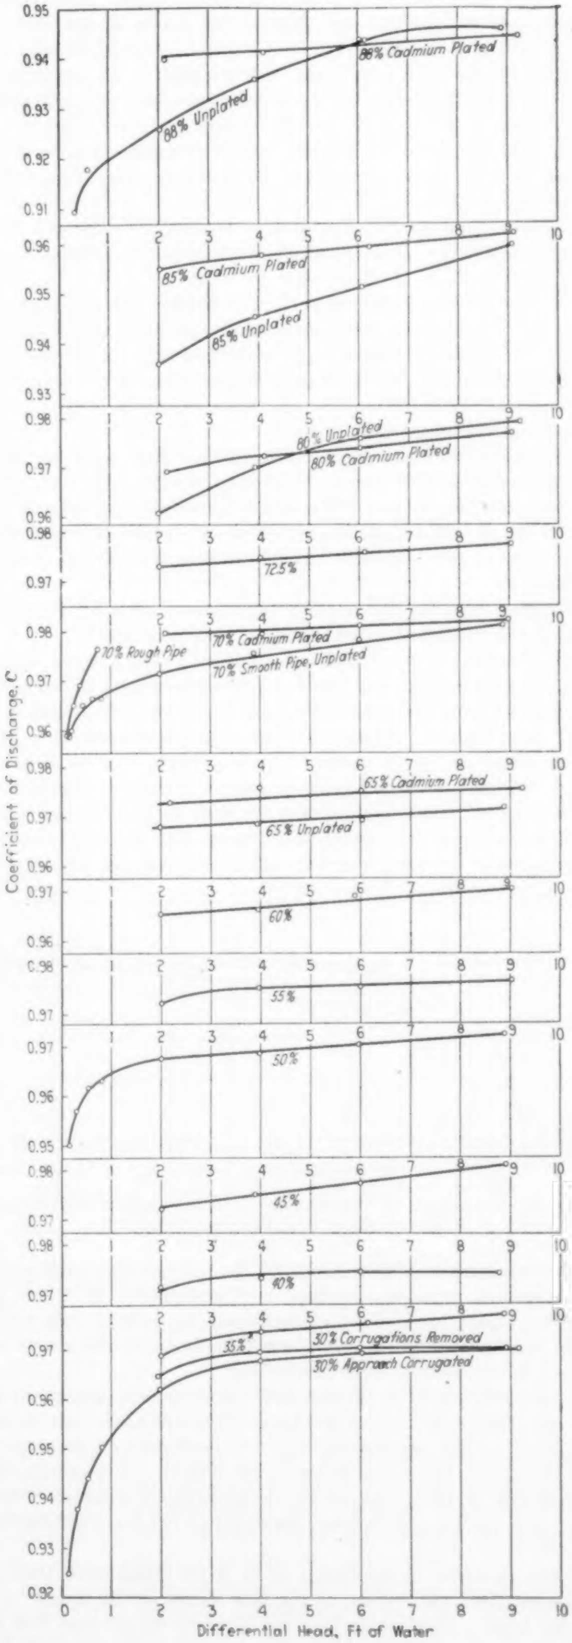

FIG. 19 (RIGHT-HAND COLUMN) VARIATION OF COEFFICIENT OF DISCHARGE WITH DIFFERENTIAL HEAD FOR FLOW NOZZLES

on the nozzle flange. On this particular nozzle part of the flange was exposed to pipe flow. The points shown on the short section of the dotted curve at low heads for the 70 per cent nozzles are the only tests made with a nozzle in the rough pipe and tend to show that roughness also increases the coefficient of a nozzle. However, these four points are not conclusive.

In general, the curves for the unplated nozzles seem to have a greater slope than do those for the plated nozzles, though this is not always true.

Pressure taps for the nozzles were taken at a point 0.8 of a pipe diameter downstream, which is about 1 in. upstream from the discharge end of the nozzle.

For the venturi tubes the coefficient head curves are given in Fig. 20. These show the same general curvature and shape as those for the flow nozzles except for the fact that the 50 per cent ratio curve is flat for differential heads above 4 ft. of water. The rest of the coefficient curves, however, are very similar to nozzles of the same ratio.

Fig. 20 shows the variation of coefficient with head for high differential heads for a 50 per cent ratio venturi tube and for a 70 per cent ratio nozzle. The nozzle curve changes slope until about 35 ft. differential head is reached, while as mentioned before the 50 per cent ratio venturi-tube curve is flat above 4 ft. differential.

Pressure taps for the venturi tubes were taken by standard piezometer rings and connections, as shown in Fig. 3.

The results presented make it possible to compare the action of three of the most used types of primary elements in the same set up and using the same calibrating apparatus. It is apparent that any type of element has certain advantages over the other elements. Any number of sharp-edged orifices if carefully constructed can be made to reproduce results consistently within a very small fraction of a per cent if the upstream pipe conditions are at all similar and proper care is taken in their installation. Nozzles, however, apparently are not as easy to reproduce, and it is the opinion of the authors that until some standard of approach contour and smoothness of nozzle is decided upon, any values of coefficient for nozzles will apply only to a nozzle which is an exact duplicate of the nozzle on which the coefficients were determined.

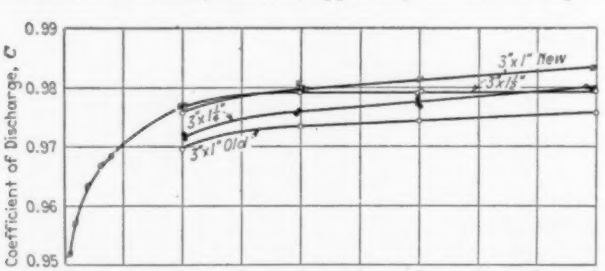

FIG. 20 VARIATION OF COEFFICIENT OF DISCHARGE WITH DIFFERENTIAL HEAD FOR VENTURI TUBES

The variation of coefficient with head is very important in all metering work, as for mechanical reasons most meters are designed on the assumption that the coefficient of discharge is constant over the whole range of the meter. This assumption apparently is erroneous, as all of the primary elements tested showed a variation with head, especially at the lower differential heads.

This variation of coefficient is of more importance than is apparent from the curves, as the flow varies as the square root of the head. This means that the head for 25 per cent flow in a meter using 9-ft. maximum head would be about 0.56 ft., and if an orifice were used with a coefficient which was correct at from 50 per cent to full flow (2.25 ft. to 9 ft. differential head), the meter would read low for 25 per cent flow, and the lower the flow the greater the error. Due to this variation at low heads the meter selected for any particular job should be, for greatest accuracy, designed to operate in the ranges of higher differential head.

For commercial metering the flat head-coefficient curve for the orifice, as compared with the sloping curve for the other two elements, should give the orifice meter a greater accuracy over a wider range of flow.

Both nozzles and orifices were apparently very sensitive to upstream pipe roughness, and great care must be taken in their installation if great precision is to be obtained when used as metering devices. By great precision is meant a degree of accuracy of the order of less than plus or minus 1 per cent.

The range of venturi tubes tested was so small that no general conclusions can be drawn about them.

EFFECT OF TEMPERATURE UPON ELEMENTS AND COEFFICIENTS

As a part of this work all of the primary elements calibrated on water were also tested, using superheated steam as the calibrating fluid. While at the present time all of the results of these runs are not ready for presentation, there were a few interesting facts discovered which it is possible to describe.

These steam tests included many tests to determine experimentally the values for the correction for compressibility, and also a great deal more work on the effect of orifice edge and nozzle roughness on coefficient. This material will be published at a later date.

Another phase investigated was the effect of temperature on the primary element and upon the coefficient of discharge of the element using superheated steam as the calibrating fluid.

The first part of this phase of the work was an investigation to determine the actual change in size of the opening in the primary element with a change in temperature, and to find whether or not the heat caused any warping of the element.

A 70 per cent steel flow nozzle was first used. It was clamped between flanges with gaskets as it would be in an actual pipe installation, and an electric heater was provided to heat the nozzle directly and the flanges indirectly by radiation and conduction from the nozzle. Thermocouples were mounted in the nozzle throat and flange in small drilled holes in order to determine the temperature of these parts. It was felt that this approximated the arrangement of the nozzle in the pipe when heated by steam flowing through the pipe and that it would show if the change in actual diameter would check the calculated value and whether or not the nozzle would warp when heated.

The nozzle was heated to about 1000 deg. fahr. and then allowed to cool slowly, and the diameter of the throat and entry was measured at regular temperature intervals. These measurements were taken by means of a telescoping gage and outside micrometers.

There was no apparent change in the relative sizes of throat or entry section of the nozzle and evidently little or no warping of the nozzle due to heat or stresses from differences in expansion between nozzles and retaining flanges. The increase in diameter of the hole was, as closely as could be measured, the same as the calculated values for this increase based on the coefficient of expansion of soft (0.12 per cent carbon) steel. Fig. 22 shows the results of these measurements. The solid line shows the theoretical diameter of this nozzle figured from the coefficient of expansion of steel of 0.12 per cent carbon, while the points shown are the actual measurements. The test points are all within 0.0008 in. of the theoretical and fall on both sides of the line, showing that the increase in diameter of the nozzle hole for any temperature can be calculated.

The same method was used in checking the expansion of a Monel metal orifice of 70 per cent ratio, except that the orifice was heated by gas rather than by electricity. It was thought that possibly the differences in coefficient of expansion between Monel and cast iron would cause the orifice plate to buckle, and so it was also checked for flatness.

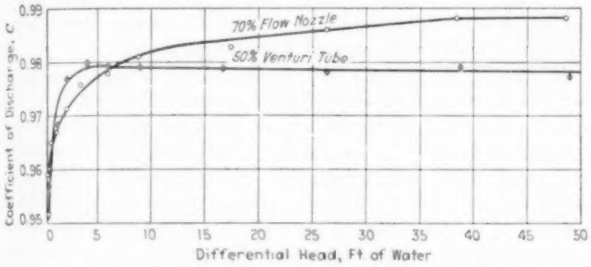

Fig. 21 Variation of Coefficient of Discharge With Differential Head for Flow Nozzle and Venturi Tube

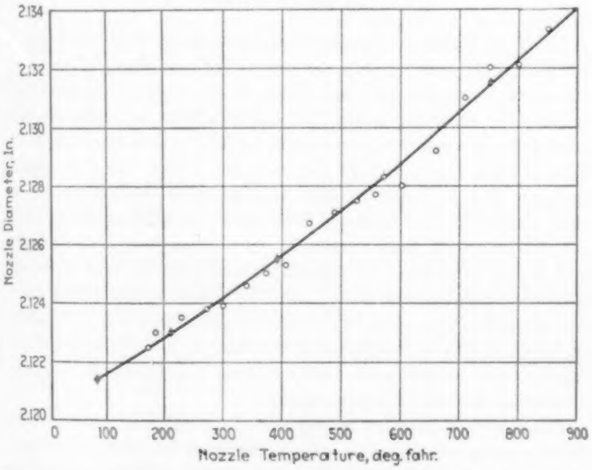

Fig. 22 Variation of Diameter of Throat With Temperature for Steel Flow Nozzle

(Circles, test points; crossed circles, calculated points.)

It was found that the orifice remained flat and that, as in the case of the nozzle, the increase in the diameter was very close to the calculated value using the theoretical coefficient of expansion. Fig. 23 shows the experimental points plotted together with the line showing the calculated diameter. The maximum variation of any point from this line was about 0.0011 in., and the test points fall on both sides of the theoretical line.

An attempt was made to do the same thing to a venturi tube, but it was found impossible with the equipment available.

After the effect of temperature in the element itself was determined, the next step was to determine the effect upon the coefficient of changing the temperature of the steam flowing through the element. To determine this effect the 70 per cent orifice was first put in place in the pipe and a series of calibration runs were made, varying the temperature and keeping all other variables as nearly constant as possible. These runs were made at approximately 5 lb. per sq. in. gage pressure and at 9 ft. of water differential head.

When the runs on the orifice were completed, the same thing was done for the 70 per cent flow nozzle and the 50 per cent venturi tube.

The results of the tests on the orifices are shown graphically in Fig. 24. The coefficients of discharge were calculated in two ways—first, based on the original diameter of the orifice and, second, based on the calculated diameter of the orifice at the temperature of the steam in the pipe. Both of these assumptions are probably erroneous. However, the second should be very nearly correct, as the temperature at the orifice should be within a few degrees of the temperature five diameters upstream.

The values for the coefficient based on the diameter of the orifice at room temperature averaged 0.5698 and varied from this average about 0.6 per cent minus and about 0.3 per cent plus. The points seem to be independent of temperature; that is, the curve of coefficient versus steam temperature is a flat, straight line. The test points do not fall exactly on the line, and there is as much variation as noted above, due to the fact that it was impossible to get exactly the same absolute pressure or the same differential head, for any two runs. Since the coefficient used here is not corrected for compressibility, any change in the compressibility factor which varies with a variation of ratio of differential head to absolute pressure would change the coefficient. However, there were enough runs made to average out this variation, and the average values should be very nearly correct for the average head.

When the values of the coefficient based on the diameter of the orifice at steam temperature were used, the curve was found to be not a flat straight line, but to have a very definite slope, with the coefficient decreasing with an increase in temperature. The amount of this variation was about 0.7 per cent for a change of temperature from 250 deg. to 650 deg. fahr. This variation of coefficient is rather difficult to account for, as there is nothing varying except temperature, volume, and viscosity.

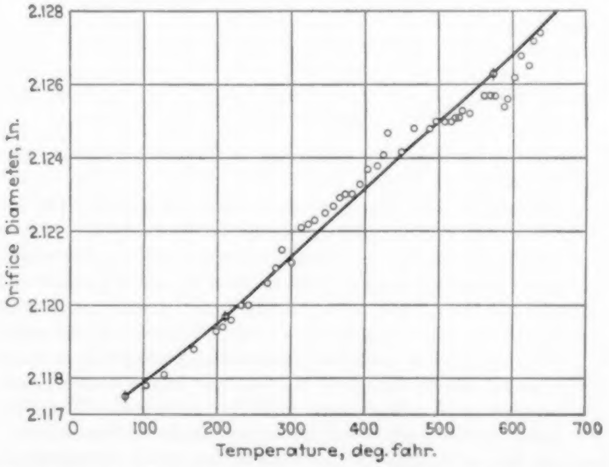

Fig. 23 Variation of Diameter of Hole With Temperature of Monel Metal Orifice Plates Between Cast-Iron Flanges

(Circles, test points; crossed circles, calculated points.)

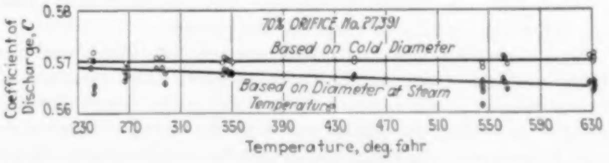

Fig. 24 Variation of Coefficient With Temperature for a 70 Per Cent Concentric Orifice

To see if these other variables could be affecting the coefficient in any way, the Reynolds number was calculated for a few of these runs and the coefficient was plotted against the Reynolds number, as shown in Fig. 25. This curve shows the coefficient increasing for an increase of the Reynolds number, but no longer as a straight-line relation, the coefficient dropping more rapidly for the lower Reynolds numbers which correspond to the higher temperatures. Since the previously published work of Ed. S. Smith, Jr. (Trans. A.S.M.E., 1930, paper HYD-52-7*b*) shows a practically flat curve for this range of Reynolds numbers, this does not seem to help any.

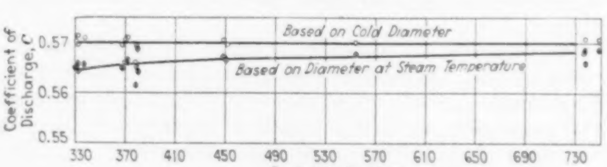

FIG. 25 VARIATION OF COEFFICIENTS OF DISCHARGE WITH REYNOLDS NUMBER FOR 70 PER CENT CONCENTRIC ORIFICE

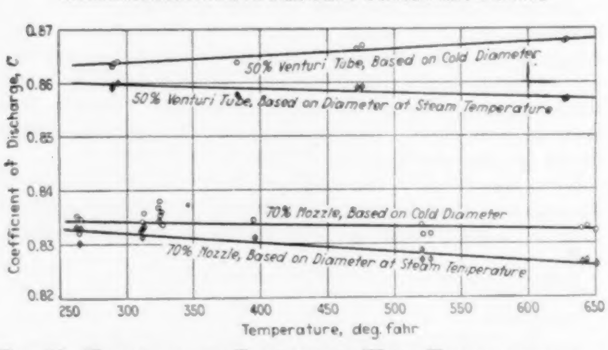

FIG. 26 VARIATION OF COEFFICIENT WITH TEMPERATURE FOR VENTURI TUBE AND FLOW NOZZLE

In connection with this analysis the authors feel that the use of the Reynolds number as a parameter for the study of metering elements is impractical, especially in the case of a square-edged orifice for metering gases. This is because, to determine the values of the Reynolds number, the diameter, pressure, and temperature at the measuring section must be known. If the point of highest velocity is used, the diameter and temperature must be estimated, and if based on the velocity at the orifice plane, the pressure and temperature must be estimated. The fact that these factors must be estimated means that all items entering into the calculation of this number are based on estimates, which makes the value of the number itself very doubtful.

The 70 per cent ratio flow nozzles and the 50 per cent venturi tube were tested also at varying temperatures. The results of these tests are plotted in Fig. 26. The results in both cases are somewhat similar to those for the orifice.

The curves for the flow nozzle are not flat, but sloped for both methods of calculating the coefficient. The variation of the coefficient based on the hot diameter of the nozzle shows a greater slope than the similar curve for the orifice. This variation is, however, only about 0.8 per cent for a similar temperature difference (250 deg. to 650 deg. fahr.).

The curves for the venturi tubes were different and more nearly according to theory. The values of the coefficient based on the cold diameter increase with temperature, while those based on the hot diameter decrease, but at a much slower rate than those for the orifices and nozzles. The variation of the "hot" coefficient for the tube is, for the range from 250 deg. to 650 deg. fahr., less than 0.5 per cent.

It is also possible that the determination of the "hot" coefficient for the venturi is not as accurate as the others, since no actual measurements of the increase of size of the venturi with temperature were made. Then, too, the fact that the venturi tested was of a different ratio than the orifice and nozzle makes direct comparison impossible.

This variation of coefficient with temperature is of importance in the design of meters for steam, as it might mean a difference of almost 1 per cent in the coefficient of discharge of the primary element if it is designed for one operating temperature and used at some other temperature. However, it appears from the data presented that, except for the venturi tubes, the effect of the expansion of the orifice can be neglected in design and the resulting coefficient will not vary with temperature.

In closing, the authors wish to state their disappointment in not being able to present at this time more of the results of the steam calibration runs. However, the mass of data collected is so great that there has not been sufficient time to study it and get it ready for presentation. It is hoped that the additional material will be ready for presentation soon and that the bulletin of the Ohio State University Experiment Station covering the complete project to date will be ready for publication shortly.[6]

Discussion

M. P. O'Brien.[7] The authors' statement that "the use of the Reynolds number as a parameter for the study of metering elements is impractical, especially in the case of square-edged orifices for metering gases," is disconcerting to engineers who have come to regard it as the most important contribution in the field of fluid mechanics in the last fifty years. If it is applied properly and is found to lead to erroneous conclusions in one case, it will make necessary a revision of our ideas on the dynamical similarity of fluid systems. In aeronautics, heat transfer, and many branches of hydraulics, especially in pipe flow, the Reynolds number has been found by many investigators to be the simplest method of coordinating data, and it is difficult to understand why it should fail in the case of flow through a sharp-edged orifice, which is so closely related in principle to the fields in which it has been found to apply.

The Reynolds number is only one of a number of dimensionless criteria upon which dynamical similarity of fluid flow depends, of which the most evident is the scale ratio of linear dimensions. This geometrical similarity of the boundaries of the fluid system extends even to the surface roughness. Other criteria are necessary to include the effects of the expansion of gases and the transfer of heat in the case of liquids or gases, and as far as the theory is concerned, all these criteria must have identical values in each of two fluid systems if dynamical similarity is to exist. Whether some of these criteria are irrelevant can only be determined by experiment, and the present paper does not appear to present sufficient evidence to warrant the conclusion that they are inapplicable. As to whether the Reynolds number is impractical or not, it is necessary that we consider the particular problem involved. If the orifices calibrated are to be used only for steam and water, then there is probably no real advantage in using the Reynolds number, but if they are to be used for metering other liquids and gases, there appears to be no method of applying these data other than by the use of the Reynolds number and a criterion representing the expansion effects. Considering the number of different fluids which are being metered, it seems desirable that all experimental data be represented in a manner sufficiently general that it can be used for computing the flow of any fluid, provided its physical properties can be specified.

---

[6] For a complete discussion of the method of calculating the results, see the appendix of the paper, "The Flow of Fluids Through Orifices in Six-Inch Pipes," Trans. A.S.M.E., 1930, paper HYD-52-7a.

[7] Associate Professor of Mechanical Engineering, University of California, Berkeley, Calif. Assoc-Mem. A.S.M.E.

In applying the Reynolds-number method, it is necessary that the viscosity and density be known, and these quantities, particularly the viscosity, seem to be somewhat in doubt in the case of superheated steam. Errors in these quantities might shift the experimental points in Fig. 25 so as to give a straight line, but this straight-line relation is not necessary from any theoretical considerations. The theory of dynamical similarity states that, if the only important variables are the velocity, viscosity, and density, the coefficient should be identical for geometrically similar orifices at the same Reynolds number. The description of the orifice used states that the plates were corrugated, and if these corrugations were not geometrically similar in the case of the 3-in. and 6-in. pipes, there is no reason to expect identical coefficients. For steam, the Reynolds number is not sufficient as a criterion of similarity, and can be applied only at equal values of the dimensionless group representing the effect of the expansion. The objection that the quantities involved in the Reynolds number are difficult to estimate seems to be without foundation, since they can all be measured for similar conditions at an equal number of diameters upstream from the orifices.

To the writer, the question of the validity of the Reynolds number appears far more important than the coefficient of discharge of steam and water, and it is hoped that this question will be thoroughly discussed in the final report on this extensive and valuable series of experiments.

Edgar Buckingham.[8] The authors' statements, near the end of the paper, regarding the Reynolds number, suggest the following remarks:

The Reynolds number may be, and is, defined in various ways according to circumstances, convenience, and personal preference; but unless something is said to the contrary, the Reynolds number for any section A_1 of a stream of fluid along a round pipe of diameter D is always understood to be the value of the expression R_D, defined by the equation

$$R_D = \frac{DS_1\rho_1}{\mu_1} \qquad [1]$$

where ρ_1 and μ_1 are the density and viscosity of the fluid, and S_1 is the mean linear speed parallel to the axis of the pipe, all referred to the section A_1, and all expressed in terms of normal units, such as "British Absolute" or C.G.S.

The speed S_1 is a fictitious one which cannot be measured directly but has to be computed from the measured rate of volume or mass flow. It is, in fact, defined by the equation

$$M = \frac{\pi}{4} D^2\rho_1 S_1 \qquad [2]$$

in which M is the mass flow, and Equation [1] may be put into the entirely equivalent form

$$R_D = \frac{4M}{\pi D\mu_1} \qquad [3]$$

If an orifice of diameter d is installed in the pipe, it is natural (though not necessary) to define the Reynolds number for the orifice by the analogous equation

$$R_d = \frac{4M}{\pi d\mu_2} \qquad [4]$$

in which μ_2 is the viscosity in the plane of the orifice; and since M is a constant, for steady flow, we have

$$R_d = R_D \frac{D\mu_1}{d\mu_2} \qquad [5]$$

It must, of course, be assumed that the viscosity-temperature curve of the fluid is known, for otherwise it is useless to discuss Reynolds numbers. If it is known, there is no difficulty in computing R_D from the observed mass flow and initial temperature, and the only doubt about the value of R_d concerns the change from μ_1 to μ_2 caused by the change in temperature.

In all ordinary cases the viscosity may be regarded as dependent only on the temperature. If the fluid is a liquid, there is no appreciable fall of temperature and Equation [5] reduces to

$$R_d = R_D \frac{D}{d} \qquad [6]$$

With a gas, the temperature falls, but the effect on R_d and on μ is usually insignificant. For example: with air at an initial temperature of 70 deg. fahr., and with a 20 per cent differential—a value seldom exceeded in metering practice—the fall of temperature all the way to the vena contracta is 32.7 deg., at most. Any dissipation by turbulence and skin friction raises the lower temperature, and the fall to the plane of the orifice is less than to the vena contracta, so that 32.7 deg. is an outside limit.

The temperature coefficient of the viscosity of air is about 0.0015, so that cooling the air 33 deg. lowers its viscosity in the ratio $(1 - 0.0015 \times 33) = 0.95$; and if we ignore the change and compute R_d from [6] instead of [5], the error can not be as much as 5 per cent. Except under extreme conditions, seldom encountered in practice, an error of this magnitude is absolutely insignificant, because the variation of the discharge coefficient caused by a 5 per cent change of viscosity is within the errors of measurement.

It is, however, perfectly legitimate to take [6] as an *exact* definition, for the following reasons:

With a given apparatus, a given gas, and given initial pressure and temperature, the whole state of affairs near the orifice is fixed by the rate of flow; and for any given value of M, the distribution of velocity, static pressure, and temperature, and therefore of density and viscosity, is fixed. Consequently, the value of R_D fixes the value of R_d for any other section of the stream, even though we may be quite unable to compute that value.

Hence it is entirely permissible to study our results by plotting them against R_D, or against R_d defined by [6]—which turns out in practice to give simpler results. We are under no obligation whatever of plotting discharge coefficients against values of the Reynolds number "at the measuring section."

Whether there is anything to be gained by going to the trouble of computing the Reynolds number is another question. Witte's experiments have shown that when R_d is greater than about 150,000, the effects of viscous forces on the motion through the orifice are within the errors of measuring the coefficient, of about $\pm$ 0.5 per cent. In the experiments to which the authors' Fig. 25 refers, the lowest value of R_d was considerably higher than this. There was therefore, in this case, no new information to be expected from plotting results in terms of the Reynolds number; and the fact that the lower curve in Fig. 25 is not a horizontal straight line is not due to viscosity but to some other cause, either physical or algebraic.

J. O. Feldmark.[9] A thorough analysis of the various curves shown in the paper brings out the following facts:

---

[8] Bureau of Standards, Washington, D. C.

[9] Flow Meter Engineer, The Brown Instrument Co., Philadelphia, Pa. Mem. A.S.M.E.

Fig. 10 shows conclusively that a sharp-edged honed orifice has a coefficient of discharge which is about two-thirds of 1 per cent lower than that for a round-edged or bored orifice. This difference can readily be attributed to the effect of the sharpness of the orifice edge. However, the writer did not find any justification for the crossing of the two curves at a diameter ratio of about 0.75.

If the writer were to draw any conclusions with regard to this discrepancy, he would say that the reason for this behavior is probably due to the unreliability of results when the orifice reaches 75 per cent of the pipe diameter in small pipe lines. In this instance a 75 per cent ratio is equal to a 2.270-in. orifice opening, as against a 3.027-in. internal pipe diameter. The orifice rim inside the pipe is therefore only $^3/_8$ in., which no doubt upsets the true differential readings.

Fig. 11 would have been of much greater value had it contained also the average concentric-orifice values for the same ratio of diameters. A comparison would then be possible between the three types of orifices (concentric, eccentric, and segmental).

Furthermore, the results of the present tests should have been plotted against the curves used up to the present time, either as published in part 1 of the A.S.M.E. Fluid Meter Report, or compared with tests made by other experimenters. In this manner a direct comparison would have been possible between the various results, bringing out clearly where the difference is, if any.

In Fig. 12 there is an attempt to compare the present tests, but it is handicapped by the fact that the three types of orifices are not extended to the same maximum- and minimum-ratio limits. Further, the comparison should have been made between the curves corresponding to the same pipe size. The introduction of a curve for 6-in. pipe, while indicating the general direction and shape, does not, however, show how much difference there is between the present 3-in. coefficient and those used previously for a 3-in. pipe.

Fig. 13, as plotted, requires a tedious selection of values in order to make a comparison between the coefficients corresponding to the various orifice ratios. It seems to the writer that by making a step further, all the honed-orifice ratios should have been plotted separately on one curve, combining all the tested ratios. The same arrangement could be made with all bored orifices. The change of the coefficient with the size of the orifice ratio would then stand out boldly for each group. The same comments apply to Figs. 15 and 16.

Fig. 14, dealing with a 50-ft. differential head, proves only that for non-compressible fluids, such as used in this test, the coefficient does not change with an increase in the differential. This, however, does not hold true for steam and gases. In this particular case, with a pressure of 85 lb. per sq. in., the compressibility effect would probably be quite an item when measuring the flow of steam. It would be worth while to repeat the same test when presenting the promised results of the steam tests.

Referring to Fig. 17, the broken line is not explained and the conclusion drawn therefrom applies only to the same limits of orifice ratios.

As to Fig. 18, the writer agrees with the authors that tests made with flow nozzles depend on the contour of the curvature. Therefore there can actually be no comparison between any two nozzles unless special pains are taken to duplicate them in every respect.

The authors state that seamless steel tubing was used on the upstream side, and extra heavy pipes on the downstream side, both bored to an exact internal diameter of 3.027 in. In going over the paper, the writer was unable to find where this arrangement was changed to the standard commercial size found in a practical application. It would be interesting to know how much difference a rough commercial pipe would make in the results as compared to those employed in this ideal laboratory installation.

Another important fact brought out was the change in the orifice coefficient with a variation in the flow temperature. The writer hopes that this will be further investigated and reported on, as promised by the authors, when the results of their steam tests are published. He fully agrees with the authors as to the importance of selecting larger differential heads for more accurate metering results, as this brings the coefficients within the range of the straight line over a wider range of flow.

Raymond P. Genereaux.[10] The authors state on the 14th page that "the use of the Reynolds number as a parameter for the study of metering elements is impractical" due to the difficulty of measuring accurately the velocity and density at the measuring section. This implies measuring separately velocity s, in feet per second, and density γ, in pounds per cubic foot, for use in Reynolds number $Ds\gamma/\mu$. The product, $s\gamma$, equals mass velocity, which is independent of pressure and temperature since its units are pounds per second per square foot. Mass velocity is obtained directly from the weight rate of flow (weight of the condensate in the case of steam) divided by the area in square feet of cross-section at any point in the equipment where the Reynolds number is to be used as the parameter. Thus, if the Reynolds number had been written as DG/μ, where D is the diameter in feet at the chosen point, G is the mass velocity in pounds per second per square foot, and μ is the viscosity in pounds per foot per second, it might have been more readily recognized as a practical tool in studying metering elements.

George L. Tuve.[11] One is much impressed with the care used by the authors in controlling all those conditions which are known to have an effect on the coefficient of discharge for primary metering elements. It is rather disappointing to note how great an effect was produced by the variation in certain conditions which have usually been considered unimportant. For instance, the flow-nozzle curves of Fig. 19 show that by such a slight change in surface conditions as that produced by cadmium plating, the coefficient may be affected to the extent of 1 to 2 per cent if the meter has a high diameter ratio and is operating at low rates of flow. A somewhat smaller difference was produced by plating on a venturi tube. Similarly, by different methods of finishing the face of a concentric orifice plate, the results of which cannot be seen except under a microscope, a change of almost 1 per cent in the coefficient of discharge is produced (see Fig. 12). In both of the above cases the general shape of the curve of coefficient against diameter ratio was materially altered.

These variations of coefficient with surface finish bring up a major question with regard to the correlation of earlier data. Presumably the primary elements used in the determination of the orifice-coefficient curves of Fig. 14 in Part 1 of the Fluid Meters Report were all finished in a similar manner, but if important differences cannot be detected with the naked eye, perhaps such differences actually existed. The same applies to the derived curves of venturi-meter coefficients of Figs. 6 and 7 in the Fluid Meters Report. This leads to the question: Are we certain that the variation of discharge coefficient with pipe diameter is correctly shown in Figs. 14, 7, and 6 in Fluid Meters, Part 1?

The effect of pipe diameter is of course taken into account when coefficients are plotted against the Reynolds number, as in the original determination of Figs. 6 and 7 in the Fluid Meters Report. The authors of the present paper reject the use of the Reynolds number for correlating data on compressible fluids, but it surely has a great advantage when dealing with liquids. Even when so applied, however, it cannot be used to correlate the data on different orifices with an accuracy much greater than 1 per cent unless the orifices in question were finished in identical manner.

[10] Chemical Engineer, E. I. du Pont de Nemours & Co., Inc., Experimental Station, Wilmington, Del. Jun. A.S.M.E.

[11] Associate Professor of Mechanical Engineering, Case School of Applied Science, Cleveland, Ohio. Assoc-Mem. A.S.M.E.

At Case School of Applied Science some experimental work is being done on the variation of orifice coefficients with the Reynolds number, and correspondence is invited from those who may be working along the same lines. In the light of the data given by the authors it would appear that all those experimenting with primary elements had best get together on methods for finishing and for specifying the finish of orifices, nozzles, and venturis if their data are to be expected to be comparable within a limit of less than 1 to 2 per cent.

H. S. Bean.[12] One very striking feature of the authors' work is the apparent pains taken in making their various measurements, particularly in the pressures and pressure differences.

A careful comparison of the numerical results shown for concentric orifices in Figs. 10 and 12 with the values from other sources has not been made, partly because it is difficult to make a satisfactory comparison with the small-scale plots. Also the exact pressure-tap locations used with these tests are not given. However, from Fig. 12, these later 3-in.-line tests appear to be in fair agreement with the earlier 6-in.-line tests. It may be mentioned here that the results of the 6-in.-line tests, as given in Tables 1 and 3 of an earlier paper by Messrs. Beitler and Bucher,[13] have been found to agree very well with the results of numerous other tests when the effects of pressure-tap location have been taken into account. It is to be regretted that the 14 tables mentioned in footnote 4 were not printed with the rest of the paper.

Figs. 13 and 14 show very clearly the effect of the orifice-edge condition upon the value of the discharge coefficients. The magnitude of this edge effect of course varies with the edge condition. In direction, and possibly in magnitude, the results shown agree with those from other tests.

In regard to the nozzle coefficients shown in Fig. 18, there is no doubt but that scattering of the test results for different nozzles is largely due to the contour of the entrance section.[14] The higher coefficient of the "rough" cadmium-plated nozzle is contrary to what would normally be expected. Possibly, as one of the authors suggested, the coefficient of friction of the cadmium surface is enough lower than that for the steel to more than offset the apparently rougher surface.

In regard to the effect of thermal expansion of the orifice plate upon the coefficient, it is interesting to note that according to Fig. 23, the orifice area at 650 deg. fahr. is 0.7 per cent greater than at 250 deg. fahr. According to Fig. 24, the coefficient of the plate based on the diameter at a temperature of 650 deg. is about 0.7 per cent lower than when based on the diameter at 250 deg. Also, for the nozzle, the area increase by Fig. 22 is about 0.6 per cent over the same temperature range, and the coefficient decrease is about 0.6 per cent.

Of course the full explanation of the change in the coefficient with changes in the orifice diameter due to the fluid temperature is by no means as simple as the above. In order to make a full explanation it would be necessary to also take account of such changes as may occur in the mass rate of flow, the different pressure, the density of the fluid, and possibly its viscosity, simultaneously with the change of fluid temperature. This would present a rather complicated problem.

The writer will await with interest the publication of the mass of data to which the authors refer in their closing paragraph.

R. E. Sprenkle.[15] Fig. 10 of the paper shows clearly the effect of orifice-edge sharpness on the coefficient. These data are borne out by additional tests, referred to on the 9th page, which were obtained by rounding the edges of some of the honed orifices previously used in determining the data shown in Fig. 10. The peculiar thing, however, is the relatively small effect that this edge rounding, or lack of sharpness, has on accuracy. Tests made by the Bailey Meter Company Laboratory on orifices having a very marked burr on the inlet side—that is, a burr at least $^1/_{64}$ in. in height—are in very close agreement with the deviation shown by Fig. 10 between sharp and bored orifices, that is, about 0.6 per cent higher value. While this shows the necessity for accuracy in orifice manufacture, nevertheless it indicates that even though the orifice edge should become slightly dull in service, the meter accuracy would not be appreciably affected.

The very "flat" coefficient curves with differential-head variation for honed or sharp-edged orifices shown in Fig. 14 indicate that for the majority of cases a very simple meter mechanism can be used without employing cams or other devices for correcting the variable coefficient to a "flat" or uniform basis. In this respect the orifice presents a distinct advantage over other types of differential pressure-producing devices. It will be noted from Figs. 19 and 20 that the variation of coefficient with head for flow nozzles is about the same as that for venturi tubes.

Referring to the authors' comment on the use of the Reynolds number as a parameter, the writer would agree that little or no good has resulted from such application. In fact, the writer and his associates have tried putting all the data obtained from these tests on a Reynolds-number basis, and have proved its futility. Reynolds' numbers showed such a wide variation in coefficient between different pipe sizes as to render them useless. Possibly this variation was due to the change in absolute roughness from one size of pipe to another, or to a lack of complete similarity. Whatever the reason, the method failed when applied to practical metering.

Two innovations or decided improvements are noted in conducting these tests, namely the use of hook-gage-type manometers for measuring small differentials accurately, and of bull's-eyes for visualizing the exact height of the condensate columns above the manometer. These are refinements not usually associated with tests of this kind, but the results obtained more than justify their use. The writer would earnestly suggest that other experimenters in the field of fluid-flow measurement take equal pains with small details such as these, as only by minute attention to the little things can really worth-while results be obtained.

Authors' Closure

The statement that "the use of the Reynolds number as a parameter is impractical," which has been questioned by Professor O'Brien and Mr. Genereaux, was made only after a large amount of time had been spent attempting to use the Reynolds number in analyzing the results of our work, not only that published, but that which is as yet unpublished. The authors feel that the conclusions stated by Dr. Buckingham in the final paragraph of his discussion cover very satisfactorily the results of our attempt to use the Reynolds number in analyzing these results. It might be stated here that the calculation of the values of the Reynolds number becomes very cumbersome when any number of computations are involved. As in all of the tests reported upon, the values of the Reynolds number are relatively high, this would tend to show that some other factor than viscosity was effecting the results.

Professor O'Brien's question about the corrugations in orifice plates can be answered by saying that the corrugations were at all times between the flanges and not on the parts of the orifice which came into contact with the flowing fluid.

Replying to Mr. Feldmark's question about the pipe, the bored tubing was used in all of this work. The inner surface of this tubing was very uniform, but had toolmarks which would cause it to be somewhat comparable to commercial pipe. This pipe was finished in this manner in order to give as nearly ideal conditions as possible. This surface, however, would become rusty and scaly much more quickly than would rolled pipe.

The authors wish to acknowledge with thanks the clarifying discussions of Dr. Buckingham, H. S. Bean, Professor Tuve, and Mr. R. E. Sprenkle.

O. W. Boston

The Elements of Milling

By O. W. Boston[1] and Charles E. Kraus,[2] Ann Arbor, Mich.

C. E. Kraus

This paper presents the results of laboratory milling tests on a variety of materials, using a pendulum-actuated single-tooth milling dynamometer. Tools of various widths having front-rake angles of 15 deg., but no side-rake or helix angles, were used. Tests were run both dry and with a number of cutting fluids. Except where deliberately allowed to dull, the cutters were considered sharp at all times.

The cutting was done with the cutter rotating in a plane perpendicular to the surface of the work, and in all cases data for two fundamental methods of cutting are shown: first, milling up in the regular way with the work being fed into the cutter, and second, milling down with the work fed with the cutter. In nearly all cases a difference in energy is found between these two methods of cutting.

Data giving the energy in foot-pounds necessary to remove a single chip are shown for thirteen widely different materials with constant feed and various values of depth, and then with constant depth and various values of feed. Several different cutting fluids were used. These data are plotted and energy equations are derived for each material, of the form $E = Cwf^x d^y$, where E is the energy in foot-pounds per chip, C a constant for the specific condition, w the width of the cutter in inches, f the feed in inches, and d the depth of cut in inches. Values of the constants are given. Corresponding formulas and values for the horsepower per cubic inch per minute are also given. No two materials give the same values of the exponents for the feed and depth variables.

Data are also shown for milling with the cutter in the sharp, dull, and very dull conditions, to determine the effect of the sharpness of the tool on the milling-energy formulas. It is found that dulling does change the formula, but has greater effect on feed than on depth of cut.

Tests were run on four materials using eleven different cutting fluids to determine the effect of cutting fluids on milling energy. It is concluded from the nature of the tests that lubrication rather than cooling has greater effect. The data show a different order for the fluids for each material, but in nearly all cases a power saving is made by their use.

Milling-energy data are also presented for a large variety of materials when the cut was held constant at 0.125 in. depth, 0.010 in. feed, and the cutter was 0.250 in. wide and had a 15-deg. front-rake angle, in order to compare these materials from a milling-energy standpoint. It is concluded that there is no way, other than actual test, to determine the milling properties of a material.

A discussion of previous milling papers has been added, and an analysis of the form of a milling chip is presented. It is concluded from this analysis that, theoretically, the coarse-tooth cutter is better than the fine-tooth cutter, when milling up, keeping the linear feed per tooth constant. When milling down, however, the fine-tooth cutter removes a chip of greater average thickness than the coarse-tooth cutter, and consequently is considered to be more efficient from a power standpoint when diameter and feed per tooth are constant.

The fine-tooth cutter cutting down produces the greatest average thickness of chip of all combinations, and is thought to be the most efficient way of milling metal when power is the chief consideration. It is shown that the average thickness of chip when both feed and depth of cut are varied is not a satisfactory basis for an energy equation.

THIS paper presents the results of a series of tests in milling a variety of ferrous and non-ferrous metals. The energy required to remove a chip of a given metal when milling "up," when the work is fed into the cutter, and that when milling "down," when the work is fed with the cutter, were determined and compared. Cutting was done wet and dry. A number of different types of cutting fluids were used, and these are listed in Table 2. Data showing the influence of variable feed with constant depth and variable depth for constant feed are shown. Formulas representing the energy required to mill a given chip as a function of the feed and depth are developed for a number of materials listed in Table 1, when cutting both wet and dry and when cutting up and cutting down. Tests were run with the cutting edge of the tool in various conditions of sharpness, such

[1] Professor, College of Engineering, University of Michigan. Mem. A.S.M.E. Professor Boston was graduated from the University of Michigan Engineering College in 1913, received a master's degree in 1917, and the degree of mechanical engineer in 1926. After graduation he was engaged at the university as instructor in engineering mechanics and mechanical engineering for four years. In October, 1917, he was commissioned in the U. S. Navy and assigned to duty in the Bureau of Ordnance on design and manufacture of submarine mines used in the North Sea blockade. From 1919 to 1921 he was engaged in industrial engineering work for the Cleveland Tractor Co., in Cleveland, as assistant to the vice-president and works manager. In the fall of 1921, he returned to the University of Michigan, where he is now professor of shop practice and director of the department of engineering shop. He is author of many papers dealing with the subject of metal cutting and is serving as A.S.M.E. representative on the Tool Steel Committee of the American Society for Testing Materials.

[2] After graduation from the high school and junior college in Grand Rapids, Mich., Mr. Kraus entered the University of Michigan in October, 1929, and is now a senior in the College of Engineering, specializing in mechanical engineering, and a member of its A.S.M.E. Student Branch. He holds an appointment as student assistant to Professor Boston in the Department of Engineering Shop.

Contributed by the Special Research Committee on Cutting of Metals and presented at the Annual Meeting, New York, N. Y., Nov. 30 to Dec. 4, 1931, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

as very sharp, dull, and very dull, to find the influence of this variable on the energy required to remove a given chip.

Experimental data are given for several metals, showing the influence of eleven different cutting fluids of various types on the energy required to remove a chip for each method of milling, that is, milling up or down. These materials are listed in Table 1.

TABLE 1 MATERIALS USED IN THE MILLING TESTS

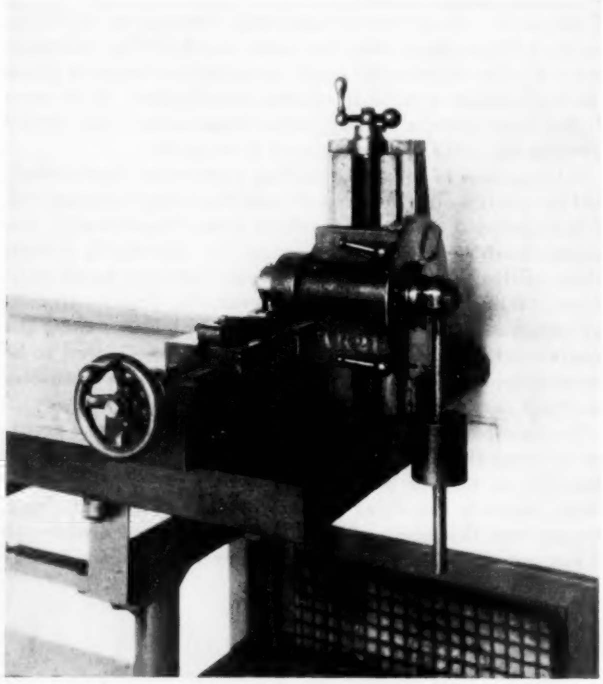

FIG. 1 THE PENDULUM-TYPE MILLING DYNAMOMETER

Finally, comparative data are given showing the average energy required to remove a given chip by the milling-up and milling-down processes for a large variety of metals when cutting dry. Additional information showing the influence of a mineral lard oil on these data is also presented. These materials are listed in Tables 22, 23, and 24.

THE MILLING CUTTERS AND TESTING EQUIPMENT

The machine used was a milling dynamometer of the pendulum type, constructed by Carl Oxford,[3] and was first described in the paper, "The Art of Milling."[4] It is illustrated in Fig. 1. It was calibrated to read directly on the graduated dial the energy in foot-pounds required to remove a given chip.

This milling machine is constructed similarly to the knee type. A single-tooth cutter is held in one end of the arbor overhanging the table. It is driven by a heavy pendulum attached to the other end of the arbor. If the pendulum be allowed to fall freely from the top vertical position, it will swing again almost to the same height, that is, nearly complete one revolution. A freely rotating pointer is carried forward with the pendulum as it rotates and indicates on a steel disk the highest position to which the pendulum swings. This position is taken as the zero reading to allow for friction in the bearings.

If the material is bolted to the table and the cutter adjusted for depth of cut and feed, a subsequent fall of the pendulum will cause a chip to be removed, and the pendulum will not swing so high after taking the chip as when taking no chip. This difference in height is a result of the energy in foot-pounds given up in forming the chip. It is the same principle as that used in impact testing machines. The face of the steel disk is graduated at its periphery, so that the reading of energy absorbed by taking the chip of any given material and size is read directly.

The single-tooth milling cutters were adjusted so as to have a radius of 1.75 in. For most tests these cutters had a rake angle or hook of 15 deg., and end- and side-clearance angles of 4 deg. After adjusting the material to be cut on the milling-machine table, the cutter was fed vertically downward from the surface to the required depth of cut as successive cuts were taken. The work was then fed horizontally the required distance for each chip. All data given in this paper were obtained by taking cuts in this manner, so that a groove was formed in the work.

THE MATERIALS TESTED

The materials tested have been reported in previous papers. They are summarized, however, in Table 1. Chemical analyses, heat treatments, and Brinell, Rockwell, and scleroscope hardness numbers are given.

THE CUTTING FLUIDS USED

The cutting fluids used in these tests are listed with their properties in Table 2. They were previously reported on in a paper entitled "Performance of Cutting Fluids."[5] They were selected to represent a wide variety of types commonly used.

The influence of the cutting fluids in tests of this nature is due probably more to lubrication than to cooling. The cutting is intermittent; that is, considerable time elapses between successive cuts, so that there is no perceptible rise in temperature of the tool, work, or cutting fluid as the tests are continued, because of the heat generated between individual cuts. The time in removing a chip is so small that there can be little heat transfer during the cutting action.

THE RESULTS OF TESTS

The tests run for this paper covered a variety of sub-classifications and are, therefore, treated separately below.

THE EFFECT OF CUTTER WIDTH

The cutter resembled an ordinary cut-off tool of the end-cutting type, being square on the end. Tests were run with cutters varying in width from 0.22 in. to 0.71 in. in an effort to determine the influence of width on the energy required to

mill metal when other factors were constant. Due to the difficulty of maintaining the same degree of sharpness and, with the wider tools, the necessity of correcting resulting data because of deflections permitting actual change in depth of cut, it was practically impossible to get favorable comparative data. It can be said, however, that when cutting in a groove, the energy required varies not as the first power of the width but as a slightly lower power. It is felt that, if the cutting were done from the top of the land, the width of the land determining the width of chip, the energy would vary more directly with the width of the cutter. The energy required to cut along the side or edge of the chip is probably not a function of the width.

In an earlier paper,[6] it was found that, when cutting on a land with a planer tool, the force expressed in pounds per square inch of chip removed was constant for a given depth of cut and variable widths, but dropped off slightly when the width of cut became less than from 0.100 to 0.200 in.

In this paper the assumption is made that the energy varies directly as the width. For the purpose of comparison, data from cutters varying in width from the 0.231 to 0.249 in. have been corrected to conform with a cutter of 0.250 in. in width. The error thus introduced is believed to be negligible.

VARIABLE-FEED-AND-DEPTH DATA

S.A.E. 1020 Steel. A number of variable-feed-and-depth tests were run on bar A-1, S.A.E. 1020 steel, using different cutting fluids, to determine the milling-energy formula per chip for this metal, and to find the effect of cutting fluids on this formula. The data are given in Tables 3 and 4, and are shown plotted in Figs. 2 and 3.

It is found that the slope of the lines drawn on log-log paper, showing the relation between energy as a function of feed for constant depth and as energy for variable depth and constant feed, is the same for all of the wide variety of cutting fluids used as for dry cutting. These lines for different cutting fluids are merely displaced vertically. This has been found to be true for the cutting fluids on a number of metals which have been cut both wet and dry.

A discussion of the effect of cutting fluids is presented later.

In Table 3 are given the results of various tests for a number of cutting fluids when cutting the S.A.E. 1020 steel with the 0.250-in.-wide cutter having 15 deg. front rake. The upper part of the table shows the feed constant at 0.010 in. and the depth varied from 0.010 to 0.150 in. in seven steps. These data are shown plotted in Fig. 3. The milling-energy values in foot-pounds per chip are plotted as ordinates, with the depth in inches as abscissas. Parallel straight lines are obtained with these data plotted on log-log paper. The solid lines represent the values for milling up, while the broken lines represent the milling energy when cutting down. One exception to this is the milling-down curve of cutting fluid No. 6 (light mineral oil), which is a broken line superimposed on the milling-up or solid line of cutting fluid No. 8 (10 per cent lard in mineral oil). In all cases the broken line for a given oil is below the solid line for that oil, indicating that for this material the energy consumed in milling down is less than when milling up. In milling up, as expressed by the solid lines, No. 10 (sulphurized mineral oil) gives the lowest values, with No. 5 (lard oil) next, then No. 8 (10 per cent lard in mineral oil), while No. 4 (a 10-to-1 soluble oil) and No. 6 (a light mineral oil) are identical at the top. The energy for dry cutting is shown still farther up. Similarly, in considering, the energy values in milling down, No. 5 cutting fluid (lard oil) is the lowest, followed in order by Nos. 10 (sul-

0.010	5.52	4.75
0.015	7.27	6.38
0.020	8.70	7.59

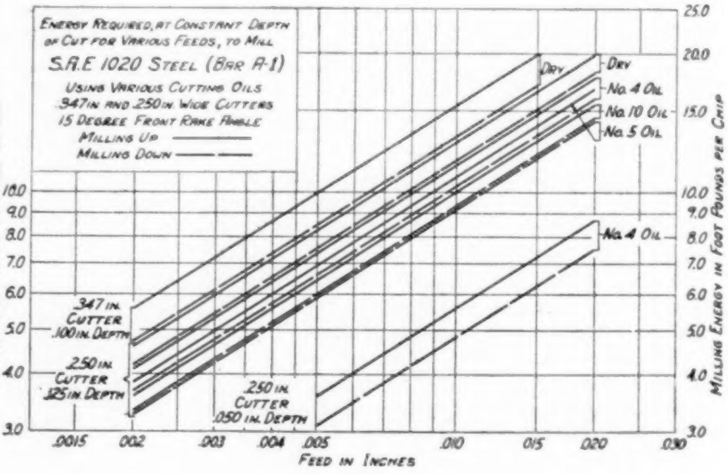

FIG. 2

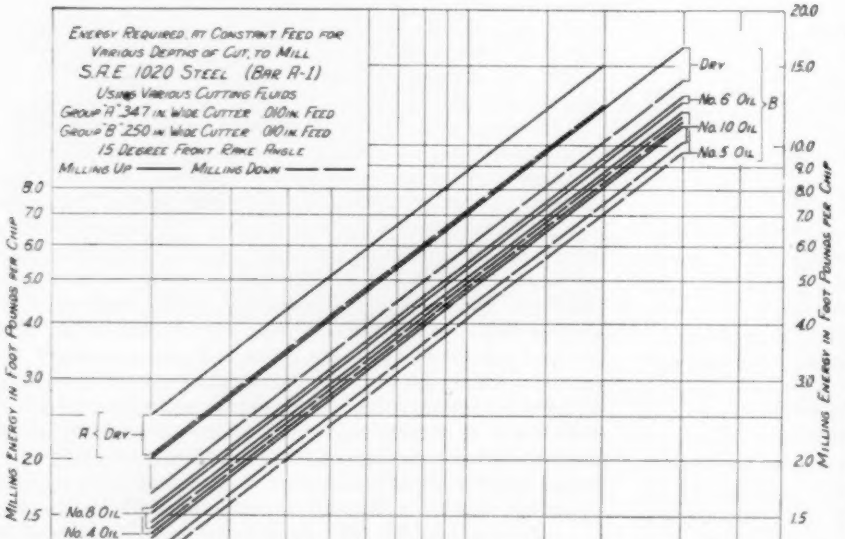

FIG. 3

phurized mineral oil), 4 (a 10-to-1 soluble oil), 8 (10 per cent lard in mineral oil), 6 (a light mineral oil), and dry.

It is interesting to note that these lines as plotted on log-log paper are parallel, so that an equation, representing the energy required to remove a chip when expressed as a function of depth of cut and feed, can be modified by changing the constant to hold for all oils.

At the bottom of Table 2 is shown another series of tests on S.A.E. 1020 steel using the 0.250-in.-wide cutter in which the depth of cut is constant at 0.125 in., while the feed is changed from 0.002 in. to 0.020 in. in five steps. These energy values are shown plotted in Fig. 2 for the 0.250-in. cutter at 0.125 in. depth. These data for cutting fluids Nos. 5, 10, 4, and dry cutting, when plotted on log-log paper, again give parallel straight lines. The broken lines represent the down-cutting energy values, while the solid lines represent the up-cutting values. Of the up-cutting lines, No. 10 is lowest, followed by Nos. 5, 4, and dry cutting, in the order of increasing value. Similarly, for down cutting No. 5 gives the lowest energy value, followed in order by Nos. 10, 4, and dry cutting. In all cases the down-cutting values are less than the up-cutting ones.

In Table 4 are listed the results of another series of milling-cutter tests on the S.A.E. 1020 steel. The upper part of the table shows tests in which the depth was varied from 0.010 in. to 0.100 in. for a constant feed of 0.010 in. These energy values are for a tool 0.347 in. wide but having the same 15-deg. front-rake angle. The cutting was done dry. These constant-feed data are shown plotted in Fig. 3 (indicated at *A*), for dry cutting.

Again, two straight but parallel lines are obtained, the broken line, representing down-cutting values, being far below the solid line which represents the up-cutting values. It is seen, however, that these lines for the 0.347-in.-wide tool are parallel to but higher than the corresponding dry-cutting lines of the 0.250-in.-wide tool, showing that the width does not influence the exponents of the variable. Table 4 in the center shows another set of milling-energy values when cutting dry with the 0.347-in. wide cutter when the depth is constant at 0.100 in. and the feed is increased from 0.002 to 0.015 in. in four steps. These data are plotted in Fig. 2 at the top, and again lines parallel for the up- and down-cutting values are obtained which also are parallel to the up- and down-cutting values of the 0.250-in.-wide cutter, showing that the exponent of feed does not vary with the width of cut.

At the bottom of Table 4 is shown still another set of data in which the 0.250-in.-wide tool was used with cutting fluid No. 4 (a 10 per cent soluble oil), with the depth of cut reduced to 0.050 in. These values are shown plotted in the lower portion of Fig. 2. Even with this shallow depth, lines parallel to the other milling-energy curves are obtained, with the milling-up-energy curves well above the milling-down-energy curves, showing that a variation in depth does not influence the exponents of the variable.

The formula for energy in foot-pounds required to remove a chip of S.A.E. 1020 steel, bar A-1, may be expressed as

$$E = Cwf^{0.64}\,d^{0.78} \qquad \ldots\ldots [1]$$

in which C is a constant for the 0.250-in.-wide tool having a 15-deg. front-rake angle, and the particular material, w the width of cutter in inches, f the feed in inches per chip, and d the depth of cut in inches. The values of C are given for the several conditions in Table 5, and summarized with other values in Table 18.

TABLE 5 VALUE OF C IN MILLING-ENERGY FORMULA ($E = Cwf^{0.64}\,d^{0.78}$), FOR S.A.E. 1020 STEEL (A-1)

(Using a 15-deg. front-rake-angle tool with no side rake)

Cutting fluid		Milling		Ratio of $\frac{\text{Down}}{\text{Up}}$
Type	No.	Up	Down	
Dry	1	5520	4650	0.843
10-to-1 emulsion	4	4320	3790	0.878
Lard	5	3980	3170	0.796
Light mineral	6	4320	4150	0.960
10 per cent lard	8	4150	3900	0.940
Sulphurized mineral oil	10	3700	3400	0.919

Also, the equation giving the horsepower per cubic inch of metal cut per minute may be expressed as

$$\text{Hp. per cu. in. per min.} = \frac{E}{33{,}000 \times \text{vol. of chip}} = \frac{E}{33{,}000\,wfd}$$

or, substituting for E from Equation [1],

$$\text{Hp. per cu. in. per min.} = \frac{Cwf^{0.64}\,d^{0.78}}{33{,}000\,wfd} = \frac{C}{33{,}000\,f^{0.36}\,d^{0.22}} \quad \ldots [2]$$

Cold-Rolled Low-Carbon Steel. A series of variable-feed-and-depth tests were run on a cold-rolled low-carbon steel. The data are given in Table 6. Lard oil (No. 5) was used, and milling cuts both up and down for each condition were taken. The data are tabulated under depths of cut of 0.025, 0.050, and 0.075 in. for a feed per chip of 0.005 and 0.010 in., respectively. In Fig. 4, curves A, B, and C show the data plotted over variable feeds for constant depths of 0.025, 0.050, and 0.075 in., respectively. These data are obtained with the cutter in a sharp condition. It is noted that there is a slight angular divergence between the solid and broken lines, that is, the cutting-up and down curves, for each depth. This appears to be an influence of degree of tool sharpness, as is discussed below. It is not of particular importance as long as the cutting tool is sharp, but when it is dull, the angular divergence becomes greater. (See Fig. 15.) For each depth the milling-down curve values are seen to be less than those for milling up by practically a constant percentage.

TABLE 6 ENERGY REQUIRED IN MILLING COLD-ROLLED LOW-CARBON STEEL

[Cutter, 0.243 in. wide; using lard oil (No. 5), milling up and down. Values plotted in Fig. 4]

	0.025 Depth		0.050 Depth		0.075 Depth	
	0.005 feed	0.010 feed	0.005 feed	0.010 feed	0.005 feed	0.010 feed
Up	1.42	2.32	2.53	4.25	3.60	6.04
Down	1.25	1.95	2.24	3.58	3.17	5.05

Lines D and E in Fig. 4 show the milling-energy values plotted for constant feeds of 0.005 and 0.010 in., respectively. For each depth, cutting-up and cutting-down lines are shown. The cutting-up and cutting-down lines are parallel in themselves, and the energy lines for different feeds also are parallel in themselves. The slope of the constant-feed lines, however, is somewhat greater than that of the constant-depth lines. Using these curves as a basis, in which lard oil was used as a lubricant, a milling-energy formula is obtained as follows:

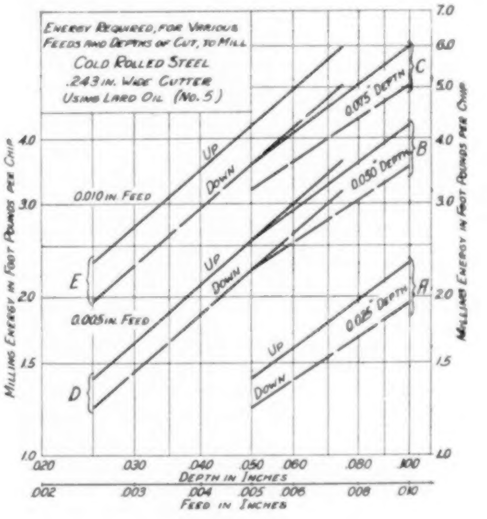

FIG. 4

$$E = Cwf^{0.73}\,d^{0.87} \qquad \ldots\ldots [3]$$

For this condition the value of C when milling up, using lard oil, is found to be 6800. In milling down, the energy equation becomes:

$$E = Cwf^{0.67}\,d^{0.87} \qquad \ldots\ldots [4]$$

For this condition the value of C, using lard oil as a lubricant, becomes 4260. These equations and constants are summarized in Table 18.

S.A.E. 3150 Steel. Milling-energy values for a constant feed of 0.010 in. for various depths of cut ranging from 0.010 to 0.125 in. are shown in the upper part of Table 7. These values are for dry cutting and are given for both up and down cutting. They are shown plotted in Fig. 5 as curves indicated at A. The down-milling-energy values are consistently lower than the corresponding values for milling up. The down and up lines, however, are parallel. The slope of these variable depth curves is unusual, being 1.01, which signifies that deep cuts are removed less efficiently from a power or energy standpoint.

for this material. The energy values for a constant depth of 0.125 in. and variable feeds for both dry cutting (No. 1) and when cutting with a sulphurized mineral oil (No. 10) are shown for both up and down cutting in the lower part of Table 7. These values are shown plotted in Fig. 5 at *B*. Four parallel lines are obtained, with the down-cutting-energy values lower than the up-cutting values for both cutting fluids Nos. 1 and 10. From these curves, a formula representing milling energy is obtained as follows:

$$E = Cwf^{0.7}\, d^{1.00} \qquad [5]$$

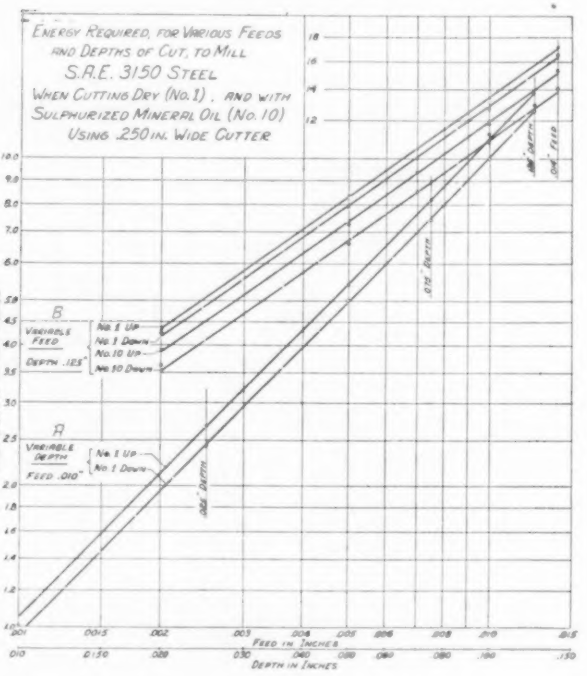

FIG. 5

which holds for both up and down cutting. The value of *C* for dry cutting (No. 1) is 11,000 for milling up and 10,600 for milling down. For the sulphurized mineral oil (No. 10) it is 9780 for milling up and 8980 for milling down. These formulas and constants are summarized in Table 18.

S.A.E. 6140 Steel. Additional milling-energy data for various depths of cut and feeds are shown in Table 8. For a constant feed of 0.010 in., the depth was varied from 0.010 to 0.150 in. when milling both up and down with a 10 per cent lard, 90 per cent mineral oil (No. 8). These values are shown plotted at *A* in Fig. 6. The broken line, representing the milling-energy values on the down stroke, is seen to be parallel to, but above, the corresponding energy values for milling up. This is the first instance in the data presented that the milling-down values have appeared to be above the milling-up values.

The lower part of Table 8 gives the results of energy values for a constant depth of 0.125 in., but for various values of feed when cutting dry and with oil No. 8. These values are shown plotted at *B* in Fig. 6. The up-and-down energy values for each of the two oils gave four parallel lines when plotted over variable feed. Again, in each instance the milling-down lines are above the corresponding milling-up lines, although the percentage difference is not large. The formula representing milling energy as a function of cutter width, feed, and depth of cut as determined from the curves in Fig. 6 may be written as

$$E = Cwf^{0.72}\, d^{0.90} \qquad [6]$$

TABLE 7 ENERGY REQUIRED IN MILLING S.A.E. 3150 STEEL

(Cutter, 0.250 in. wide; cutting dry and with sulphurized mineral oil. Values plotted in Fig. 5)

TABLE 8 ENERGY REQUIRED IN MILLING S.A.E. 6140 STEEL

[Cutter, 0.250-in. wide; cutting with a 10-per cent lard–90-per cent mineral oil (No. 8), milling up and down. Values plotted in Fig. 6]

Feed in inches	Depth in inches	Oil No. 1 (Dry) Up	Oil No. 1 (Dry) Down	Oil No. 8 Up	Oil No. 8 Down
0.010	0.010	...	...	1.45	1.55
0.010	0.025	...	...	3.40	3.57
0.010	0.050	...	...	6.45	6.75
0.010	0.075	...	...	9.60	9.70
0.010	0.100	...	...	12.35	12.60
0.010	0.125	...	...	14.80	15.30
0.010	0.150	...	...	17.15	17.39
0.001	0.125	2.90	3.00	2.65	2.71
0.003	0.125	6.45	6.69	5.85	6.37
0.005	0.125	9.65	9.55	8.77	9.10
0.010	0.125	14.91	15.85	14.51	15.22

in which the value of *C* for dry cutting (No. 1) is 10,630 for milling up and 11,220 for milling down. For oil No. 8 it is 9950 for milling up and 10,520 for milling down. These values are summarized in Table 18.

Bessemer Screw Stock. Data showing the milling energy in foot-pounds to mill a free-cutting cold-drawn steel, bar 414, are shown listed in Table 9 for a constant feed of 0.010 in. and depths of cut from 0.010 in. to 0.100 in. in four steps. Values are given for milling both up and down. Also energy values are given for a constant depth of cut of 0.100 in. and for three additional feeds of 0.005, 0.015, and 0.020 in., respectively.

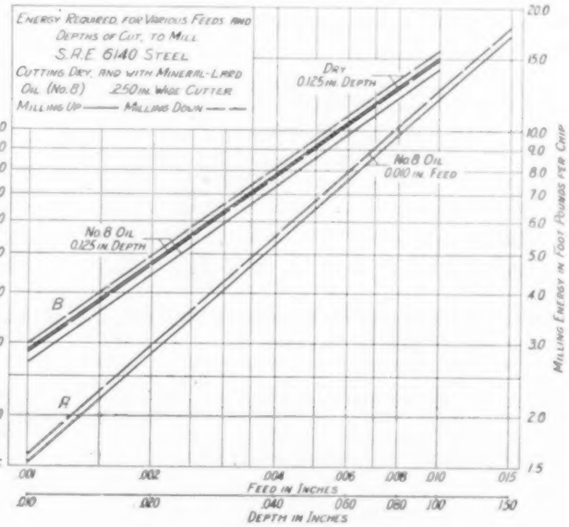

FIG. 6

These values are shown graphically in Fig. 7. The cutter width for these tests was 0.250 in., and a light mineral oil (No. 6) was used. It is seen that for the cutter width of 0.010 in. the milling-down curve is lower but parallel to the milling-up curve. Also the milling-energy curve for various feeds with a constant depth of cut of 0.100 in. shows the milling-down line lower but parallel to the milling-up line. The equation representing the energy in foot-pounds required to remove one chip of this free-cutting screw stock is found to be:

$$E = Cwf^{0.77}\,d^{0.86} \qquad [7]$$

in which C for oil No. 6 when cutting up is 8180 and when cutting down is 6720. This equation is given with others in Table 18.

High-Speed Steel. Table 10 gives data for various combinations of feed and depth when cutting both dry (No. 1) and with mineral lard oil (No. 8) when milling up and down. The values are plotted for constant depth and constant feed, respectively, on log-log paper in Fig. 8. For this combination the cutting-down-energy values are greater than those for cutting up for both constant feed and depth. Also there appears to be little difference in energy values per chip whether the annealed high-speed steel is cut dry or with a mineral lard oil (No. 8).

The equation representing the milling energy as a function of the cutter width, feed, and depth was found to be

$$E = Cwf^{0.73}\,d^{0.84} \qquad [8]$$

in which the values of C for milling up with both dry cutting (No. 1) and mineral lard oil (No. 8) were found to be practically the same at 9700. The value when milling down was found to be 10,400 for both oils Nos. 1 and 8, as given in Table 18.

Cast Iron. The milling-energy data were obtained from a set of cast-iron test bars 2 in. × 4 in. × 14 in. These bars contained 1 per cent of nickel. Readings were taken when milling dry for cuts both up and down. The milling-energy data for various cuts are given in Table 11 and plotted on log-log paper in Fig. 9.

Again it is seen that the milling-energy values when cutting down for both the constant feed of 0.010 in. and constant depth of 0.150 in. are greater than when cutting up, as was found in the case of the annealed high-speed steel. The milling-energy formula was found to be:

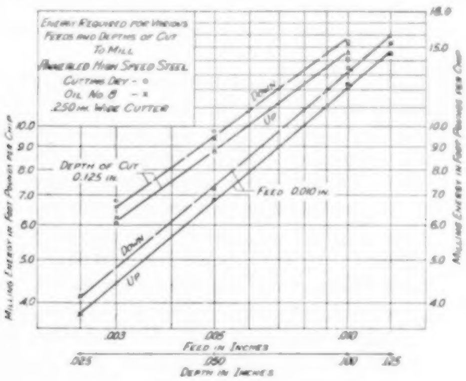

Fig. 8

$$E = Cwf^{0.41}\,d^{0.56} \qquad [9]$$

in which values of the constant C when cutting dry were found to be 595 when cutting up and 643 when cutting down. The exponents of the feed and depth in this equation are the lowest for all the metals tested. This material caused the tool to dull quickly so that considerable precaution was needed in keeping the tool cutting edge in the sharp condition.

Pure Copper. Further tests to determine the influence of variable feed and depth when milling were run on pure copper. The results of these tests are shown in Table 12, and the data are plotted in Fig. 10. Results of two series of tests are shown, the first having a constant feed of 0.010 in. with variable depths from 0.010 in. to 0.150 in. in seven steps. For these tests oil No. 8, consisting of 10 per cent lard oil in 90 per cent light mineral oil, was used. The second series of experiments were varied for values of feed between 0.001 and 0.010 in. per chip for a constant depth of cut of 0.125 in. when cutting dry (cutting fluid No. 1), and when cutting with a 10 per cent lard oil in 90 per cent light mineral oil (No. 8). For each cutting condition, cuts were made both on the up stroke and down stroke.

The results presented in Table 12 for the constant feed of 0.010 in. for variable depth are shown plotted as the two lowest lines,

TABLE 9 ENERGY REQUIRED IN MILLING FREE-CUTTING SCREW-STOCK STEEL NO. 414

[Cutter, 0.250-in. wide; cutting with light mineral oil (No. 6), milling up and down]

Feed in inches	Depth in inches	Milling Up	Milling Down

TABLE 11 ENERGY REQUIRED IN MILLING CAST IRON (CF)

[Cutter, 0.250 in. wide; cutting dry (No. 1); milling up and down]

Feed in inches	Depth in inches	Milling Up	Milling Down
0.010	0.025	2.82	3.04
0.010	0.050	4.20	4.43
0.010	0.100	6.20	6.62
0.010	0.150	7.80	8.40
0.005	0.150	5.85	6.30
0.015	0.150	9.20	9.90
0.020	0.150	10.40	11.20

indicated at *A*, in Fig. 10. The experimental points indicate the two lowest straight lines in the figure, the upper or solid one of which represents the energy required to remove the chip on the up stroke, while the broken line represents the energy required to remove the chip on the down stroke. In both instances oil No. 8 was used. It is seen that the experimental points conform quite closely to the indicated lines. The two lines are parallel, indicating that the coefficient of the variable depth in the energy or power equation remains constant.

TABLE 13 EFFECT OF SLIGHT AMOUNT OF OIL ON CUTTING ENERGY WHEN MILLING PURE COPPER

(Cutter, 0.250 in. wide; feed, 0.010 in.; depth, 0.125 in.)

	Energy in foot-pounds per chip: Dry, Clean [a]	Dry, Not clean [b]	Oil No. 8
Up	16.75	14.50	7.47
Down	11.15	10.89	6.91

[a] Tool and work cleaned with alcohol. Adhering chips removed with a clean screwdriver.

[b] Same as [a], except chips removed with fingers. Oil film on tool was not visible.

The data of Table 12 for the variable feed values are shown plotted in Fig. 10 for both dry cutting and when cutting with oil No. 8, as indicated by *B* and *C*, respectively. The depth of cut in each case was constant at 0.125 in. Uniform performance was obtained when cutting with oil No. 8 with both the up and down cuts. Each experimental point represents the average of ten successive cuts. The curves at *C*, representing the energy when cutting up and down when no lubricant was used (cutting fluid No. 1), are the results of three different tests; that is, each point represents the average energy value of 30 individual cuts. There was a noticeable lack of uniformity when cutting pure copper dry until it was noticed that the operator was removing with his finger the chips which, after being severed from the work, remained attached to the cutting edge. This led to some additional experiments, the results of which are given in Table 13. The same cutter was used, but it had been reground, and the tests were run at a later date. Cuts were successively taken as follows:

1 With the tool and work thoroughly cleaned with alcohol, for which condition, chips adhering to the cutter were pushed off with a clean screw driver.

2 The tool and work were thoroughly cleaned with alcohol, but the chips adhering to the tool were pushed off with the finger, for which condition no film of oil on the tool was detectable.

3 Tests in which oil No. 8 was employed.

Table 13 shows that on the up stroke, the energy per chip is 16.75 ft-lb. in the thoroughly clean condition, 14.5 ft-lb. when the chip was removed by the finger, and 7.47 ft-lb. when cutting oil No. 8 was used. Similarly, when cutting down, the milling-energy values were 11.15 for the clean condition, 10.89 for the condition when the chips were removed with the finger, and 6.91 when cutting fluid No. 8 was used. The differences for dry cutting between conditions *a* and *b* on the upward stroke are large. In this condition the chips were rigidly attached to the cutting edge, so that it was an effort to pry them off with the finger. There was, therefore, a noticeable contact between the finger and the cutting edge which undoubtedly left a certain moisture film. On the down stroke, however, the differences in energy values under the conditions *a* and *b* as shown in Table 13 appear to be small. In this type of cut, frequently the chips were removed with ease, and in many instances did not adhere at all after the cut.

It appears that the readings for condition *b*, in which the chips adhering to the cutting edge were removed by the finger

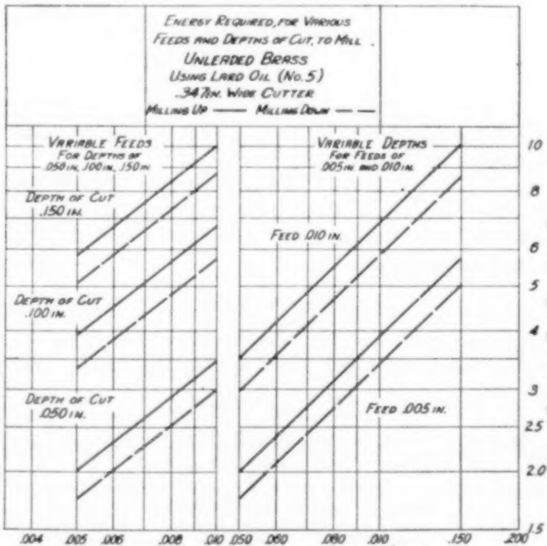
Down	1.35	2.37	1.99	3.49	3.05	5.55

on both the up and down stroke, would conform more nearly with the values indicated by the two curves C in Fig. 10. Inasmuch as the test data shown in Table 13 were obtained at a considerable time interval after the tests shown by the curves B and C in Fig. 10, the cutting tool had been reground and was unquestionably not in the same ideal condition. It seems certain, however, that if the chips had not been removed by the finger, the cutting-up curve at C for dry cutting, as shown in Fig. 10, actually would be moved upward vertically by about 30 per cent. Such a set of values in which the work and tool were thoroughly cleaned and the cutter not touched by the hand is indicated by the light solid and broken lines D, which were obtained as a final check on this controversial question. It appears that the milling-down curve at C would be affected but little by the method of removing the chip from the cutting edge.



F.G. 11

From Tables 12 and 13 energy values on the up- and down-cutting strokes for oil No. 8 are available when the cut was 0.125 in. in depth and with a feed of 0.010 in. For the up stroke from the variable-feed tests, this value is 8.3 ft-lb., as compared with 8.1 from the variable-feed tests, and with 7.47 ft-lb. as given in Table 13. Naturally these values should all be the same, if they were taken with the cutter in the same condition. This was not the case, inasmuch as the constant-feed and constant-depth data of Table 12 were each obtained in tests run at different times, and the check tests of Table 13 were run at still a later date. The discrepancies in values are due, it is believed, to the different conditions of the cutter rather than to lack of uniformity of tests or to errors.

Curves A, Fig. 10, were obtained with a cutter in a slightly duller condition than in the case of curves B and C. From curves A and B it appears that with the former, which were obtained with the cutter in a slightly duller condition, the difference varies between energy values for a given cutting condition on the up and down stroke. All this has been investigated further and is reported on later. No other material tested shows such sensitiveness to cut, quantity of oil, or mixture as this pure copper.

Two things may be noted from Fig. 10: the inclination of the constant-depth line is decidedly less than that of the constant-feed lines, and a considerable saving in energy is found for milling down when the cutter is in a reasonably sharp condition.

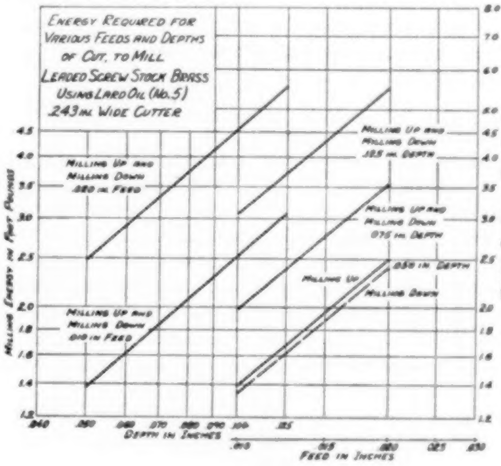


FIG. 12

The milling-energy formula for pure copper is found to be:

$$E = Cwf^{0.62} d^{0.92} \ldots\ldots\ldots\ldots [10]$$

in which C is 5980 for oil No. 1 (dry cutting) cutting up and 5090 for cutting down. For oil No. 8 (10 per cent lard oil in a light mineral oil) this constant is 3860 for cutting up and 3375 for cutting down. Also, the horsepower per cubic inch of metal removed per minute may be expressed as

$$\text{Hp. per cu. in. per min.} = \frac{C}{33{,}000\, f^{0.38}\, d^{0.08}} \ldots\ldots [11]$$

Unleaded Brass. The milling-energy tests when milling up and down for a combination of depths of cut and feeds were extended to an unleaded brass 50-A with a 0.347-in. cutter when using lard oil (No. 5). These data are given in Table 14 and are shown plotted in Fig. 11. Feeds of 0.005 and 0.010 in. were used for three depths, 0.050, 0.100, and 0.150 in., respectively.

The constant-feed variable-depth energy lines plotted in Fig. 11 show the milling-down-energy values to be below the corresponding values when milling up. For the constant-depth curves the milling energy when cutting down is also below the energy value when milling up.

The equation representing the energy as a function of cutter width, feed, and depth of cut when cutting with lard oil (No. 5) was found to be

$$E = Cwf^{0.77} d^{0.96} \ldots\ldots\ldots\ldots [12]$$

for which the value of the constant when cutting up is 6040 and when cutting down is 5170. See Table 18.

Annealed Leaded-Brass Screw Stock. An annealed leaded-brass screw stock, 187-A, was next selected as the material of interest in this study. A cutter 0.243 in. wide was used when cutting with lard oil (No. 5). Energy values when cutting up and down for feeds of 0.010 and 0.020 in., for depths of cut of 0.050, 0.075, and 0.125 in., respectively, are listed in Table 15 and shown graphically in Fig. 12.

Table 15 shows that the energy values when milling up and down are practically identical for any given cutting conditions. For a depth of cut of 0.050 in. and a feed of 0.020 in., the energy when cutting up is 2.50 ft-lb. as compared with 2.37 when cutting down. This is the greatest divergence in values noted and, in view of the consistent results otherwise obtained, is negligible.

The curves in Fig. 12 show the energy values for milling up and down and indicate the equality of the two values except for the milling-down line for the 0.050-in. depth of cut, which is shown slightly below that for milling up. The milling-energy formula for this annealed leaded brass, bar 187-A, when cutting with lard oil (No. 5) is

$$E = Cwf^{0.84}\, d^{0.87} \qquad [13]$$

When cutting with lard oil (No. 5) the constant C was found to be 3700 when cutting up or down. When cutting with a light mineral oil (No. 6) the values of C were found to be 3730 cutting up and 3700 cutting down. See Table 18.

Cold-Drawn Leaded-Brass Screw Stock. Using the 0.250-in.-wide cutter having a 15-deg. front-rake angle, energy values were determined when milling up and down with lard oil (No. 5) and mineral oil (No. 6), a cold-drawn leaded-brass screw stock, BF. The energy values for the various cuts are given in Table 16, and are shown plotted on log-log paper in Fig. 13.

The milling-down-energy values are consistently below those for milling up, and there appears to be little difference in energy values as a result of using different oils. The milling-energy lines resulting from these data give the formula

$$E = Cwf^{0.76}\, d^{0.96} \qquad [14]$$

for which the value of C, when milling up, is found to be 3830 for both lard oil (No. 5) and light mineral oil (No. 6), and 3600 for both oils when milling down. See Table 18.

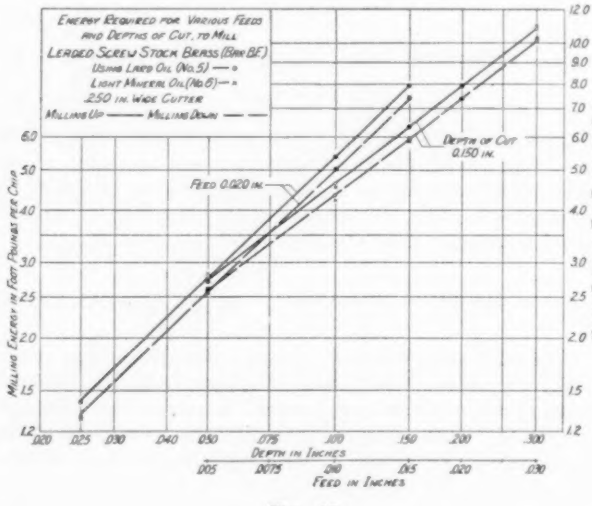

FIG. 13

Bakelite and Wood-Fiber Rod. It was thought desirable to extend these milling tests to some non-metallic materials, and for this purpose a bar of bakelite $^3/_4$ in. in diameter and another of wood fiber 1 in. in diameter were selected. The energy values are listed in Table 17 and are shown plotted on log-log paper in Fig. 14.

As shown in Fig. 14 bakelite machines with more difficulty from the energy standpoint than wood fiber. The distinctive characteristic of these lines seems to be that for the first time in the investigation, with a sharp cutter, the energy lines, when cutting up and down for a given material, are not parallel. For variable depth the energy lines for bakelite are nearly parallel but tend to converge at the lower left. The milling-down-energy values in all cases are above those when milling up. It appears, however, that, if the depth of cut were small enough or the feed were reduced sufficiently, the milling-down-energy value would fall below that for milling up.

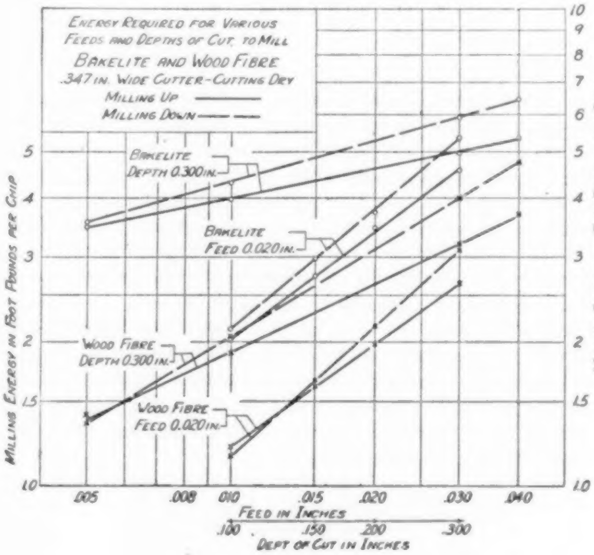

FIG. 14

For bakelite it seemed desirable to give two milling-energy equations, one representing the energy required to mill on the up stroke, and the other to mill on the down stroke. When milling up, the equation is

$$E = Cwf^{0.21}\, d^{0.75} \qquad [15]$$

When cutting dry (No. 1) the value of C is found to be 74. When milling bakelite on the down stroke, the energy equation is

$$E = Cwf^{0.29}\, d^{0.83} \qquad [16]$$

0.040	0.300	5.35	6.42	3.70	4.75

When cutting bakelite dry the value of C was found to be 130.

For wood fiber, the energy formula when cutting up was found to be

$$E = Cwf^{0.49}\, d^{0.72} \qquad [17]$$

When cutting dry, the value of C was found to be 121. When cutting the wood fiber on the down stroke, the formula was

$$E = Cwf^{0.61}\, d^{0.91} \qquad [18]$$

When cutting dry, the constant C was found to be 281. These formulas are summarized in Table 18.

Summary. The various milling-energy formulas when milling up and down with a variety of cutting fluids on thirteen different materials are summarized in Table 18. The milling energy is given in foot-pounds per chip and is given as a function of a constant C which depends upon the material being cut; the condition of cutting, whether up or down; the shape, sharpness, and size of the cutter; the feed; and the depth of cut. The general formula is

$$E = Cwf^{x}\, d^{y} \qquad [19]$$

in which E is the energy in foot-pounds per chip, C the constant for the cutter, material, and cutting fluid; w the width in inches of the cutter having a 15-deg. front-rake angle and 0-deg. side-rake angle; f the feed in inches per chip; and d the depth of cut in inches.

TABLE 18 MILLING-ENERGY AND HORSEPOWER FORMULAS AND VALUES OF THE CONSTANT C FOR VARIOUS MATERIALS AND FOR MILLING UP AND DOWN WITH VARIOUS CUTTING FLUIDS

(Formula: $E = Cwf^{x}d^{y}$, in which, C = constant for cutter, material, and cutting fluid; E = energy in foot-pounds per chip; w = width of cutter in inches having 15-deg. rake; f = feed in inches per chip; and d = depth of cut in inches)

[a] Feed in inches, 0.010; depth of cut in inches, 0.125.

Where only one formula is given, the presumption is that it represents the energy for both cutting up and down with sufficient accuracy. The constant C in the formula, however, may differ for cutting up or down, but the energy lines, when plotted on log-log paper for a constant depth or constant feed, are parallel. It is seen that the exponent of the depth d ranges in volume from a minimum of 0.56 for cast iron containing 1 per cent nickel to a maximum of 1.00 for the S.A.E. 3150 steel annealed. This indicates that for cast iron there would be a great saving in power when heavy depths of cut are taken, but no saving when cutting steel.

The exponents of the feed f ranges from 0.21 for bakelite milling up to 0.84 for annealed leaded screw-stock brass. For cast iron it is 0.41, whereas the average for the metals appears to be approximately 0.7.

Inasmuch as the average exponent of the depth appears to be much higher (approximately 0.85) than that of the feed, which averages about 0.7, it is obvious that greater economy of power is obtained when taking heavy feeds than when taking heavy cuts. The formulas indicate that the depth should be as great as possible, but it is of more importance that the feed per tooth be as great as possible.

The energy formulas for each material cut have been reduced to power formulas giving the horsepower required to cut one cubic inch per minute. These formulas are given as functions of the constant C, the feed f, and the depth of cut d. The values of the constant C are the same as those for the energy formulas and are listed at the right in Table 18 for various cutting fluids and for milling up and down.

Specific values of the horsepower per cubic inch per minute when cutting up and down with one or more cutting fluids are given for each of the materials cut. These horsepower values are for the specific cutting conditions when the cutter is $^1/_4$ in. wide, which value does not appear in the horsepower formula. The cutter was sharp and had a front-rake angle of 15 deg. and no side-rake angle. The feed, however, is 0.010 in. per chip, and the depth of cut 0.125 in. It is seen that the horsepower per cubic inch per minute when cutting the S.A.E. 1020 steel by milling up is 1.388, but when milling down is only 1.169. For this metal more power is required to mill up the usual way for all cutting fluids than when milling down. It seems desirable, therefore, from the viewpoint of power, to mill S.A.E. 1020 on the downstroke, that is, with the feed. For the S.A.E. 1020 steel, the same formulas with different constants hold for milling both up and down.

When milling the cold-rolled low-carbon steel, it was found that the energy formula for milling up is somewhat different from that when milling down. The exponent of the feed is 0.73 when milling up and only 0.67 when milling down. The horsepower per cubic inch per minute when milling up with lard oil is 0.936, and when milling down is only 0.775. This shows that the saving when milling down for this material increases with increased feed. The horsepower value when cutting the S.A.E. 6140 steel dry on the up stroke is 1.44, but when cutting down is 1.52, showing that more power is required for this material when cutting down than when cutting up. The same relation holds true when cutting this steel when 10 per cent lard oil in mineral oil (No. 8) is used. More power is required on the down stroke than on the up stroke for both dry cutting and cutting fluid No. 8 when annealed high-speed steel is cut. It is therefore seen that some materials cut easier on the down stroke, while others cut easier on the up stroke.

The Effect of Dulling

Tool-life tests are not practical using the dynamometer employed in these tests, so that further investigations of the nature studied in this paper, carried out by commercial cutters on standard milling machines both in the laboratory and by actual practice, are indicated.

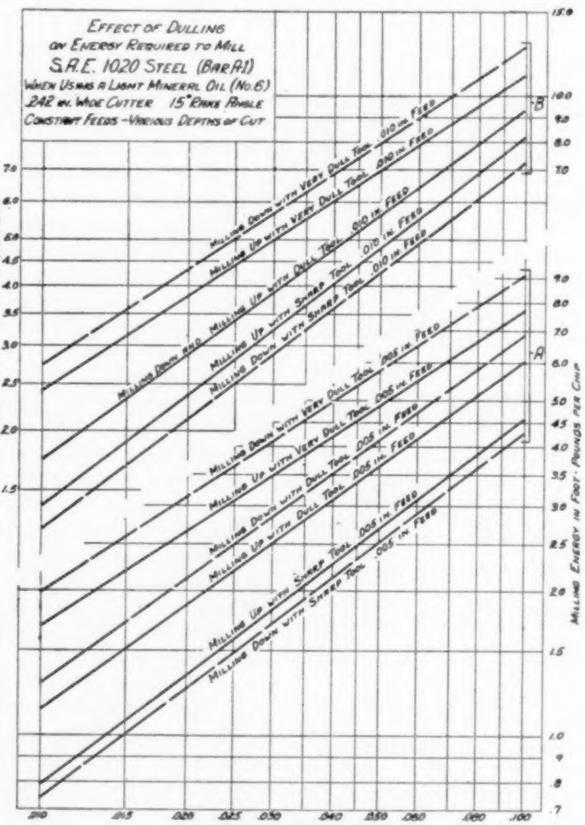

Fig. 15

It was felt desirable, however, to determine the effect of certain degrees of dullness of the cutter on the energy required in milling by the up and down processes. For this purpose a series of tests were undertaken in which the degree of dullness was made the variable.

Table 19 gives the results of a series of tests in which the milling cutter first was given a constant feed of 0.005 in. per cut and a depth of cut ranging from 0.010 to 0.100 in. in four steps. In the first test the cutter was ground and then honed so as to be as sharp as possible. For each of the depths indicated, the energy required to remove a chip is seen to be greater when cutting up than when cutting down. In the second and third series of tests, *B* and *C*, the cutter was dull and very dull, respectively.

By using a micrometer and magnifying glass, it is estimated that, in the very dull condition, the cutting edge was honed so as to form a segment of a cylinder from 0.006 to 0.007 in. in diameter. For the intermediate or dull condition the diameter is estimated to be approximately one-half that for very dull. For the dull and very dull conditions the energy values are greater when cutting down than when cutting up, which is the reverse of that indicated for the tool in the sharp condition. These values are shown plotted in Fig. 15, giving a series of lines indicated at *A*. Again, the solid line in each instance indicates milling up, while the broken line indicates milling down.

The lowest two lines of group *A* are for the tool in the sharp condition when the feed was 0.005 in. and the depth varied from 0.010 to 0.100 in. These values plotted on log-log paper give straight parallel lines, with the milling-up line above the milling-down one. The values for milling down are about 6.8 per cent below those for milling up.

The intermediate set of lines of group *A* show the milling-energy curves for the tool in a dull or intermediate condition with the feed still at 0.005 in. per chip. This shows the milling-up line to be below the milling-down one. For the dull condition the milling-down-energy values are 11.1 per cent above the milling-up-energy values.

The upper two lines of group *A* represent the milling-energy values for the 0.005-in. feed when the tool is in a very dull condition. Here again it is to be noted that the milling-down-energy values are above the milling-up values by 18.2 per cent.

The effect of dulling is very apparent from this determination. As the cutter becomes dull, the energy required to remove a chip increases. The lines become more nearly horizontal as the dullness increases, which indicates that dullness has less influence on heavier feeds and depths of cut. It is also apparent that the energy required to remove a chip increases more rapidly with dullness when cutting down than when cutting up, so that, while less energy is required in milling down with a sharp tool, much more is required as the tool becomes dull.

The variable-depth tests were repeated with a feed per cut of 0.010 in. These values for each condition of sharpness are given in the lower portion of Table 19. They are shown plotted in the upper part of Fig. 14, resulting in the group of straight lines indicated at *B*. Again the energy values for the tool in the sharp condition, when taking a feed of 0.010 in. per chip, show that the milling-up values are higher than the milling-down ones. With the tool in the dull condition at this feed, the milling-up and milling-down values become equal. The energy values for the tool in the very dull condition are reversed in that the milling-down-energy values are well above the milling-up-energy values. Again it is seen that the slope of the energy lines for the tools in the very dull condition are less than those for the tool in the sharp condition, indicating again that for heavy depths of cut the dullness has less effect.

When the feed is 0.005 in. the total increase in milling energy per chip when milling up with a very dull cutter over the milling up with a sharp cutter, is 114 per cent for a depth of cut of 0.010 in. For a depth of cut of 0.100 in. the milling-up energy for the very dull cutter is 69 per cent greater than the milling-down energy for the sharp cutter. Also, for the 0.005-in. feed, the milling-down-energy value with the very dull tool is 168 per cent greater than when milling down with a sharp tool for a depth of cut of 0.010 in. Also, for a depth of cut of 0.100 in., the milling-down-energy value for the very dull tool is 112 per cent higher than the corresponding energy value when milling down with a sharp tool.

When the feed is 0.010 in., the increase in milling-down-energy values of the very dull tool over the sharp tool is 122 per cent, as compared with a corresponding increase of 73 per cent for the milling-up values at a depth of 0.010 in. Similarly, the increase of the milling-down-energy values for the very dull tool over the milling-down values with the sharp tool for the 0.010 in. feed and 0.100 in. depth is 68 per cent, as compared with 34 per cent for the corresponding milling-up-energy values.

From Fig. 15 it is obvious that increased dulling has less influence on both heavier feeds and depths of cut.

The values of the energy required to remove a chip by milling for various degrees of dullness of the cutter, as given in Table 19, are shown in Fig. 16 plotted over variable feed for each condition of tool sharpness and for each of the four depths of cut. In the lower left-hand corner of Fig. 16 are shown the milling-energy values when cutting up and down for a depth of cut of 0.010 in. when a light mineral oil (No. 6) is used. For milling up with the sharp tool, the energy value for the depth of cut of 0.010 in. and a feed of 0.005 in. is 0.79 ft-lb., as indicated at the left. The energy value when milling up with a feed of 0.010 in. and 0.010 in. depth of cut is 1.39 ft-lb. The corresponding values for down milling are 0.74 and 1.24 ft-lb., respectively, for the 0.005-in. and 0.010-in. feed. Above these lines are shown other lines for depths of cut of 0.025, 0.050, and 0.100 in., respectively. In the center of Fig. 16 are shown the various energy values when milling up and down for the dull tool for each of the four different depths of cut. At the right are shown increasing energy values for the very dull tool for each of the four depths of cut. For the sharp tool the milling-up-energy values, as indicated by the solid lines, are above the milling-down-energy values, as indicated by the broken lines, for each of the four depths of cut.

For the cutting edge in the intermediate or dull condition, the milling-down-energy values are higher than the milling-up values for all depths of cut until the feed of 0.010 in. is reached, when they coincide. When the cutting edge of the tool is in a very dull condition, the milling-down-energy values are shown above the milling-up-energy values for all depths of cut and for all values of feed between 0.005 and 0.010 in. It is interesting to note that the lines representing energy when milling up for each degree of tool sharpness are parallel for the different depths of cut. The same statement holds true for the milling-down-energy lines, although there appears to be a great variation in the slope of the milling-down-energy lines as the sharpness of the tool is changed from sharp to dull. There is a little additional change in slope of the milling-down-energy lines as the tool sharpness is changed from dull to very dull.

The effect on the depth exponent in the milling-energy formula as a function of depth and feed is not nearly so pronounced as on the feed exponent. This seems due to the fact that the thickness of the chip is more a function of the feed than of the depth and the thicker the chip the less effect dullness might be expected to have. The effect of dulling on milling energy is quite different from that in drilling or planing where continuous chips are formed. This is probably because the duration of cut in milling is too short for the built-up edge, if it is formed, to exert an appreciable influence on the formation of the chip.

Effect of Dulling on S.A.E. 3150 Steel. As the effect of dulling is more apparent on feed than on depth, an additional test to study dulling was made on S.A.E. 3150 steel in an annealed condition, bar KF, in which a sulphurized mineral lard oil (No. 11) was used and in which the feed only was varied. The depth of cut was maintained at 0.075 in., while feeds of 0.005 and 0.010 in. were used.

Energy values were obtained when cutting both up and down with the cutting tool in the sharp, dull, and very dull conditions. These values are shown in Table 20. The conditions of dullness as shown in Fig. 17 were approximately the same as referred to in Figs. 15 and 16.

TABLE 19 EFFECT OF DULLING ON ENERGY IN MILLING S.A.E. 1020 STEEL (BAR A-1)

[Cutter, 0.242 in. wide; cutting with light mineral oil (No. 6); milling up and down with various feeds and depths of cut. Values plotted in Figs. 14 and 15]

Feed in inches	Depth in inches	A (sharp)		B (dull)		C (very dull)	
		Up	Down	Up	Down	Up	Down
0.005	0.010	0.79	0.74	1.14	1.30	1.69	1.98
0.005	0.025	1.56	1.47	2.01	2.42	3.08	3.67
0.005	0.050	2.71	2.55	3.78	4.30	4.88	5.83
0.005	0.100	4.59	4.30	6.04	6.75	7.69	9.09
0.010	0.010	1.39	1.24	1.79	1.72	2.41	2.75
0.010	0.025	2.89	2.46	3.24	3.38	4.31	4.95
0.010	0.050	4.56	4.22	5.58	5.56	7.06	8.12
0.010	0.100	8.2	7.30	9.50	9.65	11.00	12.6

In Fig. 17 the energy-value lines for different degrees of sharpness, plotted against the feed in inches for milling down, are above the milling-up-energy lines for each degree of dullness. The same general relations between energy and dullness are to be noted.

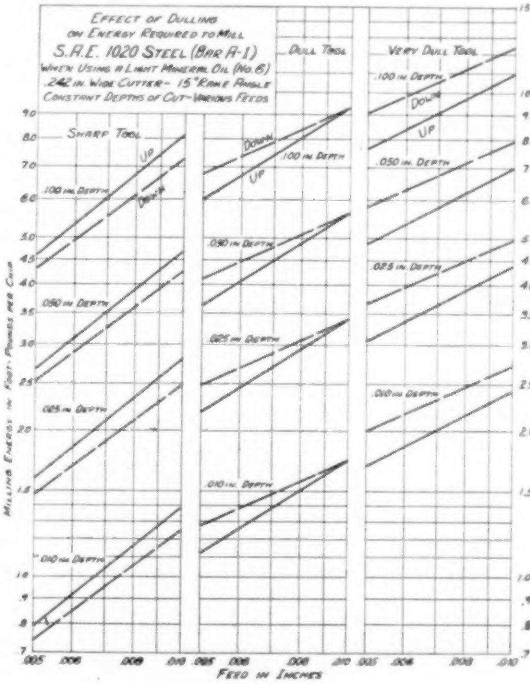

FIG. 16

EFFECT OF CUTTING FLUIDS ON MILLING ENERGY

Data for use in determining the effect of various cutting fluids on the two methods of milling, that is, milling up and milling down, were obtained when cutting four metals: S.A.E. 1020 steel (bar A-1), cold-rolled low-carbon steel, free-cutting screw-stock steel, and a leaded brass, and are given in Table 21. They are shown plotted in Figs. 18, 19, 20, and 21, respectively.

Effect in Milling S.A.E. 1020 Steel. In Table 21 the energy values are given for both the up and down cuts when the 0.347-in.-wide cutter is used, operating at 0.100-in. depth and 0.010-in. feed, in the numerical order of the oils. These energy values are shown plotted over the oil numbers in Fig. 18 for the S.A.E. 1020 steel, arranged in the order of increasing energy required in milling up. From this it is seen that the lowest value in milling up is obtained with the sulphurized mineral oil (No. 10), with lard oil (No. 5), sulphurized mineral lard oil (No. 11), mineral lard oil (No. 8), and oleic acid mineral oil (No. 9) following

TABLE 20 EFFECT OF DULLING IN ENERGY IN MILLING S.A.E. 3150 STEEL

[Cutter, 0.250 in. wide; depth, 0.075 in.; using a sulphurized mineral-lard oil (No. 11) and milling up and down. Values plotted in Fig. 16]

	A (sharp)		B (dull)		C (very dull)	
Feed	Up	Down	Up	Down	Up	Down
0.005	5.83	6.28	7.95	8.40	9.88	10.52
0.010	8.55	8.88	10.80	10.85	13.10	13.00

closely in the order named. Cutting fluids 1-to-50 soluble oil (No. 3), heavy mineral oil (No. 7), 1-to-10 soluble oil (No. 4), and light mineral oil (No. 6) follow with almost equal energy values. Borax water (No. 2) shows a material increase in energy required, but all of the oils and water compounds are distinctly below the energy values for dry cutting (cutting fluid No. 1) for milling up.

The energy values when milling down show little conformity with those for milling up. Lard oil (No. 5) shows the lowest values of energy for milling down, with the sulphurized mineral oil a close second. It is interesting to note that the water compounds, consisting of borax water (No. 2), 1-to-50 soluble oil (No. 3), and 1-to-10 soluble oil (No. 4) give the next lowest values in the order named. Again, when cutting down, the highest energy values are obtained for dry cutting (cutting fluid No. 1).

The lower part of Fig. 18 shows plotted over the cutting-fluid numbers, arranged in the order of increasing value of the ratio, the ratio of energy values when cutting down to those when cutting up. This ratio is smallest for the borax water

Leaded screw-stock brass (BF)	0.250	0.125	0.020	Up	6.83	6.75	6.89	6.93	7.00	6.93	7.02	7.05	6.99	6.69	6.55
				Down	6.31	6.27	6.20	6.18	6.18	6.15	6.16	6.18	6.22	6.27	6.17

(cutting fluid No. 2), at a value of approximately 0.8. Dry cutting (No. 1) gives the next lowest value, 0.825, whereas the mineral oils, 9, 6, and 7 show the highest values of this ratio of nearly unity.

Effect in Milling Cold-Rolled Low-Carbon Steel. The energy values in foot-pounds per chip, when milling up and down the cold-rolled low-carbon steel with each of the eleven cutting fluids, are shown in Table 21. In Fig. 19 the energy values for the cold-rolled low-carbon steel are shown plotted over the oil numbers, arranged in the order of increasing energy required when milling up.

There are comparatively slight differences between the milling-up and milling-down-energy values for the various oils, except perhaps those for borax water (No. 2). The trend for milling up and down appears to be consistent. Again, the lowest energy values are obtained for both milling up and down for the sulphurized oil (No. 10), the sulphurized mineral lard oil (No. 11), and the lard oil (No. 5). Also, the highest values for both milling up and down are obtained when cutting dry (No. 1).

In the lower part of Fig. 19 is shown plotted over the oil numbers, arranged in the order of increasing value of the ratio, the ratio of the milling-up-energy value to the milling-down value.

In this instance the lowest ratio, approximately 0.84, is obtained for borax water (No. 2), while the highest ratios are obtained for cutting fluids 6, 8, 7, and 10, each equal approximately to 1.06.

A careful study of Figs. 18 and 19 shows that the results in milling the S.A.E. 1020 steel and the cold-rolled low-carbon steel of approximately the same analysis, correspond, in a general way, for the various cutting fluids. Arranged in the order of milling energy up, cutting fluids 10, 5, 11, and 8 give the four lowest energy values for each steel. The two mineral oils No. 6 and 7 are in about the same relative position for each steel, though reversed in order. In both cases, cutting fluids No. 2 (borax water) and 1 (dry) are at the right hand of the curve, showing that for them the greatest amount of energy is required. Dry cutting (No. 1) requires considerably more energy in milling up than the other cutting fluids. The greatest difference in the two materials is perhaps manifest in the value of the ratio of energy values of down to up. Those for cold-rolled low-carbon steel are consistently higher by about 6 per cent than those for the S.A.E. 1020 steel. Here again the order of the cutting fluids, when arranged from left to right in the order of increasing value of the ratio, as shown in Figs. 18 and 19, is about the same.

For both steels borax water (No. 2) is the lowest, and the emulsions (Nos. 3 and 4) and lard oil (No. 5) are in the same relative position. Oils 6, 7, and 10 are, on the other hand, high for both steels.

Effect in Milling Free-Cutting Steel. The third material on which these various cutting-fluid milling tests were run was a free-cutting screw-stock steel (No. 414) of the bessemer type. The milling-energy values for both cutting up and cutting down for each of the cutting fluids are listed in Table 21. The values are shown plotted in Fig. 20.

It is obvious that the energy required to remove this material is, for both milling up and down, considerably less for all of the cutting fluids than when milling the S.A.E. 1020 or cold-rolled low-carbon steels. The material machines in such a way that differences between the energy values, resulting from the use of various cutting fluids, is small, and it seems worthy of note that the sulphurized oils, which usually give low energy values, do not seem to be outstanding in this respect when cutting this free-cutting steel. In fact, the sulphurized mineral lard oil gives an energy value, when milling up, higher than all of the other oils, and even higher than soluble oil (No. 3). Oils 7, 10, and 11, however, show up to advantage on the down milling. As in the case of the two low-carbon steels, cutting fluids Nos. 2 and 1, borax water and dry cutting, respectively, give the highest energy values for the free-cutting steel when milling up. The borax water (No. 2) gives the second highest energy values when milling the free-cutting screw-stock steel, whereas they give relatively small values for down milling on the two low-carbon steels.

The value of the ratio of the energy required to mill down to that required to mill up is shown at the bottom of Fig. 20. These values cover a rather narrow range as compared with the corresponding values for the low-carbon steels, the lowest being 0.89 for heavy mineral oil (No. 7), and the highest value being 0.98 for the mineral lard oil (No. 8).

Effect in Milling Leaded Brass. The energy values per chip when milling a leaded screw-stock brass (BF) with a 0.250-in.-wide cutter having a 15-deg. front-rake angle when taking a depth of cut of 0.125 in. and a feed of 0.020 in. per chip for various cutting fluids, are shown at the bottom of Table 21. Chips were removed by milling both up and down. The values are shown plotted in Fig. 21.

While the feed has been increased over that used on the steels, the energy values are seen to be relatively low. Also, the differences in energy values for various cutting fluids are small. The energy values when milling up and down, as shown in Fig. 21, are plotted over the cutting fluid numbers, arranged in numerical order, due to the small differences in values for the different fluids. The milling-down curve is practically a straight horizontal line.

The highest energy value developed when milling down, however, is when cutting dry (No. 1), and the second highest when cutting with borax water (No. 2) and sulphurized mineral oil (No. 10). The lowest values are obtained with the straight mineral oils (Nos. 6 and 7) and the sulphurized mineral lard oil (No. 11). When milling up, however, the lowest values are obtained with the sulphurized oils (Nos. 10 and 11), with borax water (No. 2) a distant third. Little difference appears between the energy values for the other oils.

In the lower part of Fig. 21 are shown plotted the ratios of the energy values when cutting down to those when cutting up. The total variation is small, being 0.877 for the heavy mineral oil (No. 7) and 0.94 for the sulphurized mineral lard oil (No. 11).

Finish and Tool Life

While it was not the authors' intention to present data on the subject of finish and its relation to tool life in this paper, a number of observations were made which consistently point to certain conclusions. Perhaps the finish and tool life obtained on a comparatively frail dynamometer, such as that used in the tests made, may not check with similar findings on a regular commercial machine and operations.

It was noticed that the tendency to chatter when milling up is pronounced, especially as the tool becomes dull. In only a few instances were chatter marks visible on the finished surface when cutting was done on the down stroke. Milling up invariably gives a shinier finish, due probably to a burnishing action at the very start of the cut. Milling down seems to give a surface which is flatter and freer from ridges resulting from the feed, and the resulting cut surfaces often had a dull, torn appearance. Ridges were invariably found when milling up with heavy feeds.

Dulling seemed to have little effect on the condition of the surface when milling down, and it may follow that if the cutter life is based on finish, its life will be greater when milling down than when milling up.

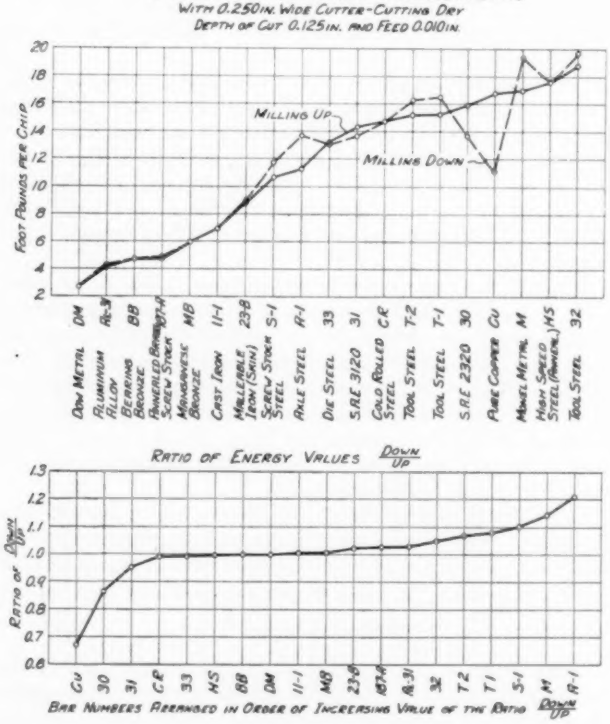

FIG. 22

COMPARING A VARIETY OF MATERIALS BY MILLING ENERGY

For the purpose of obtaining additional information on the influence of milling up or down on the energy values in foot-pounds required to remove a given chip, comparative tests have been made on a wide variety of ferrous and non-ferrous materials. All tests were run dry (No. 1) with a cutter 0.250 in. wide when taking a depth of cut of 0.125 in. and a feed of 0.010 in.

THE MATERIALS TESTED

The materials used in this study are listed in Tables 22, 23, and 24. Those in Table 22 included a variety of steels formerly reported on in a study of machinability.[7] The size of the bar, its chemical analysis, and the Brinell, Rockwell, and scleroscope hardness values are given.

[1] Materials used in "Power Required to Drill Cast Iron and Steel," Trans. A.S.M.E., vol. 52 (1930), MSP-52-2. Paper shows photomicrographs.

Table 23 lists those steels reported on in a study of drilling.[8] These bars were mostly forgings 2 in. × 4 in. in section, and were all in an annealed condition.

A number of cold-drawn steels are shown with their chemical analyses and hardness numbers in Table 24. These have previously been reported on in a study of machining properties.[9]

Photomicrographs (of all of these materials) are given in the respective references.

[d] Chrome.
[e] Nickel.

Results of Tests

The various values of energy in foot-pounds required to remove a specific chip are shown plotted over the different materials in Fig. 22. The materials are arranged from left to right in the order of increasing energy values for the condition of milling up. The energy values for milling down are superimposed and are shown to follow the milling-up line quite favorably. A number of interesting facts are evident. For the non-ferrous metals—cast iron, malleable cast iron, as well as the cold-rolled low-carbon steel, the die steel, and annealed high-speed steel—there appears to be very little difference between the milling-energy values when milling up and down. The value of the ratio of the energy required when milling down to that for milling up is practically unity.

Copper and monel metal are exceptions and show opposite characteristics. Of all the metals tested, copper has the lowest value of the ratio of energy down to up, this being only 0.668. Monel metal requires more energy when cutting down than when cutting up and has a ratio of energy values equal to 1.14. The three tool steels as well as the axle steel and screw-stock steel (S-1) also show greater energy values for milling down than for milling up, all giving values ranging from 1.05 to 1.21.

It is interesting also to note that the S.A.E. 2320 and 3120 steels, the only alloy steels except the die steel, show the values of the ratio considerably below unity, which indicates that in machining these metals it is desirable to mill down rather than up from a power standpoint.

The energy values when milling the standard chip 0.250 in. wide and 0.125 in. deep at a 0.010-in. feed with a 15-deg. front-rake cutter, for the group of carbon- and alloy-steel forgings are shown plotted in Fig. 23. The materials are arranged as abscissas from left to right in the order of increasing energy when milling up. This curve indicates the possibility of a relation to the energy values of two factors for each series of metals, namely, the carbon content and the temperature of annealing.

In the S.A.E. 61 series, for example, the energy value for S.A.E. 6120 is greater than that for S.A.E. 6130, which in turn is greater than that for 6140, which also in turn is greater than that for 6150. This indicates that the energy values increase as the percentage of carbon decreases and, with the exception of S.A.E. 6150, the value of the ratio of milling energy down to up increases as the percentage of carbon increases. The S.A.E. 6150 has a low ratio value of only 0.93. The S.A.E. 6150 steel, as shown in Table 23, was normalized at 1650 deg. fahr. and annealed at 1550 deg. fahr., giving a Brinell number of 187, whereas S.A.E. 6120, 6130, and 6140 all were annealed at 1500 deg. fahr. and reannealed at 1400 deg., giving Brinell numbers of 137, 156, and 163, respectively. This shows the Brinell number to be in direct proportion to the carbon content. This might indicate that the higher annealing temperature causes the material to machine easier. The arrangement for the S.A.E. 61 series confirms the arrangement previously shown in a paper on drilling[10] in which the S.A.E. 6150 has the lowest torque, followed in order by S.A.E. 6140, 6130, and 6120.

The same general tendency is shown for the S.A.E. 23 series. S.A.E. 2320 which was annealed at 1600 deg. fahr. shows lower milling-energy values than S.A.E. 2330 and 2340, which were annealed at 1500 deg. and reannealed at 1400 deg. This same relation was found also in the drilling experiments. The ratio value of energy required to mill down as compared with that for milling up is below unity for the S.A.E. 2320, equal to unity for S.A.E. 2340, and slightly above unity for S.A.E. 2330.

It will be noted that for the majority of these steels, less energy is required for milling down than for milling up.

As a conclusion, similar milling data for a variety of cold-drawn steels are shown plotted in Fig. 24. Again the bars are arranged as abscissa from left to right in the order of increasing milling energy when milling up. In the majority of cases, a saving is found in milling down and, in general, of about the same proportion.

---

[10] Trans. A.S.M.E., vol. 52 (1930), MSP-52-2, p. 19.

Bars 420, a manganese screw-stock steel, and 422, an S.A.E. 6140 steel, seem to be exceptions in that they are the only ones to show a material increase in energy in milling down over milling up. A curve showing the value of the ratio of milling down to milling up is also shown in Fig. 24, plotted over the materials arranged from left to right in order of increasing value of the ratio. The lowest ratio value is 0.885 for bar 413, a free-machining rustless steel. The ratio is fairly uniform at 0.95 for the majority of the metals, and only the last four to the right show ratio values above unity.

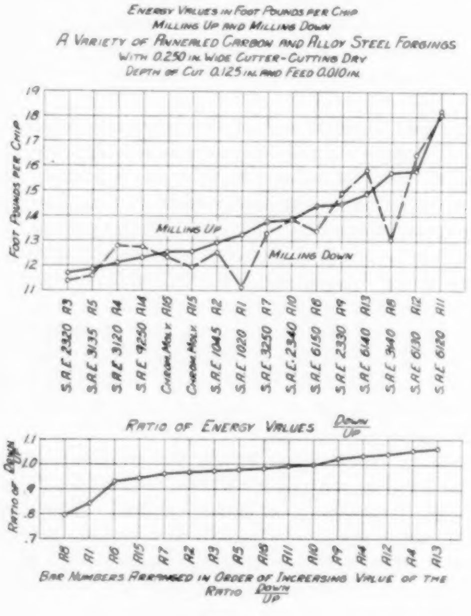

Fig. 23

Supplementary Milling-Energy Data Comparing Metals Cut With a Cutting Fluid

In order that some comparison of milling-energy data when using a lubricant with those when cutting dry might be made, a variety of metals were remachined, using a 10 per cent lard oil in 90 per cent mineral oil (No. 8) instead of dry cutting (No. 1). These milling-energy values in foot-pounds per chip when milling up and down are shown in Table 28. In making these check runs, the tool was supposedly in a sharp condition, although it was not freshly ground, so that the energy values under the same cutting conditions did not vary appreciably. It is to be noted, however, that with this mineral-lard oil, the energy values when milling up and down on S.A.E. 6150 steel (A-6) are both higher than when milling dry, as shown in Table 26. Also, the milling-up-energy value for the S.A.E. 6140 steel (A-13), in Table 28, when using cutting fluid No. 8 is slightly higher than the corresponding value when milling dry, as shown in Table 26.

TABLE 25 ENERGY REQUIRED TO MILL A VARIETY OF FERROUS AND NON-FERROUS METALS

[Cutter, 0.250 in. wide; 0.125 in. depth; 0.010 in. feed; ft-lb. per chip when cutting dry (No. 1); cutting up and down]

Bar No.	Material	Milling Up	Milling Down
	Cold-rolled steel	14.77	14.65
187-A	Annealed brass screw stock	4.72	4.85
BB	Bearing bronze	4.71	4.71
MB	Manganese bronze	5.95	5.98
Al-31	Aluminum alloy	4.16	4.29
Cu	Pure copper	16.72	11.16
M	Monel	16.97	19.40
DM	Dow metal	2.65	2.65
11-1	Cast iron	6.88	6.91
23-B	Malleable iron (skin)	8.77	8.91
H.S.	Clarite high-speed steel, annealed	17.55	17.50
30	S.A.E. 2320	15.86	13.70
31	S.A.E. 3120	14.30	13.65
32	Tool steel, 1.03 per cent carbon	18.75	19.70
33	Die steel	13.20	13.09
T-1	Tool steel	15.25	16.45
T-2	Tool steel	15.20	16.28
A-1	Axle steel	11.29	13.65
S-1	Screw-stock steel	10.65	11.75

In nearly all cases where the milling-down-energy values were less for dry cutting than those for milling up, they are less when cutting fluid No. 8 was used. The annealed high-speed steel and monel metal, however, are glaring exceptions. For the high-speed steel when cutting dry, the energy value was 17.5 when cutting up and down. When cutting fluid No. 8 was used, the energy value when milling up is only 14.55, and when milling down is 15.25, a considerable saving because of the lubricant.

For monel metal, using the mineral-lard oil, 16.11 ft-lb. are required when milling up and 12.50 when milling down as compared with 16.97 when milling up dry and 19.40 when milling down dry, again showing a great saving, and particularly a greater saving when cutting down. A great saving is shown in the energy value required to mill copper when using the mineral-lard oil over that when cutting dry. In general, considerable and consistent savings in energy are made when milling metals both up and down when a cutting fluid is used.

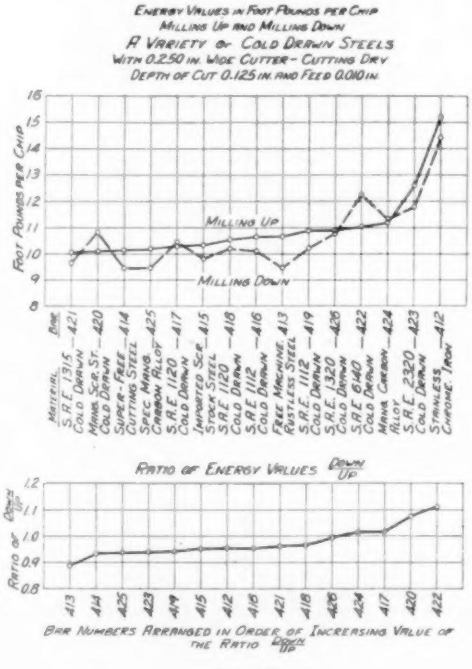

Fig. 24

Discussssion of Milling Data of This and Other Papers

Considering the importance of milling operation in modern production work, it seems strange that more has not been done to put milling on a scientific bases. Early cutters had a large number of teeth, each ground radially, that is, they had no front rake or side rake. Such cutters were used extensively until the last few years.

In 1911, when a paper on "Milling Cutters and Their Effi-

ciency"[11] by A. L. DeLeeuw was published, some coarse-tooth cutters with moderate rake angles and helix angles made their appearance. From that time until a paper by Prof. John Airey and Carl J. Oxford, entitled "The Art of Milling,"[12] was presented in 1921, little improvement seems to have been made in industrial practice. Many valuable data were given in this latter paper as to the effect of feed and depth of cut as well as the influence of rake and helix angles on the power required to mill metals. Cutter design was considered, and formulas were suggested for determining the number of teeth in a cutter. The paper aroused interest in the subject, and, in the next few years, several additional research projects were carried out.

Milling data, showing the energy in foot-pounds per chip as a function of the feed in inches, have been taken from Tables 1, 2, and 3 of Airey and Oxford's paper and plotted on log-log paper in Fig. 25. This has been done to compare these data with the results obtained by the authors. Curves are drawn for three materials: cast iron, machine steel, and tool steel. For each material, four tools were used, having zero, 10, 20, and 30 deg. front rake, respectively. In a number of instances it seems desirable that the experimental data should have been checked. For instance, in cutting machine steel with a feed of 0.0025 in., the 20-deg. side cutter gave energy values below the 30-deg. cutter. For all other feeds, the energy value for the 20-deg. cutter is higher. This would therefore indicate that the value for the 20-deg.-rake tool is low.

It seems obvious, however, that the influence of the rake angle is more to raise or lower the energy lines than it is to change their direction. Also, the exponent of the feed in the energy equation for cast iron is shown by the slope of the energy-feed lines to be very near to the value for machine steel. The authors did not find this to be the case. It may be that there is a difference between the cast irons used in the two sets of tests. In the case of machine steel, the exponent of the feed indicated in Fig. 25 is about 0.65, which compares very favorably with 0.64 for the S.A.E. 1020 steel shown in the authors' Table 18.

In general, it appears that the energy-feed lines for the three materials shown in Fig. 25 are parallel.

In 1923 a paper by Fred A. Parsons, entitled "Power Consumed in Milling,"[13] presented perhaps what are the most complete data up to the present time on the power required to mill various metals. Formulas on the basis of average thickness of chip were given for soft steel, several cast irons, yellow brass castings, and commercial aluminum castings. The general formula for milling was developed as follows:

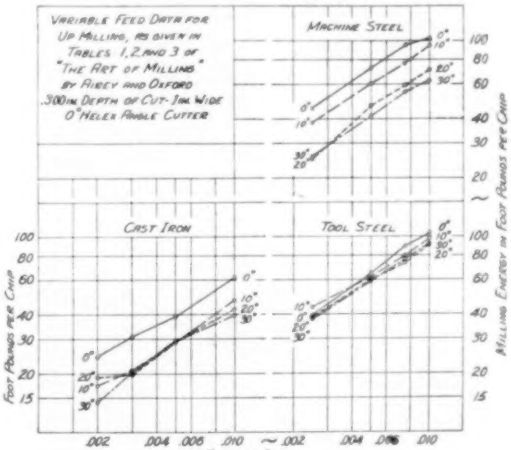

FIG. 25

$$\text{Cubic inches per horsepower per minute} = C\sqrt[x]{\text{A.T.C.}}$$

An attempt has been made to check Mr. Parsons' results, using the authors' data as given in Table 18. Mr. Parsons' data are based on the A.T.C. (average thickness of chip), which is computed from the feed f, for the depth of cut d, and the diameter of the cutter D, all expressed in inches, from the following equation:

$$\text{A.T.C.} = f\sqrt{\frac{d}{D}\left(1-\frac{d}{D}\right)}$$

Values of average thickness of chip were calculated for feeds of 0.003, 0.006, 0.009, and 0.012 in. for each of three depths of 0.010, 0.100, and 1.000 in., respectively. The diameter of the cutter used by the authors is 3.5 in. These values of average thickness of chip are shown in the right-hand column of Table 29, for the various combinations of feed and depth. The cubic inches of metal removed per horsepower-minute were then calculated for these feeds and depths from the horsepower formulas for a number of metals similar to (but probably not exactly like) those tested by Mr. Parsons. These values are shown in Table 29.

TABLE 29 CALCULATED VALUES OF AVERAGE THICKNESS OF CHIP (A.T.C.) AND CUBIC INCHES OF METAL REMOVED PER HORSEPOWER PER MINUTE FOR VARIOUS MATERIALS, FEEDS, AND DEPTHS OF CUT

[When milling up only with cutting fluid No. 1 (dry) and lard oil (No. 5). Diameter of cutter, 3.5 in.]

Feed in inches	Depth in inches	Cold-rolled, fluid No. 5	Bar A-1, S.A.E. 1020 Fluid No. 1	Bar A-1, S.A.E. 1020 Fluid No. 5	BF screw-stock brass, fluid No. 5	CF cast iron, fluid No. 1	Average thickness of chip, in.
0.003	0.010	0.565	0.266	0.369	1.77	0.252	0.00016
0.006	0.010	0.67	0.332	0.461	2.1	0.358	0.00032
0.009	0.010	0.747	0.395	0.548	2.32	0.454	0.00048
0.012	0.010	0.808	0.432	0.600	2.48	0.538	0.00064
0.003	0.100	0.762	0.445	0.617	1.94	0.696	0.0005
0.006	0.100	0.904	0.556	0.772	2.3	0.980	0.001
0.009	0.100	1.007	0.661	0.918	2.54	1.25	0.0015
0.012	0.100	1.087	0.723	1.004	2.72	1.49	0.002
0.003	1.00	1.03	0.740	1.027	2.14	1.91	0.00136
0.006	1.00	1.22	0.924	1.28	2.54	2.72	0.00271
0.009	1.00	1.36	1.10	1.53	2.81	3.45	0.00407
0.012	1.00	1.47	1.20	1.67	3.00	4.08	0.00542

These data are shown plotted graphically on log-log paper over average thickness of chip in Fig. 26. A number of facts are immediately apparent. The cubic-inches-per-horsepower-per-minute values of constant depth of cut but with variable feed appear, in all cases, to fall very nearly on a straight line, one line for each depth. Only in the case of cold-rolled steel is it possible to approximate all computed values with one straight line. When cutting free-cutting brass with lard oil (No. 5), for instance, Fig. 26 shows three distinct lines, one for each constant depth of cut indicated immediately below the line, for its range of feeds. These three straight lines appear to be almost parallel.

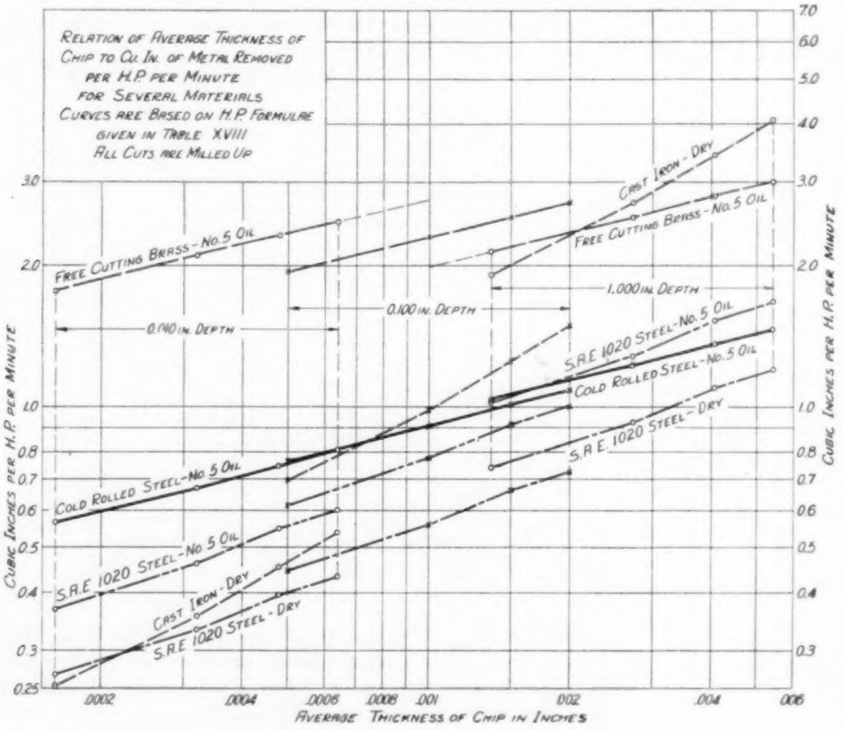

FIG. 26

Considering these three lines, it is seen that, when the depth of cut is 0.010 in., approximately $2^1/_2$ cu. in. of free-cutting brass are removed per horsepower-minute when the average thickness of chip is 0.00064 in. When the depth of cut is 0.100 in., $2^1/_2$ cu. in. are removed per horsepower-minute when the average thickness of chip is about 0.00136 in. When the depth of cut is 1.000 in., the same $2^1/_2$ cu. in. are removed per horsepower-minute when the average thickness of chip is about 0.0027 in. Therefore, it is seen that by varying the depth the same value of cubic inches per horsepower per minute is obtained for three distinctly different average thicknesses of chip.

Similarly, if the three straight lines shown for free-cutting brass when cutting with lard oil (No. 5) were extended to intersect the vertical line over the average thickness of chip of 0.001 in., the cubic inches removed per horsepower-minute are about 2.75 when the depth is 0.010 in., about 2.3 when the depth is 0.100 in., and about 2.0 when the depth of cut is 1.000 in.

The corresponding relations of the cubic-inch-per-horsepower-minute values for the three depths of cut when cutting cast iron diverge much more than those just illustrated for brass. Cold-rolled low-carbon steel, however, when cut with lard oil (No. 5) gives three lines which are almost identical. This one material, then, in a general way, confirms Mr. Parsons' results, although the others, even the S.A.E. 1020 steel, show a material divergency.

The reason for this divergence is apparent from a logical consideration of the variables involved in the formula. From

$$\text{A.T.C.} = f\sqrt{\frac{d}{D}\left(1 - \frac{d}{D}\right)}$$

it is seen that for relatively small values of d/D, the A.T.C. varies as $f\sqrt[2]{d/D}$, or as $fd^{0.5}$ since D is constant. Also, from the authors' formulas, the cubic inches per horsepower per minute equal a constant times $f^a d^b$, or (cu. in. per hp-min.)$^{1/a}$ varies as $fd^{b/a}$.

Therefore, in order for an equation of the formula

$$\text{Cubic inches per horsepower per minute} = C\sqrt{\text{A.T.C.}}$$

to hold for any given metal, it is necessary that the ratio of b/a equal 0.5. Values of b/a are seen from Table 18 to vary from zero for S.A.E. 3150 (KF) to 0.746 for cast iron (bar CF), so it is obviously inaccurate to use the A.T.C. as the variable in a general milling formula for cuts of this type. This is unfortunate, because the average thickness of chip seems to be a logical basis for determining cutting qualities.

A GRAPHICAL ANALYSIS OF CHIP SHAPE

Referring again to Airey and Oxford's paper on "The Art of Milling,"[14] one of the conclusions reached is that, given the same feed per tooth, two cutters with different numbers of teeth will have the same efficiency. The horsepowers per cubic inch removed per minute will be identical, although the cutter with the larger number of teeth will remove more metal in a given period of time because of the greater accumulated feed per revolution of the cutter per minute.

General practice at that time favored the coarse-tooth cutter. This led Prof. J. H. Hall and B. P. Graves to undertake a series of investigations at the plant of the Brown & Sharpe Manufacturing Company.[15] The conclusions which they reached were that coarse-tooth cutters were quite decidedly superior to fine-tooth cutters even when the feed per tooth was held constant.

---

[14] Trans. A.S.M.E., vol. 43 (1921), pp. 549–587.

[15] Ibid., vol. 45 (1923), pp. 165–191.

In the milling machine used by the authors in accumulating the data presented in this paper, the work was held stationary while a single chip was removed. In actual practice, as a cutter rotates uniformly, the work is fed uniformly into the cutter so that, in some respects, the data presented by the authors do not conform with practical milling. An analysis was therefore made as to the amount of the error introduced when the work is held stationary as compared with results when the work is fed into the cutter. This analysis becomes more important when the cutting up or cutting down is considered. A graphical analysis of the shape of the undistorted chip removed by a single tooth of each of two cutters having 4 and 20 teeth, respectively, is shown both for up cutting at A and C and for down cutting at B and D in Fig. 27. These illustrations represent the conditions which would be maintained if the cutter had an outside diameter of 3.5 in. and in every case a feed of 0.250 in. per tooth. This excessive feed is used for purpose of graphic illustration.

At A the 4-tooth cutter is taking a chip in the conventional manner, that is, milling up against the feed. At B the same cutter is shown when milling down or cutting with the feed. Also, at C is shown the 20-tooth cutter milling up, while at D it is shown cutting down. In all cases the length of the chip parallel to the finished surface of the work is indicated by L_A, L_B, etc. For purpose of comparison, this horizontal projection of the true length of the chip will suffice.

Since metal is removed more efficiently for the greater thicknesses of chip, it is apparent from Fig. 27 that the thickest and shortest chip occurs at position D where the 20-tooth cutter is milling down. It is also apparent, when milling down with a 4-tooth cutter, that a thicker chip is obtained than when milling up with a 4-tooth cutter. Increasing the number of teeth in the cutter when milling down increases the chip thickness and so logically increases the efficiency of the cutter.

It is also seen that when milling up, the chip is thinnest and longest when the number of teeth is greatest. Summarizing, it is seen that, comparing cutters A and C, that is, the coarse-tooth and the fine-tooth, both when milling up in the conventional manner, that the thicker chip is obtained with equal feeds per tooth for the coarse-tooth cutter, resulting in greater efficiency for the coarse-tooth cutter. This seems to confirm the conclusions set forth by Graves and Hall, inasmuch as all of their conclusions were based on the conditions for milling up. It appears, then, that A is more efficient than C, that B is more efficient than A, and that D is more efficient than B. In other words, the fine-tooth cutter cutting up is the worst possible condition, and the fine-tooth cutter cutting down is the best, keeping the feed per tooth and depth of cut constant.

In many instances the data presented by the authors show that down milling is more efficient than up milling from an energy or power point of view. In such instances these differences would be increased in favor of down milling by virtue of the explanation just given when applied to practical milling in which the work moves while being cut.

Conclusions

In arriving at conclusions covering the experimental data presented in this paper, it is to be understood that the cutters were supposed to have been in an uniformly sharp condition at all times. A small amount of dulling has such a decided effect on the energy values that some inaccuracy, for this reason, is inevitable. The data have been accumulated over a period of time and have not always been taken methodically. Data determined in one series of tests may show slight differences when compared with corresponding data determined for other purposes. For this reason, check runs on many tests have been made and, where close agreement was not found, three and sometimes four individual checks were made. Standard practice was to make each experimental point the average of at least ten successive cuts. It is felt that the data presented are accurate to a very close degree and that the following conclusions are justified:

1 When cutting a groove it is found that energy values do not increase directly with cutter width for narrow widths, but at a slightly lower rate. Data are not available to determine exactly what this rate is, but the assumption is made, which is not far from correct, that the energy values do vary directly as the width of the cutter.

2 In all cases the energy values expressed in foot-pounds per chip are found to vary with the feed at rates, varying with different materials, from $f^{0.21}$ for bakelite to $f^{0.84}$ for annealed free-cutting brass.

The exponents of feed for a given material are not always the same when milling up as when milling down. They appear to be close enough, however, for practical purposes.

Varying the cutting fluids, other conditions remaining the same, does not change the exponents of the feed for any of the materials tested. It simply moves the straight line on log-log paper up or down.

3 Energy values in foot-pounds per chip vary with the depth of cut for the different materials tested from $d^{0.56}$ for cast iron to $d^{1.00}$ for S.A.E. 3150 steel annealed.

The exponent is the same when milling up or down and regardless of the cutting fluid used when cutting all metals, but is not strictly so when cutting bakelite and wood fiber.

4 No two materials have been found which give the same milling-energy formula, and the authors know of no way of predetermining either the constants or the exponents of the feed and depth of cut except by making actual milling tests under given conditions for the particular metal.

5 Contrary to many other types of metal cutting, the energy value in foot-pounds per chip increases rapidly and quite uniformly as the milling cutter becomes dull.

6 The effect of cutting fluids is variable, as they react differently for various materials. Borax water, which tends to produce a low torque in drilling or low power in turning, gives consistently high energy values in milling.

7 The finish of the work is, in general, better when milling down than when milling up. The surface is flatter when milling down but less shiny, appearing to be torn rather than burnished.

8 Very little tendency to chatter was noticed when milling down, but in many cases chatter was objectionable when milling up. The data on the subject are too limited in the work reported for final conclusions to be drawn.

9 When milling a wide variety of materials, using the same width of cutter, depth of cut, and feed per chip, values of the ratio of energy when cutting down to that when cutting up were found to vary from 0.668 for copper to 1.21 for axle steel. For the majority of metals, some saving was found for milling down over milling up. On many materials, however, the reverse is true.

10 The value of the ratio of milling down to milling up for the S.A.E. 61 series and the S.A.E. 23 series steels was found to increase for increase in carbon content and Brinell hardness, and decrease for an increase in normalizing and annealing temperatures. The actual energy values in foot-pounds per chip are found to decrease with increasing carbon content and increased normalizing and annealing temperatures.

11 With the exception of pure copper and monel metal, small differences were found between the milling-energy values when milling down and up for the non-ferrous metals tested.

12 For most of the free-cutting high-sulphur steels, a rather uniform saving was found when milling down.

13 Formulas have been presented representing the energy required to remove a single chip under standardized conditions when milling up and down for a number of ferrous, non-ferrous, and non-metallic materials. These are summarized in Table 18. Corresponding formulas, representing horsepower per cubic inch per minute for these standardized conditions of milling up and down, also are given with actual horsepower-per-cubic-inch-per-minute values for each material.

14 In general, considerable and consistent savings in energy are made when milling metals both up and down with a mineral-lard oil as a lubricant.

15 It is believed that the average thickness of chip is not a sufficiently definite basis on which to base energy or power values in milling, due to the fact that under similar cutting conditions, such as feed per tooth, the thickness of chip will vary as the number of teeth in the cutter varies for the same diameter of cutter when milling up or down. Also, the average thickness of chip varies under otherwise equal cutting conditions for the same number of teeth in the cutter when cutting up or down. As Dr. Salomon has shown, the average thickness of chip under otherwise equal cutting conditions is greatest for cutters of small diameter and least for cutters of greatest diameter.

16 From a graphical analysis of chip shape, the following is found: (*a*) In practice, down milling gives thicker chips and should give greater efficiency than milling up, all other conditions being the same.

(*b*) As the number of teeth in the cutter increase with the same cutter diameter, the thickness of chip for milling up decreases, indicating that the cutter with few teeth would be more efficient when the feed per tooth is constant.

(*c*) As the number of teeth increase, the thickness of chip for down milling increases, indicating that the cutter with few teeth would be less efficient.

17 As a final conclusion, the authors feel that the results of this paper should be substantiated, in regard to finish, power, and tool life, by records secured from various jobs in industrial plants. In these tests, records should be kept for similar cutters or the same cutter when milling up and milling down, and for cutters of the same diameter having different numbers of teeth when milling up and milling down. Additional information from industrial practice also should be obtained, using cutters with varying helix, rake, and clearance angles. These tests should cover a variety of materials, cutting fluids, feeds, depths of cut, and types of cut.

ACKNOWLEDGMENTS

The authors wish to express their appreciation to Carl J. Oxford, chief engineer of the National Twist Drill and Tool Company, for the use of the milling dynamometer. Mr. Theodore Thoren, a student in the Department of Mechanical Engineering, has been of real assistance in preparing the drawings and in working up the data. The work covered in this paper was done in the laboratories of the Department of Engineering Shop at the University of Michigan, Ann Arbor, Mich.

Discussion

O. W. Winter.[16] There is probably no field of engineering wherein more has been accomplished in the way of results and with less known from a scientific viewpoint than the field of machine-shop practice. In this particular case, it is believed, there is less known about milling than any other operation, with the possible exception of grinding. There have been exhaustive tests made on turning, drilling, and planing. This in a way is to be expected.

There are more variables that enter into a milling operation than in any of the aforementioned operations. This circumstance makes any milling research work complicated and utterly prevents any general assumptions being made. This necessitates a comparatively large number of tests in order to tie in all variable factors, and hence the concurrent expense and time required. Consequently, past investigations on this subject, while commendable and contributing, were not thorough enough.

The authors have made a worth-while advance. It is apparent they intend to get at the elements of milling. They will agree, however, that there is still much work to be done.

For some time the writer has been connected with a project of "milling-cutter efficiency." There have been considerable time, energy, and money spent on this work. This research uses standard-design milling cutters of various types on several common materials, noting the milling action, power consumed, etc. In the first year's work over 20,000 tests were run on cast iron and nickel-chromium steels, covering as many variable factors as possible. The following year about 10,000 tests were run on aluminum alloys. The results are not yet ready for publication.

In the meantime, it should be both interesting and enlightening to compare the results obtained by the authors and the writer. This cooperative comparison, coupled with further investigations, should do much to bring the subject of milling out of the darkness of guesswork and into the light of exact science.

James A. Hall.[17] There have been presented many interesting and valuable data on the energy required for milling a large variety of materials under a number of different conditions. All of these tests have been made with a single-tooth cutter which moves with a variable speed as the energy of the falling weight of a dynamometer is dissipated by the resistance of the cut, while in practice the milling cutter moves at a constant speed and several teeth may be cutting at one time. The work also moves with relation to the center of the cutter in practice, while there was no relative movement of these parts while these test cuts were in progress. There is no apparent reason why these variations from practical milling should make an appreciable difference in the relative values of the results. With reference to their absolute accuracy, it is noted that the power required in practice is influenced by the machine as well as by the cutter, but the data of these tests should not vary widely from results secured in the shop.

[16] Detroit, Mich. Jun. A.S.M.E.

[17] Professor of Mechanical Engineering, Brown University, Providence, R. I. Mem. A.S.M.E.

The equations for horsepower required on the eleventh page are of particular interest. One of the conclusions to be drawn from them may be illustrated by a milling machine which is working to the limit of its power capacity, using a 24-tooth cutter with a feed of, say, 0.006 in. per tooth. If this cutter is replaced by one with eight teeth, leaving everything else (width, depth of cut, feed per revolution, speed, etc.) the same, the feed per tooth will be increased to 0.018 in. If the material being cut is S.A.E. 1020 steel, the equations of the paper show that the power required for the same machine output as before will have dropped over 32 per cent. The machine will then carry with ease a cut that formerly may have been carried only with difficulty.

The authors refer to tests made some years ago by Benjamin P. Graves and the writer in which the advantages of coarse-tooth cutters were demonstrated. These tests were made with standard cutters on a standard milling machine, and great care was taken to have accurate values of the power delivered to the cutter. Savings comparable to that given in the foregoing illustration were found when commercial fine-tooth cutters were replaced by others with fewer teeth. On the other hand, when a series of feeds per tooth were secured by changing the speed of coarse-tooth cutters, a saving in power due to the larger chips was apparent, but the amount was considerably less than the value given by the equations of this paper.

If cast iron were substituted for steel in the foregoing illustration, the energy equation would give the horsepower needed for the coarse-tooth cutter as approximately half that required for the fine-tooth cutter, the work output being the same for both. If bakelite were the material being cut, the saving in power due to the use of the coarse-tooth cutter in the illustration would be over 57 per cent. These are greater savings than would normally be expected.

The authors present an interesting discussion of the effect of cutting with and against the work on the relative merits of fine- and coarse-tooth cutters. Due to the differences in the relative motion of the cutting edge and the work when the comparison is made on a chip-per-tooth basis, the chip will have a greater average thickness cutting down with the fine-tooth cutter, while the reverse will be true when cutting up. As the power required should vary roughly in proportion to the average chip thickness, the authors come to the conclusion that coarse-tooth cutters have greater advantages when cutting up and fine-tooth when cutting down. They apply their reasoning to the tests made by Mr. Graves and the writer to explain why the cutters with fewer teeth gave better results even compared on a chip-per-tooth basis. This may well be the answer to this question, as the differences in those tests were comparatively slight when cutters of sufficient coarseness were being used.

The advantages of fine-tooth cutters when hook or climb milling, as noted in the preceding paragraph, are realized only if the feed per tooth is the same as with the coarse cutters. To get the same feed per tooth with finer-tooth cutters, the feed in inches per minute must be increased, resulting in greater pressures between the cutter and work and more power input into the machine, or the surface speed of the cutter must be reduced, which also results in greater pressure between the work and cutter, although the power requirement remains the same. For instance, if the power capacity of the machine is reached with a coarse-tooth cutter running at a surface speed of 100 ft. per min. and taking the maximum permissible feed per tooth, a fine-tooth cutter with twice the number of teeth would have to run at 50 ft. per min. This would result in doubling the pressure between work and cutter.

If the proper number of teeth in the cutter is to be chosen for any job, the first and most important question is to determine the largest possible chip per tooth consistent with the structural strength of the cutter and the strength of the work. The number of teeth would then depend on the power capacity of the machine and on the strength and rigidity of the work, fixture, arbor, etc. Higher speeds and fewer teeth in the cutter will result in lower pressures on these parts. The finish required or danger of chatter or shock may be modifying conditions. The choice of the proper number of teeth depends on the proper evaluation of these factors. Under any condition the problem cannot be properly settled without taking the machine into account.

This paper emphasizes the great importance of using the maximum feed per tooth. The experience at the Brown & Sharpe plant indicates this may be fully as important from the standpoint of the life of the cutter between grinds. It would be interesting to have a discussion at some future time of the factors limiting chip size as a further step to putting cutter design on a scientific basis.

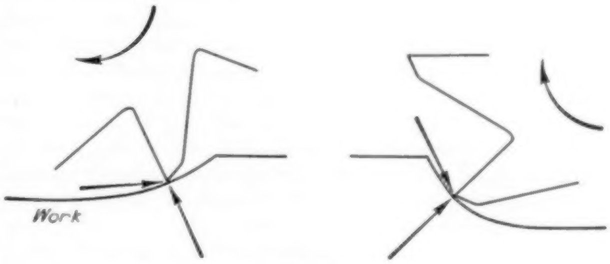

Fig. 28

In the tests described in this paper all of the cuts were made with a blade the outer edge of which moved in an arc of 1$^3/_4$-in. radius corresponding to a 3$^1/_2$-in. cutter. If a 2-in. cutter had been used, the length of the arc moved through by the cutter surface would have been less and the average thickness of the chip would have been greater for any given feed and depth of cut. Conversely, the opposite would have occurred if a 5-in. cutter had been used.

The writer assumes that the authors intended the formulas given to apply to a 3$^1/_2$-in. cutter only, and wonders if they made any investigation to show how the constants and coefficients were modified by varying the cutter diameter. In this connection it is unfortunate, from the shop standpoint, that they could not find the average chip thickness a suitable standard of comparison, as this would have combined all feeds, depths of cut, and cutter diameters on a common basis.

The maximum depth of cut used on any of the metals tested was 0.150 in. The writer wonders if the energy requirements would still follow a straight line on logarithmic paper if very deep cuts, $^3/_4$ in. or more, had been tried, and would like to inquire if any experiments were made along this line.

The discussion of the differences in power requirements cutting up and cutting down on the work is of particular interest. Which method to use on any particular job is also a problem that cannot be finally settled without taking into account the effect on the machine and fixture of the forces acting between the cutting and the work. These may be separated into tangential and radial components, as shown in the diagrams (Fig. 28). In average milling the radial force will exceed 50 per cent of the tangential force. If the vertical components of these forces are added, it will be noted that the pressure tending to push the cutter upward away from the work may be many times greater when cutting down than when cutting up. This pressure will result in greater deflections when cutting down, and increases the difficulty of milling flat surfaces on work of varying width. There is also more trouble of running the cutter back over the work. To take care of this condition, heavier arbors and more rigid set-ups will be required with this new type of milling.

In the usual type of milling, the forces always tend to push the work along the table and away from the cutter. In milling down, the horizontal components of the tangential and normal pressures may tend to pull the work along under the cutter. If this happens, it may result momentarily in excessive chips per tooth and in extreme pressures between work and cutter, resulting possibly in breakage of cutters or fixtures. The cutter must therefore be very well supported, have a foolproof fastening to the table, and the table must have enough drag on its ways or such a rigid mounting that there is no tendency for it to jump ahead. These represent some typical problems that must be met if the practice of milling down on the work is to be adopted.

A. N. GODDARD.[18] Any one carefully reading the paper will have some appreciation of the great amount of time and effort it represents on the part of the authors, even though it presents thought on but a very small unit of a very large subject, and only an elementary study of that unit, namely, "cutting up" versus "cutting down," and the energy required by each method in the process of removing metal by milling. Data have been gathered and tabulated, curves plotted, and results noted for quite a wide range of metals. This at least is a worthy attack on the problem, and goes farther than many previous papers have in a study of this general problem.

At the outset it is noted that these tests were run with tools in the condition of "sharp," "dull," and "very dull," and that energy measurements were attempted under these three conditions. These terms mean nothing in a scientific description, and one is quite "at sea" until he gets well beyond many tables of data and curves and finds in the middle of the paper an attempt at a description of the two latter conditions, but no definition of a *sharp* tool. It is a simple matter to determine whether a cutting edge has a 0.001-in. radius or one of 0.006 in. or 0.010 in., and this should be predetermined in such a test. In actual practice the edge of a metal-cutting tool, such especially as a milling cutter, when dull is not in the condition of an edge that has been stoned to a good radius, but many times when seeming to be that way microscopic inspection indicates that the process of dulling was first the crumbling away of small particles of the keen edge, and then the jagged points wore down by abrasion.

Again, in the Conclusions, it is stated that "a small amount of dulling has such a decided effect on the energy values that some inaccuracy for this reason is inevitable." Most of these data represent work done with comparatively small tools averaging from $^1/_4$ to $^3/_8$ in. in width, and with these almost infantile tools the energy values were so small, it seems, that slight inaccuracies would possibly produce large errors in results. It is hard to harmonize the thoughts in this paper as to the condition of the cutting edge with the theory expounded by the author in a previous paper in which it was shown that the cutting edge of a tool did not actually do the cutting, but rather built up at once a cold-weld wedge of the metal being cut on the nose of the cutting tool, this wedge being pried off the metal from then on.

Many tables and plotted curves throughout the paper speak of "constant" feed. The writer cannot appreciate how this is possible in any hand-fed mechanism and would question the use of this term and the data based on it. Doubt as to this term is further increased by the statement at the top of the 21st page that the data presented were gathered by holding the work stationary while a single chip was being removed. It is granted that "this is contrary to actual practice," so an analysis was made to determine the amount of error this introduced. This would seem to be quibbling with theory in the absence of practice and makes one reluctant to accept results.

All the experiments upon which the milling data are supposed to be based were made with a single-point tool, cutting one chip at a time through a limited arc of swing, with no feed of the work while the tool was cutting and with variable power applied to the tool. From these experiments and by graphical analysis the paper proceeds to *deduce* what would *probably* happen with a *real* milling cutter in a *real* milling machine. One deduction is that "increasing the number of teeth in a cutter when "cutting down" increases the chip thickness and so logically increases the efficiency of the cutter."

By how much can one increase the number of teeth? Where does this deduction lead us to? Would a rotary file be more efficient "cutting down" than "cutting up?" Chip clogging is a prominent source of cutter inefficiency and that is caused by fine-tooth cutters. The writer is only trying here to show what abstract theoretical reasoning may lead to if one goes too far; and why the need of such theorizing when practical means are at hand from which to obtain practical data?

Referring back to the equipment used in gathering these data, "the pendulum-type milling dynamometer" as described is not a mechanical power-operated machine. It has no constant source of energy actuating the cutting tool; the work is not mechanically fed under the cutting tool during the actual cutting. In fact, the machine is described briefly as having the same principle as an impact testing machine. In this machine the tool is not rotating at a constant speed as it approaches the cut nor as it passes through the cut. Being actuated by a partially impeded falling weight, it approaches the cut at a constantly accelerated speed; it strikes the cut with an impact, and its progress through the cut is not constant, but rather a constantly decelerated speed due to the dying energy of the falling body whose fall it serves to brake. It is being supplied with a dying-out energy due not only to its braking effect on the weight, but further to the fact that the weight constantly being diverted from its free-falling path, varies the energy supply from maximum to zero.

The effects so produced are more in accord with a cold chisel receiving the stored energy of a hammer blow. It seems, however, that this method is very far from correct in endeavoring to arrive at correct data on the practice of milling as performed on a machine supplying constant power at constant speed with constant table feed, all these constants being variable but controllable at the will of the operator and using a multiple-point rotary cutting tool.

The conclusions of the paper are quite detailed at the end, but are very well and more briefly summarized in the abstract given at the opening. The writer will therefore consider them briefly as there stated:

(*a*) "In nearly all cases a difference in energy is found between these two methods of cutting—cutting down and cutting up."

(*b*) "No two materials give the same values of the exponents for the feed and depth variables."

(*c*) "It is concluded from the nature of the tests that lubrication rather than cooling has greater effect."

(*d*) "In nearly all cases a power saving is made by their use."

---

[18] President, Goddard & Goddard Company, Inc., Detroit, Mich. Mem. A.S.M.E.

(*e*) "It is concluded that there is no way, other than actual test, to determine the milling properties of a material."

(*f*) "It is concluded from this analysis that, theoretically, the coarse-tooth cutter is better than the fine-tooth cutter, when milling up, keeping the linear feed per tooth constant. When milling down, however, the fine-tooth cutter removes a chip of greater average thickness than the coarse-tooth cutter, and consequently is considered to be more efficient from a power standpoint when diameter and feed per tooth are constant.

(*g*) "The fine-tooth cutter cutting down is thought to be the most efficient way of milling metal when power is the chief consideration."

The first five of these conclusions are borne out by practice; in fact, are common knowledge in the industry, and would be generally true in any machine using rotating tools.

The conclusion (*f*) is not borne out in practice.

The conclusion (*g*) is doubtful as to relative pitch of cutter and inconsequential as to power efficiency.

Under the caption "Discussion of Milling Data of This and Other Papers," it is stated that "from the time of Mr. De Leeuw's paper on 'Milling Cutters and Their Efficiency,' which was presented in 1911, until a paper on 'The Art of Milling' by Prof. John Airey and Carl J. Oxford in 1921, little improvement seems to have been made in industrial practice." This refers to improvement in design of rake angles, tooth form, tooth spacing, and results obtained. A correction of this statement is suggested, as the writer personally made a very intensive study of milling cutters and made many improvements in their design which very materially increased the efficiency of milling practice. This work was begun in 1918, and by 1921 was widely known by advertising, by catalogs, and by application in many shops throughout the country. Our whole output of cutters was along these improved lines before any research was undertaken by Professor Airey and Mr. Oxford. Papers were not presented to the A.S.M.E. on the subject as the writer was too busy, but the work was done.

In conclusion, the writer is led to ask from the practical viewpoint, What does it all mean—what real knowledge as to the art or practice of milling is here contributed? Here is a very long and serious paper on "milling down" versus "milling up" with the relative power requirements by the two methods as the chief consideration. "Power" never is the chief consideration in milling, nor for that matter in the very large majority of metal-machining operations; it is quite the minor factor.

Keen advertising of machine tools today is certainly not far off the main point in directing prospects to the superiority of one's product. Note then the current ads of two of the largest manufacturers of milling machines. The slogan of one is "If it can be milled, mill it faster." The symbol of the other is a milling cutter with wings denoting speed of operation and the saving of time.

The time of doing the work; character of finish; accuracy of dimension; freedom from distortion when work is removed from machine; down time of machine for redressing tools and changing set-ups due to dulling—these are the important considerations in the manufacturing plant that is going to survive today. Then why not study such problems both scientifically and practically? The authors just glimpse this thought in the final (17th) conclusion, but why not concentrate study on some of these vital problems in our university laboratories that are constantly asking for funds for research from manufacturers? The authors feel that "little has been done to put milling on a scientific basis." While there is much that is not yet known, there is a very great amount of explicit and factual information regarding milling. There are established practices in various industries in the field of milling today that are astounding. To cite but a simple example, milling and sawing brass and tough tin bronze is done at speeds and feeds that would leave woodworking machinery far in the rear, and not with tungsten-carbide tools but with straight high-speed steel.

Milling-machine manufacturers and milling-cutter manufacturers have a fund of information that would be surprising reading if compiled in a single book, but by the time the book was compiled it would be ancient history, such is progress today.

It would be a most worthy effort for a professor of engineering to attempt to collect and classify, from the many sources available, such data. It would be a real contribution to the metal-working industries. At least it would be a very informative basis of departure for further research. Can we not thus get a closer contact between university research and industrial need?

This discussion may seem like a harsh and unkind criticism, but nothing is further from the spirit of it. If it be criticism, it is hoped it may be constructive.

Fred A. Parsons.[19] The comparative up-cutting and down-cutting tests, as well as the tests with different cutting fluids, are particularly timely. The apparatus used, however, appears to be open to some criticism in that it does not duplicate the operation of commercial milling machines. Particularly it appears that in the authors' machine the speed of the cutting tool was not constant during chip removal; also that the work piece was not advanced during chip removal; also that the cuts were all grooving cuts. It may be that these departures from usual practice without proper allowance therefor account at least in part for the failure of the authors' tests to check more nearly with the conclusions and formulas given in the writer's paper of 1923, with which a comparison is drawn by the authors. The nature of a grooving cut is such that the writer's 1923 formulas for average thickness of chip would not apply as the authors have applied them. The true average chip thickness for grooving cuts must take some account of the sides of the cut as well as the bottom width, similar to the writer's 1923 formulas for form cutters. When so corrected, the authors' Fig. 26 will correspond much more closely to the writer's 1923 formulas. These were in any event only advanced as approximations making it possible to put the power computations on a usable slide rule. Several well-recognized factors were therefore not taken into consideration. It appears probable that in computing the true average chip thickness for milling, the number of teeth in the cutter should be taken into account as well as the up or down nature of the cut, and perhaps other factors as well; but it is thought not proved that the true average chip thickness is not the most usable basic measure of power required for metal cutting. It may be added that in milling practice the conditions when cutting up where considerable of the power used is transmitted through the relatively inefficient feed train may cause for this reason alone the decidedly different total machine power from that when cutting down.

Hans Ernst.[20] Any investigation which leads to a better understanding of the numerous factors involved in the complex process of milling, should be highly commended. In the present instance, the authors are to be congratulated on the contribution which they have made by the investigation of some of the more obscure factors, such as direction of cut with respect to feed and the action of cutting fluids.

The pendulum type of dynamometer used by the authors undoubtedly provides a simple method of determining (with considerable accuracy) the energy dissipated in the removal of a given chip under the conditions imposed, and eliminates many of the difficulties and uncertainties presented by other methods; nevertheless, it also introduces limitations in the application of the data obtained.

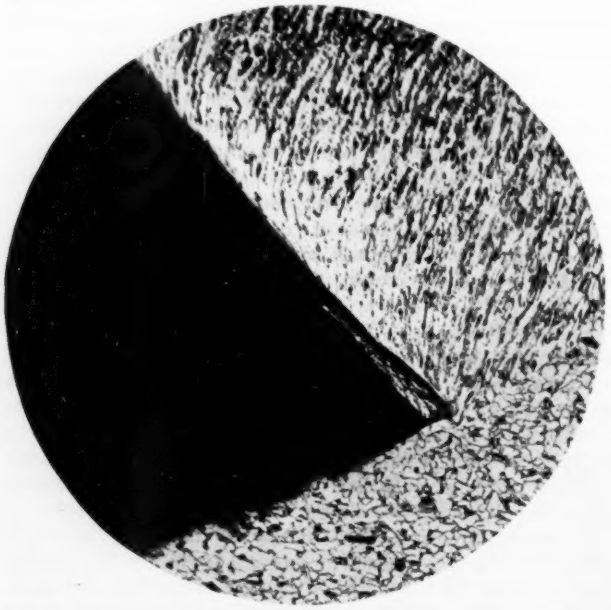

FIG. 29 PHOTOMICROGRAPH OF CHIP PARTIALLY REMOVED FROM WORK (MILLING UP) × 75

(Cutter stopped suddenly near end of cut. Material, S.A.E. 1112 steel; depth of cut, $^1/_4$ in.; feed per tooth, 0.020 in. Note built-up edge preceding nose of cutting tool.)

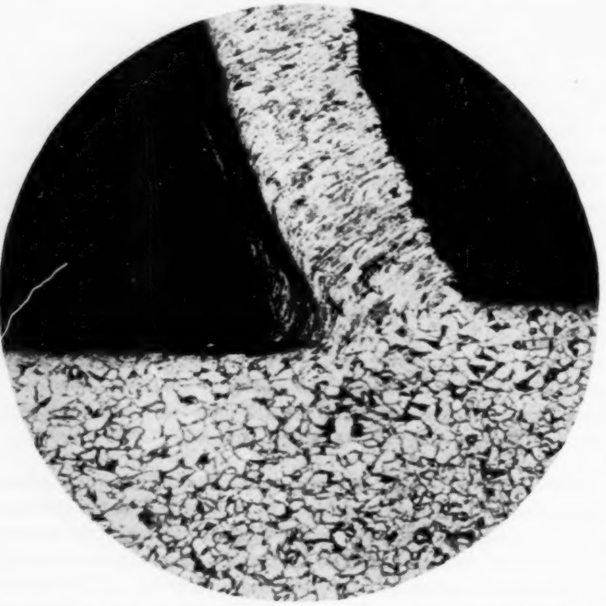

FIG. 30 SAME AS FIG. 29, BUT CUTTING DOWN × 100

(Note presence of built-up edge.)

With this type of dynamometer no information can be obtained in regard to the relative direction and magnitude of the several components of the cutting force; consequently, the data secured do not materially help in the design of a milling-machine structure, except in so far as they may indicate the maximum power which must be transmitted to the cutter for any given set of conditions. For the same reason they provide no guide to a rational explanation or analysis of the many unaccountable relationships which have been observed by the authors and presented in this paper.

For instance, in Figs. 3 and 18, which illustrate the results of tests of S.A.E. 1020 steel, there is shown a relatively small difference between the energy required for milling up and milling down when using cutting fluids Nos. 6 and 8, but a very large difference when using No. 5 fluid. When milling the free-cutting screw-stock steel, however, the difference in energy up and down is about equal for both No. 5 and No. 8, but considerably greater for No. 6. Similarly, the sequence of the fluid numbers, when arranged in order of the ratio Down/Up is totally different for each of the materials tested. This includes even the condition of cutting dry.

An interesting and useful addition to this investigation, which may shed some light on these perplexing issues, would be the micrographic study of the chips resulting from each series of tests. A careful comparison of chip structure will usually reveal much of importance, particularly in regard to the formation and effect of the "built-up edge" and the extent to which chatter will affect the amount of energy dissipated in chip removal.

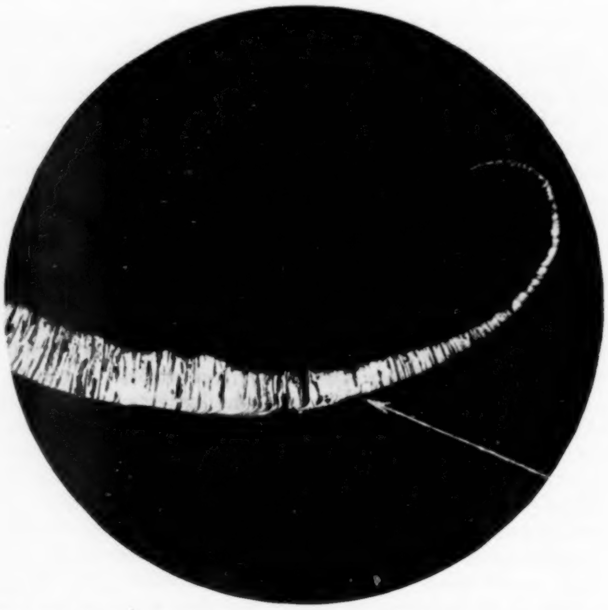

FIG. 31 "THIN END" PORTION OF CHIP REMOVED BY CUTTING UP (BEGINNING OF CHIP) × 30

(Material, S.A.E. 1020 steel; depth of cut, $^{13}/_{32}$ in.; feed per tooth, 0.013 in. *A*, built-up edge begins to form here.)

On the 13th page the authors state that "the duration of the cut in milling is too short for the built-up edge, if it is formed, to exert an appreciable influence on the formation of the chip." This is entirely contrary to our own experience. Under almost all normal milling conditions the built-up edge begins to form shortly after the beginning of each chip, and thereafter profoundly affects the formation of the remainder of the chip and the relationship and magnitude of the cutting-force components.

The existence of the "built-up edge" during both upward and downward milling is clearly shown by the accompanying photomicrographs Figs. 29 to 32.

Fig. 29 shows a chip partially removed from the work by milling up, while Fig. 30 shows the same condition by milling down; in each case the cutter was stopped suddenly while in the act of removing the chip. In each picture the small wedge-shaped portion, or built-up edge, is seen preceding the edge of the cutting tool and protecting the extreme edge from abrasion by the flowing chip. This effect continues until the chip is finally severed from the work, with the built-up edge firmly attached at the end.

Figs. 31 and 32 show the "thin end" portions of chips removed by milling up and milling down, under otherwise identical conditions. In each case the depth of cut was $^{13}/_{32}$ in., the feed per tooth 0.013 in., and the material S.A.E. 1020. The difference in chip shape and structure is striking. The downwardly milled chip is flatter and of much more uniform thickness toward the leaving end than the upwardly milled chip. In upward milling, the initial thickness of the chip is zero, and its rate of increase of thickness relatively slow. Hence, at the beginning of this chip (as shown in Fig. 33) there is no built-up edge, and the extreme edge of the cutting tooth is in contact with the work. The resistance to chip flow against the smooth face of the tooth is therefore small, and the chip is cleanly removed from the work and freely curled. As the chip thickness increases, the built-up edge is developed, the resistance to flow increases, and the chip section becomes thicker and flatter. Thus the chip from upward milling assumes the characteristic wedge shape, closely curled at its thin end, as shown in Figs. 31 and 33.

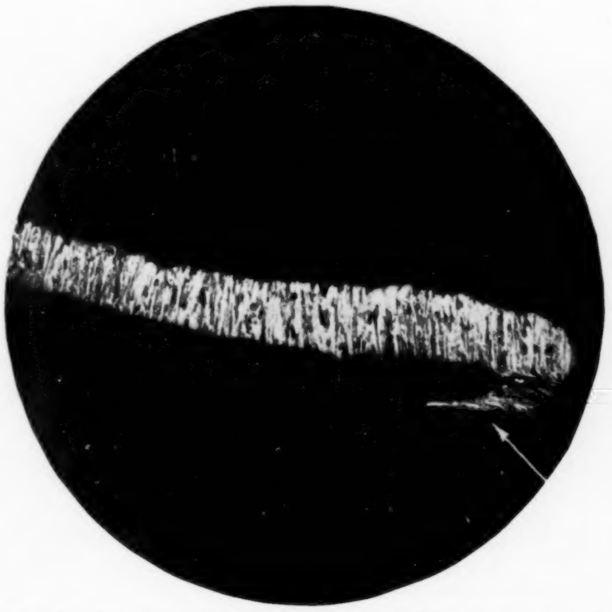

Fig. 32 "Thin End" Portion of Chip Removed by Cutting Down (End of Chip) × 30

(*B*, built-up edge attached to chip. Material, depth of cut, and feed per tooth same as in Fig. 31.)

In downward milling the thickness of the chip is a maximum almost at its beginning; consequently, the built-up edge is formed much more rapidly, and when once formed, persists to the extreme end. In Fig. 32 the remnant of built-up edge is shown attached to the leaving end of the chip. Thus the extreme edge of the cutting tooth is protected during a considerable portion of its engagement with the work.

Many questions are suggested by a study of this paper. On S.A.E. 1020 steel the authors found that the energy required for milling down is less than that for milling up when the cutter is sharp, but that the situation is reversed when the cutter becomes dull; the down energy being then greater than the up. What, therefore, is the effect of dulling upon the ratio of "down" to "up" energy on materials such as S.A.E. 6140, or high-speed steel, where the down energy was found to be greater than the up, even with a sharp cutter? It would also be interesting to know the effect of the various cutting fluids on materials such as these. It is unfortunate that not one of these materials was included in the tests reported in Table 21.

The most definite result of this investigation appears to be the establishment of formulas for the energy required per chip.

On the third page the authors state that, for any particular material, the energy curves for constant depth with respect to feed and for constant feed with respect to depth (for all the cutting fluids tested) could be represented by parallel straight lines when drawn on log-log paper. This is equivalent to stating that the exponents a and b are constant for any one material. This is substantiated by a large number of such charts on a variety of materials; consequently, we must assume that under the particular conditions of each test, such a relationship did hold true. Nevertheless there are some inconsistencies for which it is difficult to account.

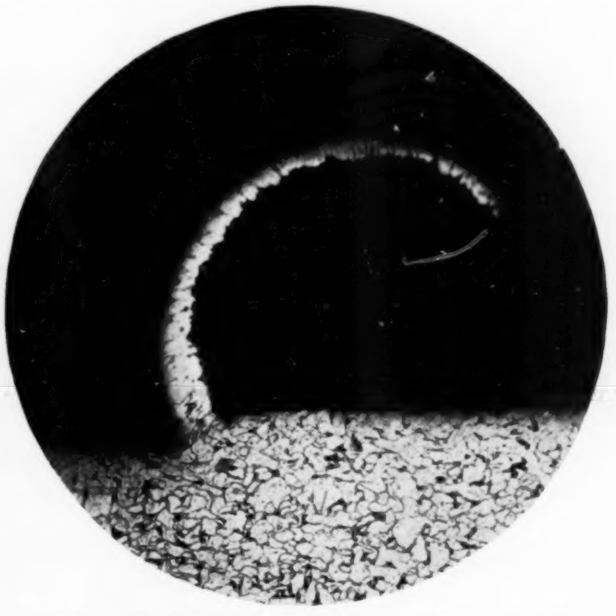

Fig. 33 Chip Partially Removed From Work × 100

(Beginning of chip, cutting up. Note absence of built-up edge.)

On the basis of the data shown in Fig. 5, which represents the results of tests on S.A.E. 3150, the exponent of f is found to have the value 0.70 for both the cutting fluids tested, and for both up and down cutting. Furthermore, the energy required for up cutting, with both the fluids, is appreciably higher than for down cutting. In Fig. 17, on the other hand, where the effect of cutter dulling is shown for the same material, the value of the exponent of f is approximately 0.56 when cutting up and approximately 0.50 when cutting down. In this series of tests, even when the cutter is sharp, the energy for cutting down is shown to be somewhat higher than for cutting up. This discrepancy between the two series of tests can scarcely be explained on the basis of the difference in cutting fluid, as all the other tests have shown the exponent of f to be independent of this factor.

The difference between the energy required for cutting up and cutting down, under the different conditions, as well as the effect of dulling (as shown in Figs. 15 and 16) may be explained

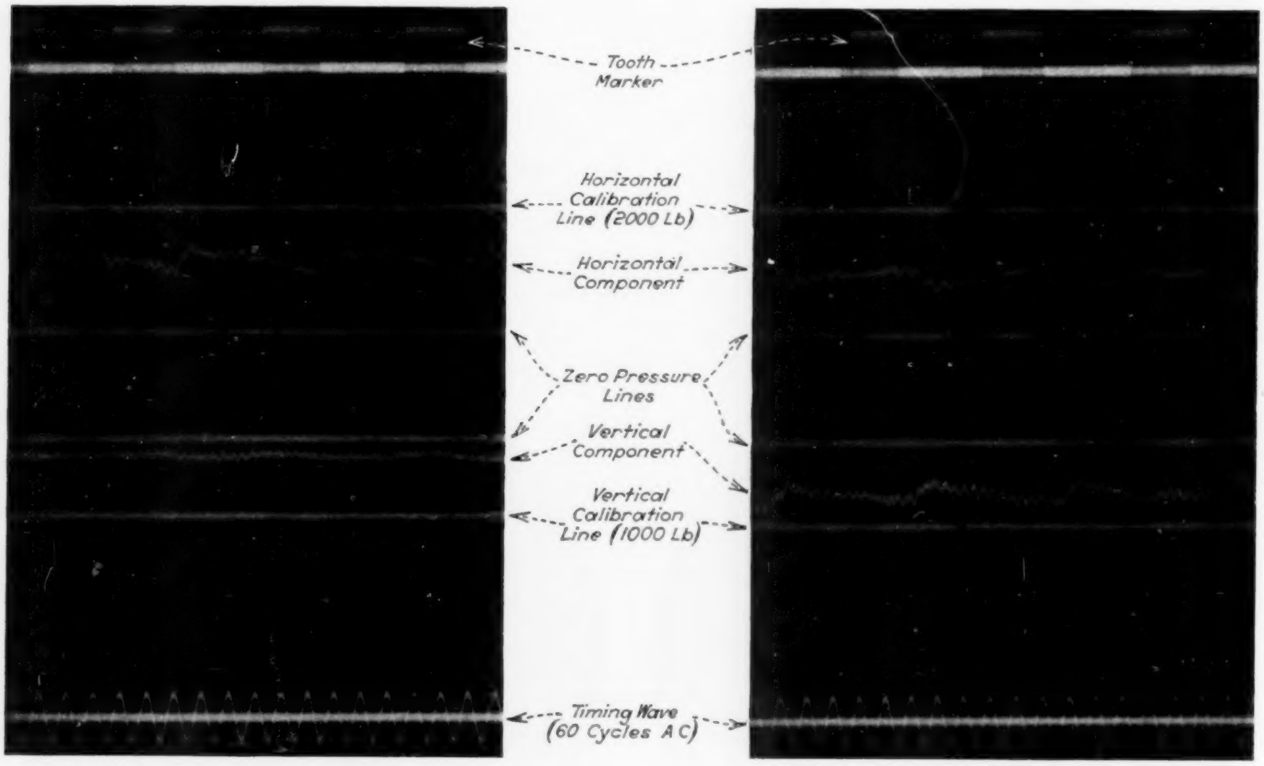

Fig. 34 Cutting Up

Fig. 35 Cutting Down

FIGS. 34 AND 35 OSCILLOGRAMS OF HORIZONTAL AND VERTICAL CUTTING-FORCE COMPONENTS
(Material, cast iron; depth of cut, 0.125 in.; feed per tooth, 0.012 in.)

on the basis of the radical difference between the relative magnitude of the cutting-force components for the two types of cut.

The accompanying oscillograms (Figs. 34 and 35) show the instantaneous values of the horizontal and vertical components in a particular case of milling cast iron with a feed per tooth of 0.012 in. and a depth of 0.125 in. Fig. 34 shows the condition of cutting up, and Fig. 35 that of cutting down. These records were made with an oscillograph operating in conjunction with a special dynamometer, designed to record extremely rapid force fluctuations in both a horizontal and a vertical plane. Calibration, tooth marker, and timing lines are carried on each chart.

A comparison of these records will show a marked difference in the character of the force-component curves for the two types of cut.

By integrating these curves, and subsequently recombining them to obtain the resultant tangential force on the cutter, the energy per chip may readily be calculated. Further work with this instrument will enable a definite comparison to be made between energy values under normal milling conditions and those obtained by the authors with the pendulum dynamometer.

G. A. Bouvier.[21] The writer cannot agree with some of the previous discussers that the authors' data are of little practical use because the method of test is so different from conventional milling practice, but feels, rather, that they are to be commended for recognizing that the only way to obtain an understanding of the fundamentals of milling is to break the general problem up into its elements in such a way that detailed studies of the subject can be made. It should make little difference if, in the analyses of the elements, simple devices are used for test purposes, because carefully gathered data can be analyzed with due consideration for the variations from practice. Furthermore, under these conditions far more accurate conclusions can be drawn than would be possible if highly complicated steps involving many variables were attempted. A thorough understanding of any engineering problem can be obtained only by careful isolation one by one of the many factors in the problem. It is surprising that so much really fundamental information has been obtained by the authors with a comparatively simple testing device. In further and more extensive work, they can be assured at least that they will be following the proper research road. The complexity of our work is too often increased by our insistence on making the problem complicated, with the false idea that we must do so in order to simulate ordinary shop practice.

Roger D. Prosser.[22] One of the conclusions reached in this interesting paper is that milling down is more efficient than milling up, as far as the power requirements are concerned. The tests were run with steel cutters, but if we consider the application of cemented-carbide cutters, which is becoming more and more important every day, it will probably be necessary to modify this conclusion, on account of the fact that the slight increase in power consumption will doubtless become a very minor factor in comparison with the greatly increased cutting speeds and length of tool life obtainable with the cemented-carbide-tipped cutters.

With reference to Fig. 27, showing the chip formation in milling up and milling down, it will be seen that, when milling down, the tooth must start with quite a heavy cut, which tapers off to nothing at the bottom. When milling up, the tooth starts with a very light cut, which increases up to the top. Furthermore, the average chip thickness when milling up is smaller than when milling down, taking the same feed and depth of cut. Thus milling up would appear to be much better for cemented-carbide cutters than milling down, as the tooth starts to cut with less shock, and the pressure on the cutting edge is less throughout the cutting. This is important, due to the very hard and comparatively brittle nature of the cemented carbide as compared with high-speed steel.

[22] Thomas Prosser & Son, New York, N. Y. Assoc. A.S.M.E.

It would be interesting to see further tests conducted, with the idea of extending the scope of this paper to include the cemented-carbide cutting materials.

Edward G. Herbert.[23] More than 20 years ago the writer's attention was drawn to the fact that file teeth were always cut with a negative rake, generally between 0 and —15 deg. and the teeth of milling cutters with zero rake. The writer's knowledge of the action of cutting tools, or what he then believed to be knowledge and now knows to have been ignorance, prompted him to suggest to the makers of files and milling cutters that these tools would cut much better if the teeth had a positive rake. The file makers and cutter makers acknowledged that the tools might be more efficient if made so, but pointed out that the tools did in fact cut in a highly efficient manner as made, and they gave clearly to understand that they did not propose to abandon a tooth shape which ought not to cut well but did, in favor of a shape which ought to cut better but might not.

After nearly a quarter of a century the writer finds that file teeth still have negative rake, that power hacksaws have zero rake, that many, perhaps most, milling cutters have zero rake, and that all of them cut metal in a highly efficient manner.

The explanation of this anomaly, the efficient cutting action of apparently inefficient tooth forms, is now known. It is illustrated by the two micrographs of undetached chips made by a hacksaw cutting through a steel bar $1^1/_2$ in. in diameter. (Figs. 36 and 37.) They clearly show that the cutting is not done by the tooth of inefficient form, but by the very efficient "built-up edge." In some cases it has been found that the built-up edge was specially acute and well formed and the cutting was correspondingly efficient. In other cases the edge was absent or ill formed and cutting was inefficient.

The chief feeling after reading the paper is one of wonder, first, as to what was happening in front of the tools, and second, why the authors did not use the simple and obvious method of sectioning undetached chips to find out what was happening.

The chips shown in Figs. 36 and 37 were formed by a tooth which had traversed less than 1 in. It is known that fully developed built-up edges may be formed and discarded as many as 50 times per second. And the built-up edge is not merely an incident of cutting; it is the cutting agent. Surely a study of the elements of milling should include an investigation of chip formation under the conditions adopted.

A great part of this investigation was directed to comparing the efficiency of "cutting up" and "cutting down" on various metals and with various lubricants, efficiency being measured by power absorbed.

This method of measuring efficiency calls for comment, because power consumption is by no means the first concern of the practical engineer, and because it is not at all certain that the power consumed in the Oxford dynamometer would correspond at all closely with the power consumed in a milling machine.

In practical milling it is usual to provide ample power for the work in hand, and, what is more important, ample rigidity in tool and work. The chief concern is the rapid removal of metal with adequate accuracy of finish; the second concern is the saving from damage of expensive cutters; and the third, if it is a concern at all, economy of power.

In milling up, a milling machine is required to drive the cutter through the work and also to drive the work against the cutter. In milling down, the work is not driven against the cutter. The action of the feed mechanism is rather to regulate the rate at which the work is dragged back by the cutter. The feed mechanism is practically running light. In the Oxford dynamometer this distinction is absent, and the power consumption takes account of only one of the two factors. It seems probable that in actual milling the saving in power by cutting down would be in all cases greater than these experiments indicate. There might be a net saving on all materials and under all cutting conditions. Whether this saving of power would justify the general adoption of a practice which is not free from difficulties and dangers is open to question.

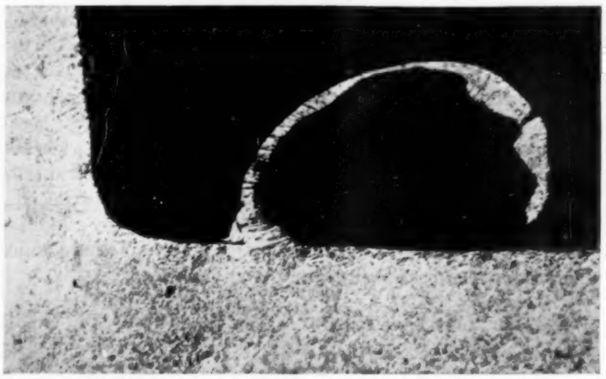

Fig. 36 Hacksaw Chip in Steel × 20

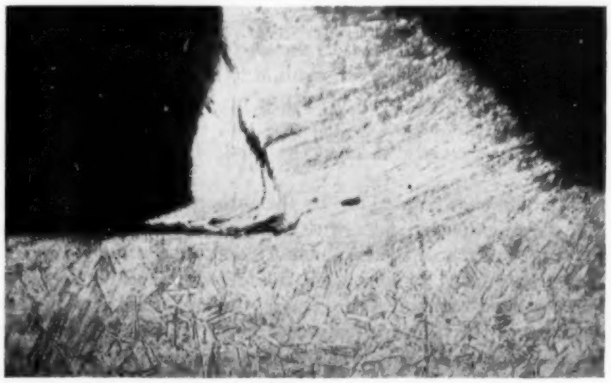

Fig. 37 Hacksaw Chip in Steel × 100

The method of cutting adopted by the authors was virtually that of hitting the specimen with an axe and taking off a wedge-shaped chip. The blow was heavy enough to remove the chip, but a slowing down of the axe was essential to the method of measurement. The action somewhat resembled that of a milling machine with such a slack belt or such a deficiency of power that it would slow up every time a tooth engaged with the work. Is it certain that data obtained from a limping milling machine could be directly applied to normal milling with ample power and uniform speed of rotation?

---

[23] Director, Edward G. Herbert, Ltd., Atlas Works, Levenshulme, Manchester, England. Mem. A.S.M.E.

This is by no means intended as destructive criticism. In investigating a complex operation like milling, a simplification is necessary; otherwise the tests would become so unwieldy and the results so involved that any useful deductions would be rendered difficult or impossible. One such simplification, the use of a single-tooth instead of a multiple-tooth cutter, seems entirely justified. The other simplification, whereby the energy absorbed in a single pass of a pendulum-driven tool is taken as a measure of the efficiency of milling in a power-driven machine with power feed, may or may not be justified. It would be easy to trace a logical connection, thus: low absorption of energy; slight deformation of the cut material; low evolution of heat; the possibility of running the cutter at a high speed without damage by overheating; hence high production at low cost.

The validity of the connection thus suggested could be tested by a study of chip formation, which might be expected to show why, on a given metal, cutting from the thin end of the wedge takes more or takes less power than cutting from the thick end.

Its validity could be established by running some check tests with a normal cutter and machine, to find whether the condition indicated by the experiments as efficient did in fact permit a greater output than those indicated as inefficient; whether, in short, the results of the experiments could be translated into dollars and cents. If contact could thus be established, if only at a few points, between the artificial laboratory conditions and the conditions of the workshop, the authors could indeed claim to have laid the industry under an obligation.

Geh. Regierungsrat Prof. A. Wallichs[24] **and Dr.-Ing. H. Schallbroch.**[25] In order to make it possible to evaluate the magnitudes presented in this report dealing with the chip removal for various materials in comparison with earlier or later experiments of the same kind, it would be necessary to have a drawing showing the exact shape of the cutter. It is particularly essential to have the profile of the cutter, showing whether a side curvature is present as well as the dimensions of the arbor. If there were to be given, in addition to a drawing of the cutter, also a drawing of the place of cutting on the piece being worked (in two projections, all in perspective), this would enable the reader to see clearly at once the kind of chip removal being employed.

The difference pointed out by the authors between the method of cutting employed here with the work piece stationary and moved forward only by the amount f, and the continuous moving of the piece being worked, while the tooth turns as on the actual milling machine, is much greater than the authors believe. Because of this the application of down milling, recommended partly because of the lower work in foot-pounds per single chip, is not justified. As a matter of fact this forward motion ("down" in the direction of the rotation of the miller) is in practice not common, because of the unequal work and other objectionable features due to undesirable backlash of the work against the tooth.

A further difference may be established as due to the fact that the cutter tooth on an ordinary miller cuts the work at a constant velocity, while the single tooth of the device employed here lags in the matter of velocity while going through the work. As admitted by the author of the original paper, there is a further objection to this method from the point of view of practical conditions in milling, and that is the limited efficiency of the work coolant (namely, lubrication, but no cooling); a further objection lies to the evaluation of tests made with cutting teeth which, before running the test, were deliberately and uniformly dulled at the edge. The usual dulling of the cutting edges on actual millers unquestionably causes inequalities of operation which are much more difficult to observe. The application of the conclusions of the authors to actual milling practice will encounter certain difficulties due to the fact that the influence of cutting speed, so important in all processes of chipping, has been left out of consideration. It was recognized by F. W. Taylor as the most important variable in all processes making chips, and investigations made within the last decade have brought out particularly clearly how strongly the speed of cutting affects the life of the tool as well as the characteristics of the surface on the work.

It has been shown on radically different processes producing chips (turning, boring, milling) that the force of cutting proper (not the energy consumption of the machine, which naturally increases with the velocity of cutting) does not increase or decrease in any regular manner with the speed of cutting, but remains practically the same with all velocities of cutting in the same process of producing chips. Because of this it is difficult to draw, from the energy consumed in cutting, any reliable conclusion as to the life of the tool.

If we consider the chip cutting of the work only from the point of view of consumption of energy, then the data obtained with the simple experimental set-up used by the authors are in good accord with the data obtained in shop tests on milling published by Fr. Beckh.[26] The observations of Fr. Beckh to the effect that the energy consumption of the millers tested by him with eight to sixteen teeth is proportional to the width of cutting W and the depth of cut d, and increases in a somewhat lower ratio than the increase of feed f, would seem to be supported by the results of the authors with the single-tooth equipment.

At the beginning of each chapter of their work, the authors of the paper are very careful to point out the limitation of their method and caution the reader against too general applications of their data to actual milling processes. This makes their investigation very valuable, and one may congratulate the authors on having carefully done this work and clearly arranged the results.

Dr.-Ing. Georg Schlesinger.[27] Referring to the writer's own experimental work at the Experimental Laboratory for Machine Tools at Charlottenburg and on the basis of these tests, together with the data obtained by other German research workers, the writer has endeavored to combine the theoretical and experimental information hitherto available in reference to the process of milling in such a manner as to obtain general, very comprehensive, and yet simple equations having the advantage (as compared with other equations previously proposed) that they present truly geometrical relations unassailable from the mathematical point of view and yet in good accord with data obtained experimentally.

In so far as they cover the calculation of the work consumption of a single tooth these formulas read as follows. The work of the tooth is:

$$A_Z = K_M \times a \times b \times s_Z \quad [20]$$

The following notation is here used:

A_Z = work of a single tooth in kg-mm.
K_M = specific cutting force in kg. per sq. mm.
a = depth of cut in mm.
b = width of cut in mm.
s_Z = feed per tooth in mm.

---

[24] Aachen, Germany. Mem. A.S.M.E.

[25] Aachen, Germany.

[26] Fr. Beckh, "Die Metallbearbeitung mittels Walzenfräsern," *Maschinenbau*, 5 (1926), pp. 497 to 504 and 557 to 561.

[27] Professor of Mechanical Engineering, Technische Hochschule, Berlin, Germany. Mem. A.S.M.E.

The specific cutting force is

$$K_M = f(h_M) \quad \ldots\ldots\ldots\ldots\ldots\ldots [21]$$

in which

$$h_M = s_Z \times \sqrt{(a/d)} \quad \ldots\ldots\ldots\ldots\ldots\ldots [22]$$

is the thickness of the chip midway in the cut and d is the diameter of the milling cutter in millimeters.

Whether the shape of this functional graph plotted on log log paper is a straight line or a curve has not yet been determined, but the specific cutting force K_M may be expressed in the form of an experimental curve, as has been done by the discusser himself in *Werkstattstechnik*, 1931, p. 413. (See Fig. 38.)

If in this figure the slightly curved line plotted on log log paper for the type of steel St. 50.11 (notation according to the German Standards DIN 1611) is approximately replaced by a straight line which is, however, valid only for the range from $h_M = 20\mu$ (microns) to 100μ, Equation [21] becomes

$$K_M = k \times h_M{}^Z = 150\ h_M{}^{-0.28} \ldots [21a]$$

Here $k = 150$ has been obtained by extrapolation of the experimental line in Fig. 38 assumed to be straight and extended up to the point 1 mm. $= 1000\mu$; $Z = 0.28$ is obtained as tangent α = the inclination of the experimental curve (straight line). It would have been more precise and less subject to objection if one could read the values off the experimental curve itself, i.e., in its curved shape.

By thickness midway in the cut h_M is meant the thickness of the chip at that point determined for the average force and hence for the work of removing the chip by a single tooth as has been done by Boston and Kraus.

From these three general equations the Boston and Kraus equation can be obtained by a simple mathematical operation. It is $E = C \times w \times f^x \times d^y$. Here E is the work of a single tooth in foot-pounds; C, the constant for the milling tooth (0.250 in. wide with a 15-deg. cutting angle) and given material of the work; w, width of cut in inches; f, path of a single tooth in the direction of feed in inches; d, depth of cut in inches.

If the discusser's notation and the metric system are used and the values changed to the American system of units only at the end, the following may be derived from the three fundamental equations as stated above:

$$h_M = s_Z \times \sqrt{(a/d)} = s_Z \times a^{0.5} \times d^{-0.5} \ldots\ldots [25]$$

From [22], and from curve in Fig. 38 for the type of steel referred to above ("St. 50.11") can be obtained approximately:

$$K_M = 150 \times h_M{}^{-0.28} \ldots\ldots \text{compare } [21a]$$

Then, by combining the two, there is obtained

$$K_M = 150(s_Z \times a^{0.5} \times d^{-0.5})^{-0.28} = 150 \times s_Z{}^{-0.28} \times a^{-0.14} \times d^{0.14} \ldots\ldots\ldots [24]$$

But it has been stated above:

$$A_Z = K_M \times a \times b \times s_Z \ldots\ldots \text{compare } [20]$$

Hence we obtain by substituting the values of [24] in Equation [20]:

$$A_Z = (150 \times s_Z{}^{-0.28} \times a^{-0.14} \times d^{0.14}) \times a \times b \times s_Z$$
$$= 150 \times d^{0.14} \times b \times s_Z{}^{0.72} \times a^{0.86} \ldots\ldots\ldots\ldots\ldots [25]$$

Equation [25] corresponds exactly to the Boston and Kraus equation for cold-rolled low-carbon steel, as is evident by comparing the two equations:

$$\text{Schlesinger:}\quad A_Z = (150 \times d^{0.14}) \times b \times s_Z{}^{0.72} \times a^{0.86}$$
$$\text{Boston:}\quad E = 6800 \times w \times f^{0.73} \times d^{0.87}$$

(6800 and the exponents have been taken from Table 18 of the Boston and Kraus paper.)

The following correspondence in the two formulas has been found:

Schlesinger	Boston and Kraus	
A_Z in kg-mm.	E in foot-pounds	= work of a single tooth
b in mm.	w in inches	= width of cut
s_Z in mm.	f in inches	= feed per tooth
a in mm.	d in inches	= depth of cut

From the above comparison the following may be derived:

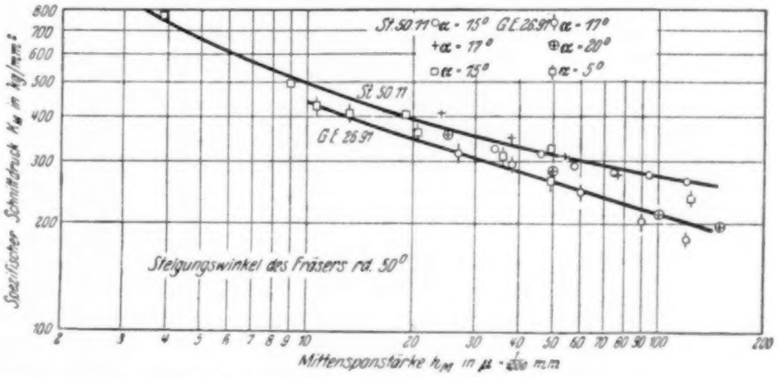

FIG. 38 RESULTS OF MEASUREMENTS OF THE SPECIFIC CUTTING PRESSURE IN MILLING STEEL AND CAST IRON (FROM THE ADB INVESTIGATIONS)

(*Specifischer Schnittdrock K_M in kg/mm.²* = Specific cutting pressure K_M in kg. per sq. mm. *Steigungswinkel des Fräsers rd.* 50° = Helix angle of milling cutter about 50 deg. *Mittenspanstärke h_M in $\mu \cdot {}^1/_{1000}$ mm.* = Chip thickness h_M midway in cut in thousandths of a millimeter.)

The exponents in the two equations set side by side are practically the same; namely, for tooth feed 0.72 and 0.73 and for depth of cut 0.86 and 0.87. But from the generalized and therefore more comprehensive equations of the discusser one may assume that there must exist a certain relation between these two exponents, which in his case may be written as follows:

$$\left.\begin{aligned} 1 - 0.72 &= 0.28 \\ 1 - 0.86 &= 0.14 \end{aligned}\right\} 2 \times 0.14 = 0.28$$

These relations as shown by the more comprehensive equations must, however, necessarily apply for all materials. The differences between the exponents and unity must be in the ratio of 1 to 2. Hence the experiments carried out by Boston and Kraus must be capable of being expressed by a single characteristic curve of the type $K_M = f(h_M)$. The specific cutting pressure is functionally related to the thickness of chip midway in the cut.

This experimental curve may, with precision sufficient for practical purposes, be expressed by a straight line on a double logarithmic paper, and a simple algebraic formula may be then derived for this line in the usual manner. Under no conditions, however, can it be said that the curves given by Boston and Kraus represent two experimental curves independent of each other. $A_Z = f(s_Z)$, energy consumption of a tooth as depending on the tooth feed, and $A_Z = f(a)$, energy consumption of a tooth as depending on depth of cut.

In many cases, but not always, the necessary connection between the two exponents in the Boston and Kraus equations is present with a certain amount of precision. Apart from the slight variations which might have been due to experimental error, but which in view of the very great care exercised by Boston and Kraus may amount to comparatively little, we may be dealing here perhaps with the fundamental weakness of the experimental apparatus used. The results obtained with the pendulum dynamometer do not in every instance coincide with the amounts of energy expended in actual milling, as will be shown more completely later in this discussion. In the first place we may ask in how far the constants in the two juxtaposed equations coincide with each other. There must be an agreement between $150 \times d^{0.14}$ in the metric system and 6800 in the American system of units.

It will be noted from the more comprehensive equations of discusser that the constant comprises the diameter of the milling cutter and is affected by an exponent which is dependent on the experimental curve, and in the present case is about the seventh root of the milling-cutter diameter. The influence of the diameter, however, is slight, as when the diameter is doubled the constant increases by only about 10 per cent. The more comprehensive formula, however, brings out this influence.

Boston and Kraus were working with an installation in which the milling-cutter diameter corresponded to $d = 3.5$ in. $= 89$ mm. From this the constant in the discusser's modified equation would be:

$$150 \times 89^{0.14} = 150 \times 1.87 = 280$$

In recomputing this constant in terms of the American system of units, b, sz, and a must be converted from millimeters into inches by using the factor:

$$25.4^{1+0.72+0.86} = 25.4^{2.58} = 4220$$

and furthermore kg-mm. must be change to ft-lb. by dividing by 138. This gives

$$280 \times \frac{4220}{138} = 8550$$

which compares with 6800 in the American experiments.

The constants of the German experiments are therefore about 25 per cent higher. Apart from the difference in the materials of the work which were used in the experiments, the discusser is inclined to explain this in part by the fact that, contrary to the American experimental apparatus, in German tests on milling, cutters with inclined teeth were used, which is in accordance with present machine-shop practice. And according to his experience, this type of cutter possesses a higher specific cutting force, which means that it must be granted constants of higher values. This proof of the two sets of experimental values shows a notable agreement between them. It might be therefore recommended to use in evaluating the experimental results the more general and simpler equations, as this would increase the practical value of the material obtained in the experiments. It may be added that in the Charlottenburg tests actual milling cutters were used; that is, a practice more approaching the actual operations.

As regards the employment of a pendulum dynamometer, it may be pointed out that it creates conditions in the removal of the chip which are different from those occurring in actual milling. The difference pointed out in the paper—namely, that in one instance the work is stationary during the process of cutting, while in the other is fed forward—is, in the discusser's opinion, not of predominating practical importance.

He considers as more important the fact that where the pendulum dynamometer is used the speed of cutting does not remain constant during the process of cutting (passage of tooth through the work). The pendulum in full swing has at the two peak positions of the weight a velocity of zero, while at the lowest position of the weight it attains the highest speed of cutting. Moreover, the removal of the chip additionally retards the pendulum and thereby causes a variation on the speed of cutting; moreover, this variation is different in milling *in* the direction of feed from what it is *against* the direction of feed.

There are materials which exhibit only a slight dependence of the specific cutting force on the velocity of cutting which applies to very many of the ferrous metals. With these metals there is the best chance of obtaining an agreement between the values measured with the pendulum dynamometer and those obtained in actual milling, and this agreement is shown on an example referred to. In other cases, the application of the pendulum dynamometer for the determination of milling coefficients seems to be objectionable. It does not appear to be a mere accident that the correspondence between the exponents in the expression for feed and depth of cut, as indicated in Table 18 of the paper, is found to exist in the majority of ferrous metals, but not in the case of other materials, such as brass. In the latter, however, the discusser has been able to demonstrate a strong influence of the speed of cutting, particularly when the angle of cutting was unfavorable, and he did it with the measuring apparatus set directly on the machine tool and leaving the state of operation of the machine unaffected as far as was possible. It may be worth noticing in this connection that according to Fig. 22 of the Boston and Kraus paper the greatest inequality in energy consumption in milling in both directions is found to be present in the case of metals in which the influence of the speed of cutting has been demonstrated, especially with an unfavorably selected angle, and the angle of 15 deg. mostly used by Boston and Kraus in the cases of light metals unfortunately belongs to this category.

A further objection to the use of the pendulum dynamometer is seen in the circumstance that it is impossible to determine by calibration the additional friction produced in the bearings during cutting. It becomes necessary to exercise the greatest care in order to keep this friction as low as possible. Because of this, the discusser considers it preferable to keep the path of the pendulum weight, as is done in the pendulum hammer in an impact testing machine, in the same plane with the path of the cutting tooth. Apart, however, from these considerations against the application of the values measured by means of the pendulum dynamometer to actual milling, without having previously established by comparative tests directly on a working milling machine the permissible limits of such an application with irreproachable precision, the pendulum dynamometer can solve only a small part of the problems arising in the milling process. For a complete solution of the milling process, it is not sufficient to know the peripheral force on the milling tool, the average value of which may be determined by calculation from the measurement of energy consumption of a milling cutting, providing this value is applicable to actual working conditions. In addition to this, it is necessary to know the three components of the cutting force perpendicular to each other, as it is only then that the magnitude and direction of the cutting force can be determined.

With the measuring apparatus designed by the discusser (*American Machinist*, 1930, p. 578, Fig. 7), these three components can be read off directly or plotted on an operating milling machine. It is only when one knows all of these that one can determine how to execute a milling operation in the best way on a given milling machine, being able to form a correct judgment not only of the energy required for driving the spindle, but also—and this is perhaps of greater importance—of the strength of the machine frame and of its deformation, which is highly important as regards accuracy of the work machined. In this connection the discusser speaks briefly on the Boston and Kraus tests with dull cutters which once more confirm in a beautiful manner that in the case of milling the same relations hold good as in other forms of cutting. When the cutting edges are dull, the force required becomes greater, and this increase of force (and hence of the energy consumption of a milling tooth in milling) is shown according to the discusser's tests in a much higher degree by the radial component of the cutting force than by the peripheral, which latter component only is measured by Boston and Kraus.

Referring to the Berlin experiments on turning, the discusser hopes that it will be possible to establish a criterion for the dulling of a milling cutter by measuring the *radial* component of the cutting force. He is working in this direction in his Berlin laboratory.

Authors' Closure

The authors are grateful indeed to those who have discussed this paper with such thoroughness. It is gratifying to see that real interest has been aroused on the several phases of milling discussed. Before answering the various questions raised, it appears proper to outline the conditions under which this work was undertaken.

The authors started this investigation on milling with a single objective—to learn something definite about milling. This paper is the first of four contemplated. The second paper, now nearing completion, deals with additional elements, such as the influence of land or groove cutting, variable rake, variable side rake or helix, etc., using the same single-tooth pendulum tester. Work for the third paper is well under way. A No. 3-B plain milling machine with a 10-hp. direct-drive motor is equipped with a wattmeter for measuring the gross and net input power, and a dynamometer that registers graphically the two vertical and the one horizontal components of the cutting force is mounted on the table. This dynamometer will permit the determination of the magnitude and direction of the resultant cutting force. The wattmeter will be used only as a check. Several sets of cutters of different types, each type with a single variable, such as number of teeth, rake angle, helix angle, etc., have been supplied by cutter manufacturers. Eleven cutting fluids, representing typical types in use, have been supplied also. Eight metals, representing different types, already are available. It is hoped that results may be obtained with this equipment that will confirm those resulting from the study of elements.

The fourth paper, as planned, is to present milling data from actual manufacturing conditions that will confirm or throw additional light on the several problems investigated. Judging from preliminary attempts, it will be most difficult to obtain reliable information for the fourth paper.

Milling equipment used in manufacture represents millions of dollars, yet almost every one will admit that milling is an art based on cut-and-try methods. The authors are not connected with the milling industry, and, without remuneration, have sought to learn something definite, something that could be duplicated, and something that could be used for predeterminations in practice. This paper sets forth conclusions based on experimental data. Personal opinions have been suppressed.

The pendulum-type tester used was considered adequate for the preliminary study of "The Elements of Milling." It has been used for several years in the study of machinability and has been found to be a simple and quick machine to operate and sufficiently accurate for the purpose. Milling energy per chip for various metals has been found to compare quite favorably with data obtained from the same metals by other standardized methods of tests.

Most milling data are based on wattmeter readings for gross power input. Sometimes the machines have been calibrated to compare the prony brake power on the spindle with the gross input. In most of such tests, the feeding power of the table is neglected. The authors have found that the efficiency based on brake horsepower at the spindle divided by the gross power input determined by a wattmeter is as low as 25 per cent on two available machines of different makes. The small difference in power, due to the variable being studied, may be less than normal variations in the wattmeter readings. Under the most favorable conditions with such a set-up, satisfactory results cannot be expected. This is one of the reasons why the pendulum-type dynamometer involving a single-tooth cutter is believed to be more satisfactory in this elementary work.

The type of machine used in the tests has been commented on by several. This type of machine is particularly valuable, inasmuch as both the head, after feeding the cutter to depth, and table, after advancing the work each time equal to the tooth feed, are locked in position. This feature is favorable particularly for the down-milling experiments in which rigidity, omission of back lash, etc. are required.

Several discussers have raised the question that the pendulum-type dynamometer used does not permit the work to move with or against the cutter while the chip is being removed, as is done in a regular milling machine. It is true that the work was stationary when the chip was removed. Fig. 27 was prepared to show that the projected length of the chip is changed when a feeding motion of the work is introduced. In cutting up, as shown at *A* and *C* in Fig. 27, this feeding motion of the work would cause the values of L_A and L_C to be increased slightly over those for no feeding motion. When the depth of cut is $^1/_8$ in. and the feed per tooth 0.010 in., the value of L_C shown at *C* in Fig. 27 is approximately 0.7 in. for a 3.5-in.-diameter cutter with no feeding motion of the work. With the 20-tooth cutter, as shown, if the work moved uniformly to provide the feed per tooth, the value of L_C would be increased by approximately 0.0124 in., or 1.7 per cent, while the cutter tooth sweeps through an angle, from the bottom to the top of the cut, of approximately 22 deg. and 20 min., which is 6.2 per cent of a complete revolution. This small increase in the value of L_C would reduce the average thickness of chip but slightly and thereby increase the energy consumption but slightly. Similarly, in down cutting, the values of L_B and L_D, as shown at *B* and *D*, respectively, in Fig. 27, would be reduced slightly from those for no feeding motion, consequently thickening the chip. Increasing the length of the chip, reducing its average thickness when cutting up, and reducing the length of the chip, increasing the average thickness when cutting down, as would be the case if the pendulum machine were replaced by a milling machine, would tend to increase slightly the difference between the energy values when cutting up and when cutting down. It was felt desirable, however, in these preliminary experiments to keep the work stationary so as to study better the influence of up cutting versus down cutting. It is hoped that this statement can be confirmed by the more practical tests in the work now being done for the third paper.

The fact that constant speed is not obtained during the cut by the single tooth of the pendulum-type dynamometer has been referred to by several. It is thought there is a probability that a variable speed which differs from commercial practice would affect the value of the energy readings. The authors appreciate this fact. It has been proved previously by them that drilling torque and thrust do not vary over a wide range of speed variation. (Trans. A.S.M.E., Vol. 52, 1930, paper, MSP-52-2.) Gottwein has shown that, in turning, there is practically no change in cutting force over a wide range of speed. The authors have confirmed this using a Losenhausen dynamometer. These results would seem to be confirmed in Figs. 4 and 11, in which cuts both up and down have been taken for the same range of variable feeds but for three different depths of cut. Without a doubt there is a greater slowing up of the cutter for the greater depths of cut than for the shallow depths of cut. The slopes of all six lines in each case, as well as those where the depth has been varied for feed values of 0.005 and 0.010 in., respectively, are the same, indicating that the exponents of the formula are not changed by the variable speed.

An analysis of the speeds of the single-tooth cutter show the following:

Velocity at the start of cut $= 70.2/h\sqrt{(2h)}$

Velocity at the finish of cut $= 70.2/h\sqrt{(2h - d - x)}$

in which h is the distance from the center of the shaft to the center of gravity of the pendulum, d is the vertical distance through which the center of gravity of the pendulum moves while engaged in a cut, and x is the vertical distance of the center of gravity below the original top dead-center or vertical starting position of the pendulum after making a swing, when taking a chip.

When 1 ft-lb. of energy is given up by the pendulum, $d = x$ in the formula for velocity at the finish of the cut. It is found that the velocity at the start is 98.5 ft. per min., and the velocity at the finish is 95 ft. per min. for up milling. For down milling, with the same assumption as above, it is found that the velocity both at the start and finish of the cut is equal to 96.7 ft. per min.

When the energy given up by the pendulum is equal to 10 ft-lb., the value of x in the equations is 0.728 ft. For this condition the velocity at the start is found to be 98.5 ft. per min., and the velocity at the finish is found to be 76.8 ft. per min. for up milling. For down milling under the same conditions, the velocity of the cutter at the start is found to be 96.7 ft. per min., and the velocity at the finish is found to be 79 ft. per min. The 10 ft-lb. of energy given up by the pendulum would correspond to a depth of cut of 0.150 in. and a feed of 0.030 in. when cutting the free-cutting brass, or a depth of 0.150 in. and a feed of 0.020 in. when cutting cast iron, or approximately 0.100 in. depth of cut and 0.015 in. feed when cutting free-cutting steel. All of these cuts represent the heavier ones used in the experiments with the 0.250 in. wide cutter, so that the speed variations would represent nearly the maximum. It is believed that these small speed changes do not appreciably affect the results obtained.

Professor Hall raises several questions not covered in the foregoing discussion. It is believed that the large savings in power when cutting various materials by using heavy feeds rather than fine feeds may be due to the fact that the savings indicated are based on the net energy values at the tool point. Presumably those used by Professor Hall in his comparison are based on net gross power in savings, which would not be so high in per cent. Professor Hall is correct in assuming that the formulas presented in the paper are for a cutter $3^1/_2$ in. in diameter. No other diameter was experimented with. Dr. Schlesinger states that "The influence of the diameter, however, is slight, as when the diameter is doubled, the constant increases but only about 10 per cent." Inasmuch as the tests used in the paper had a maximum depth of 0.150 in., the authors are not in a position to predict what might happen at greater depths. Experiments now in progress will involve this point, however.

Mr. Goddard has raised the question as to the condition of a sharp cutter. All tests, except those run under the heading of sharp, dull, and very dull cutters, were run with cutters supposedly sharp. They were ground on a tool-room surface grinder, so that, from all appearance, keen cutting edges were obtained. The conditions of the dull and very dull cutters definitely are outlined under that heading. Mr. Goddard's discussion of the built-up nose formed on the face of the cutting tool is very ably discussed by Mr. Ernst. The views expressed by Mr. Ernst are in complete accordance with those of the authors. By constant feed was meant that, for a series of tests, the work was advanced the same amount for each chip removed. During such a series of tests, the depth, the width of the tool, the cutting fluid, etc. might have been varied.

The discussion by Mr. Ernst is decidedly enlightening. The authors did not intend to convey the idea that they believed the built-up edge was not formed in milling up, but rather that it was not formed from the beginning of the cut as when cutting down. Their observations in removing chips by up and down cutting agree with those expressed and illustrated by Mr. Ernst. The authors have not as yet made photomicrographs of chips, but have had that in mind.

The remarks of Mr. Herbert add materially to the value of the paper. His opinions agree substantially with those of Mr. Ernst and the authors as far as the formation of the built-up edge is concerned.

It is believed that the questions raised by Professor Wallichs and Dr. Shallbroch have been answered in part in the general discussion at the beginning of the closure. Apparently, milling down is not being used as generally in Europe as in the United States. It is interesting to note that the results of Fr. Beckh, in using regular milling cutters having eight to sixteen teeth, agree substantially with those of the authors determined with the single tooth equipment. It also is encouraging to note, from Dr. Schlesinger's discussion, the complete agreement between the results of tests with regular milling cutters on standard milling machines and those obtained by the authors with their single-tooth cutter. This agreement tends to confirm the authors' statements regarding the negligible effect of the variable speed and lack of movement of the work during the cut, which have been criticized.

Foaming and Priming of Boiler Water

By C. W. FOULK,[1] COLUMBUS, OHIO

A rapidly increasing interest in the subject of the foaming and priming of boiler water is shown by the fact that as many papers have appeared during the last three or four years as in the preceding 20 or 30 years. New information about the behavior of suspended solids and of dissolved salts has been brought out, and a helpful theory of foam formation has also been advanced. It would be inferred from recent work that too broad generalizations in regard to foaming and priming of boiler water should not be made, because in some cases the design of the boiler profoundly affects the behavior of the water.

A PAPER presented by the author under the title, "Present Knowledge of Foaming and Priming of Boiler Water With Suggestions for Research," constituted the 1926 report of Subcommittee No. 3 of the Boiler Feedwater Studies Committee (1),[2] and was published early in 1927 in the Journal of the American Water Works Association (2). The 1927 annual report of Subcommittee No. 3 was a review of two papers on foaming and priming (3). These two reports brought the subject fairly well to date and therefore the papers reviewed here will begin where the 1927 report ended.

A Physico-Chemical Theory of Foams

The major cause of wet steam is often more physical or mechanical than chemical, but even in such cases the physico-chemical properties of the water play an important role, and it is worth noting that in all cases that have come to the author's attention the most important chemical property of the water is the degree to which it is capable of forming liquid films. This formation of films is sometimes an obscure, but nevertheless a frequent determining factor in wet steam. Film formation, particularly a mass of spherical films, or a foam, is therefore one of the most important characteristics of a water, and has been so recognized from the first. Obviously then, the study of the causes of wet steam without a physico-chemical theory of foams, or film formation, was like a game of blind man's buff because there was nothing to serve as guide. The earlier general papers on foams confused the formation of films with the question of their stability after formation, and these two points were so intermingled that it was impossible to disentangle them. The author felt this so keenly in his own researches that efforts were directed toward finding a general theory, and in the 1927 report of Subcommittee No. 3 (3), such a theory was offered. It was subsequently published in a more elaborated form (4), from which the following brief statement of the theory is quoted:

> "Liquid films are always formed by the approach to each other, usually with an extension of area, of two already formed liquid surfaces. In the case of solutions the mechanical force acting to bring the surfaces together meets with resistance when the layer of liquid between the surfaces becomes very thin, with the result that a film is produced. In the case of pure liquids no such resistance is encountered and consequently the two surfaces merge and vanish. The reason for the counter force in the case of solutions is the difference in concentration between the surface layer of the liquid and the mass of the liquid. Solute either concentrates in the surface or recedes from the surface. In either case this movement of matter takes place against diffusion and it will, therefore, require work to restore the equality of concentration; in other words, thin surface layers will resist a force to mix them. This theory harmonizes the puzzling facts that both positively and negatively adsorbed dissolved matter causes foam in liquids and explains why pure liquids do not foam." The statement is also made that, "film formation and film stability are separate questions which have often been confused in the literature."

This first paper contained little or no experimental evidence, a lack now remedied by the quite recent publication (4*a*) of a paper in *Industrial and Engineering Chemistry*. In this second paper data and graphs are offered in support of the theory.

The mechanical part of the theory, namely, that liquid surfaces on approaching each other cease their approach when very close together if the liquid is a solution, is proved by a simple experiment. Two bubbles are caused to issue from orifices placed near each other in the liquid the film-forming properties of which are being examined. If the liquid is a solution the bubbles flatten against each other, that is, they cease their approach when very close because a liquid film is formed between them. If, however, the two bubbles are in a pure liquid, like distilled water, or in a very dilute solution, they do not cease approaching, because no film is formed between them and the two bubbles merge together into a larger one as soon as they touch each other. By counting a large number of such contacts of two bubbles in the liquid and noting the number of times the bubbles do not coalesce on touching, that is, the number of times a film is formed between them, a quantitative measure of the film-forming tendency of the liquid is obtained. It will be observed that in this experiment the tendency to film formation is the dominant property measured. The stability of the films plays a minor role.

The stability of a film, however, plays the chief role—the role of the villain—in a boiler-water drama, and therefore, there should be some way of measuring it. This seems in a fair way of being accomplished in a simple manner with an instrument described in this experimental paper. It was designed in the author's laboratory by Hansley (5) who called it a dynamic foam meter because the measurements are made while the foam is being produced.

A Dynamic Foam Meter

The apparatus in question is nothing more than a glass tube closed at one end with a porous septum, and so mounted that a current of air can be blown through the septum into the liquid

---

[1] Professor of Analytical Chemistry, The Ohio State University. Mr. Foulk was educated at The Ohio State University, receiving the degree of A.B. in 1894. He studied two years in the Physical Chemical Institute at Leipsig, and for several years immediately after graduation did commercial analytical work. He joined the Ohio State University as assistant in quantitative analysis and moved up through the various grades to his present position. He has become especially interested in industrial water problems, and is the author of several papers on foaming and priming of boiler water.

[2] Numbers in parentheses apply to literature references at the end of the article.

Contributed by the Joint Research Committee on Boiler Feedwater Studies and presented at the Annual Meeting, New York, N. Y., Nov. 30 to Dec. 4, 1931, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

under examination in the tube. If a pure liquid or a very dilute solution is in the tube the bubbles of air issuing from the pores of the septum merge at once into larger bubbles and these larger bubbles on touching each other coalesce again to form still larger ones. The column of liquid in the tube is thus full of large bubbles and there is little or no foam on the surface. If now some soluble matter is added, sodium sulphate for example, in gradually increasing concentration, it will be seen that the bubbles rising through the liquid gradually become smaller, that is, the coalescence of small bubbles as they emerge from the pores of the septum, gradually becomes less because of the resistance to mixing offered by the layers of solution constituting the interior surfaces of the bubbles, until at a certain concentration the coalescence ceases and the solution takes on a "white" appearance due to the mass of tiny air bubbles in it. In other words, the bubbles retain the size they have on emerging from the pores of the septum. In addition to this phenomenon a layer of foam forms on the surface of the liquid. The thickness of this foam layer is determined by the steady state between the rate of formation of the bubbles and the stability of the bubble films. The height of the foam layer is not the measure of the stability of the foam, but it is proportional to it, and the instrument therefore serves to compare the foam-forming tendency, or the foaminess of different liquids.

It is proposed, in the author's laboratory, to make a thorough study of this instrument, particularly with the view of standardizing it so that different investigators can obtain comparable results.

The direct measurement of bubble stability, which, of course, must be stated in units of time, has recently been made in a very simple manner by Talmud and Suchowolskaja (6). They determined the number of seconds during which individual bubbles lasted on the surface of the solutions tested. The results in so far as it was possible to compare them agreed very well with those obtained with the foam meter.

A Theory of Antifoams

Boiler-water chemists will also be interested in one of the corollaries from the theory since it offers a general theory for guiding an investigator in search of antifoams. Since the theory of film formation states that films or foams are formed only in those cases in which the dissolved matter either concentrates in the surface (positive adsorption) or recedes from the surface (negative adsorption), the question naturally arises, what happens if two substances are dissolved in the same liquid, one exhibiting positive adsorption and the other negative adsorption? A corollary from the theory answers this question by stating that in such cases there will be certain mixtures that do not foam because positive and negative adsorption cancel each other, if the amounts of the two substances present are in the right proportion.

Various non-foaming mixtures of foam-forming substances were found and are recorded in the paper. Perhaps the most interesting is the pair sodium sulphate and soap. A solution of sodium sulphate in the dynamic foam meter described foams vigorously because the salt is negatively adsorbed. The foaming is instantly stopped by the addition of a minute amount of soap, which is strongly positively adsorbed.

This experiment shows the danger of hasty generalization in the study of foaming. As a rule the addition of soap to a water solution makes it foam, assuming of course that there is no chemical action on the soap, but it is seen, there are exceptions.

It is also worth recording at this point that four or five years ago the author was appealed to by the chemists engaged in concentrating some of the heavy brines that were being worked up in the west for potassium salts. These brines produced a great deal of foam which, it was accidentally discovered, could be dispelled by the addition of a little soap. The reviewer was asked to explain this strange phenomenon, and at that time was unable to do so. Now the situation is clear on the basis of the corollary referred to above, and it is interesting to observe that here was an actual instance of the commercial use of soap as an antifoam.

Particle Size of Suspended Solids

German engineers and chemists have lately turned their attention to foaming and priming, and recently Niehaus (7) has published a general paper entitled "Physico-Chemical Considerations on the Problem of Boiler-Water Foaming." This interesting article aims to set forth the existing general facts and theories, but it contains no references to American investigations. Niehaus lays special emphasis on particle size as a factor in the stabilization of foam by suspended solids and states that there is a certain size which has the maximum stabilizing power. Anything above or below this has less effect. He gives this optimum size as that lying on the border of colloidal and gross dispersion. The effect of various soluble substances in the boiler water is ascribed by Niehaus to their influence on the particle size of the solids. The specific effects in this direction of such substances as caustic soda, sodium carbonate, phosphates, magnesium sulphate, and sodium chloride are discussed. One of the most interesting items in the summary at the end of the paper is the statement that soluble phosphates should be kept below 15 to 20 mg. per l. This is a very low concentration and the reviewer wonders whether American experience is in agreement with Niehaus.

Projection of Droplets by Bursting Bubbles

In 1927 (2) the author pointed out that apparently no one had yet studied the well-known fact that a bubble bursting on the surface of a liquid frequently throws a droplet of the liquid upward, sometimes to the height of 4 or 5 in. This phenomenon, which might well have an effect on the amount of water in steam, is a part of the mechanism of effervescence and has been studied under that title by Craven and Stuhlman (8). The author unfortunately has seen only an abstract of their paper. The upward projection of liquid droplets is mentioned in this abstract, but is not explained, nor is there any detail on the effect of such changing conditions as occur in a boiler water. The author has also studied this phenomenon and is able to say that the droplet thrown upward is not part of the ruptured bubble film as is commonly supposed, but has its origin in the center of the depression in the liquid surface on which the bubble exists just before bursting. When the bubble film bursts the pressure which causes this depression is relieved and the liquid rises. In doing so the center of the depressed area rises faster than the rest with the result that a drop necks off and is thrown up. The phenomenon can be produced by directing a current of air downward against a liquid surface and then suddenly interrupting the air. The depressed area flies up and the necking off of the projected droplet can be observed. The author has not seen Craven and Stuhlman's complete paper and therefore cannot say whether they have explained the projection of droplets the same way or not. This question of projected droplets is worthy of study from the standpoint of boiler-water foaming and priming, and is one of the topics to be investigated at some future time in the author's laboratory.

This concludes the more theoretical information that has come out during the last few years. Whatever the verdict of the future may be, the author is finding this theoretical matter a serviceable guide in his present work. For example, the theory of film formation furnishes an explanation for the strange results obtained in the investigation next to be described.

An Unusual Cause of Water in Steam

Through the courtesy of the Paige-Jones Company of Hammond, Indiana, the author has at his disposal a somewhat elaborate experimental boiler consisting of a horizontal drum 4 in. in diameter and 5 ft. 6 in. long, into the ends of which is connected a water tube. Both of these connections are close to the lower side of the drum. A year ago the Engineering Experiment Station of The Ohio State University furnished funds for hiring an experienced chemist to help in the work on the problem of foaming and priming. It was first proposed to repeat the experiments of Joseph and Hancock (9) and later of Hancock (10), who it will be recalled, operated an experimental steel boiler working at pressures up to 150 lb. and found that the solid matter which they used had no effect on the amount of water thrown into the steam. The outcome of these experiments is so contrary to general opinion that it seemed desirable to repeat them with a different type of boiler. The boiler which Joseph and Hancock used, by the way, was a simple drum lying on its side and heated along the bottom with a gas flame.

In order to furnish an appropriate background for the proposed experiments with suspended solids the water-tube boiler was first operated a number of times with distilled water and then with solutions of various salts at different concentrations, but with no solid matter present. The results of these preliminary experiments were more astonishing by far than the findings of Joseph and Hancock, because it was found that the throwing of water into the steam decreased regularly as the concentration of salt in the water increased. This was such an amazing situation that its study was pursued instead of investigating the effect of solid matter as first proposed.

In brief a large number of experiments were performed with solutions of sodium chloride, sodium sulphate, sodium carbonate, and sodium hydroxide. The amount of water thrown into the steam was measured by the chemical method, allowance being made in all cases for the progressive concentration in the boiler. The experiments showed, first that the level of water in the drum had perhaps the greatest effect, and in the sense that the lower this was the less water, other things being equal, appeared in the steam. Secondly, other things being equal, there was considerable difference among the salts. Sodium sulphate and sodium carbonate and hydroxide gave less water in the steam than the chloride. This, it will be observed, is also contrary to popular belief and other experimental evidence. Scores of experiments were made so that there is no doubt about the observations. The author is compelled to say that at the time he had no idea as to why such peculiar results were obtained. It was necessary, however, to find an explanation and accordingly a pyrex glass boiler was constructed of precisely the same design and almost the same size as the steel one. This glass boiler was operated a number of times at pressures of 12 or 13 lb., but since it had been shown in the work with the steel boiler that the same effects were produced at atmospheric pressure as at higher pressure the glass boiler was operated at atmospheric pressure. It was at once seen why the peculiar phenomenon described above took place. Waves were propogated along the length of the drum and the bulk of the water appearing in the steam was due to the crests of these waves hitting the steam outlet which was on the top of the drum about two-thirds of the length of the drum from the end at which the steam entered from the water tube. These waves were highest in the case of distilled water and dilute salt solutions. As the concentration of the salts increased, the waves flattened out and not so many crests hit the steam outlet. This then was a simple physical explanation of the anomalous results. There remained, however, the problem of why the dissolved salt had this peculiar effect on the height of the waves. Observation of the glass boiler in operation seemed to show that the steam bubbles in the case of the distilled water and dilute solutions were very much larger than in the cases of the more concentrated salt solutions. The words "seemed to show" are used advisedly because the rate at which the steam bubbles moved through the tube was so high that visual observation was not conclusive, particularly in the case of the more concentrated salt solutions.

The theory of film formation outlined calls for small steam bubbles in salt solution because the bubbles do not merge together to form larger ones as would be the case with distilled water. It was evident that if such a difference in bubble size could be proved the higher waves in the distilled water are then simply explained by the greater surges or pulsations set up by the larger bubbles issuing from the water tube. Instantaneous photographs of the tube would, of course, answer the question and consequently such were taken. Exposures of about 0.002 sec. were necessary to catch the individual bubbles. The outcome was conclusive. The steam bubbles were very much smaller in the salt solutions and consequently they set up smaller waves along the length of the drum when they emerged from the water tube.

The author wishes to point out that in this obscure case of foaming and priming, the theory of film formation suggested the explanation which was then proved to be correct by the instantaneous photographs.

It may possibly be said that the state of affairs observed was so unusual that it could never occur in a commercial installation. This, however, is probably not true because two practical engineers, who heard the paper presented at the Indianapolis meeting of the American Chemical Society (1930), told the author of experiences of a similar character, namely, of boilers that tolerated an enormous concentration of dissolved matter in the water.

The author also wishes to make another observation. Suppose that this series of experiments had been made by one with no particular background of knowledge and experience in the peculiar behavior of boiler water. Such a hypothetical investigator would probably have generalized on the basis of the data obtained with the steel boiler, and would have reported that the generally held opinion that foaming and priming is promoted by increased concentration of salts in the water is all wrong, because he had experimented and found the contrary to be true. It merely shows once more the enormous complexity of the problem. Indeed, it is doubtful if any complete generalization may be made. What actually happens is perhaps in all cases a certain combination of the physico-chemical properties of the water modified by the design of the boiler and the manner in which the boiler is operated.

These results will soon be offered for publication together with diagrams of the apparatus employed and reproductions of the photographs.

Effect of Suspended Solids

The effect of suspended solids in the boiler has received new attention since the publications of Joseph and Hancock (9 and 10). The author has also made a beginning on this problem. It will be recalled that his first paper in 1924 (11) recorded many experiments on the boiling of salt solutions, with and without solid matter, in glass vessels in the laboratory. Six widely different kinds of solids were used and since they all stabilized the foams of the boiling salt solutions it was natural to infer that all kinds of solids would have the same effect. The author now knows that such a generalization is too broad, and in a paper presented at the Indianapolis Meeting (1930) of the American Chemical Society new data and points of view were advanced. The essential points of this investigation are as follows: Boiling experiments were carried out in glass vessels, and also determinations were made of the surface viscosity and surface tension of cold solutions on the surface of which finely divided solid matter was floated. These latter experiments with surface viscosity and surface tension were made largely to satisfy scientific curiosity, because it seemed desirable to leave no stone unturned in the pursuit of the problem. All that need be said here about the outcome is that the results were in harmony with existing theories. One simple experiment, however, is worth mentioning. By the use of a special technic, the surface of water or of salt solutions could be kept covered by a layer of floating solid particles, and it was found that under these conditions bubbles a centimeter or more in diameter could be formed on the surface and lifted out on paper. The paper would, of course, absorb the excess of liquid and if the bubbles were then protected under a bell jar until all the liquid had evaporated, the solid particles were left behind like a vaulted ceiling of fairy workmanship. This bit of laboratory by-play showed that under favorable conditions the stabilization of a bubble film by solid matter is 100 per cent.

Two apparently new pieces of information were developed by the boiling experiments. First, it was clearly shown that different kinds of solid matter exhibit greatly different effects in stabilizing the foams of boiling salt solutions. Finely ground flint, for example, had absolutely no stabilizing effect, that is, the specimen of flint used did not. It is a reasonable hypothesis to assume that stabilization by solid matter is proportional to the tendency of the solids to float on the surface, and that the flotability is in turn inversely proportional to the tendency of the solid to be wet by the solution. Ground flint for example is instantly wet by the solutions used and instantly sinks. It had no effect on the foaming.

Experimental data from the art of ore flotation suggested the probability that absorbed oil in boiler scale is the cause of its high stabilizing effect. Experiments were, therefore, made by extracting with ether and benzene the oil from a specimen of boiler scale which in its original form greatly increased the foaming of a boiling salt solution. The extracted scale was found to have lost nearly all of its foam-stabilizing properties. Other experiments were made by strongly igniting an oil-bearing scale in order to destroy the oil and then after shaking it with water to extract the soluble mineral matter produced by the ignition, it was found that the residue had very little effect in stabilizing foams.

Experiments were also made with specimens of dolomite, limestone, and boiler scale, all of which were very efficient in increasing foaming, in order to see what effect prolonged boiling at atmospheric pressure would have. The following interesting results were obtained. The dolomite lost its foam-stabilizing properties on about 3 hr. boiling, the limestone after about 10 hr. boiling, and boiler scale after about 11 hr. After these boiling solutions had ceased to foam the boiling was stopped and the liquid filtered. In all cases fresh solid matter added to the salt solution which had been used in the experiment produced the usual amount of foam thus showing that the part of the foaminess which was due to the solution had not been affected. On the other hand, when the filtered off solid matter, which had been washed several times, was added to a fresh salt solution no foaming was produced, thus showing conclusively that the solid matter had lost its foam-stabilizing properties.

The author has the following suggestions to make about this experiment. If a given type of solid matter loses its foam-stabilizing power in 10 hr. boiling at atmospheric pressure, it will probably lose it much faster in the same solution boiling at the temperature of a high-pressure boiler. At any rate it is a good working hypothesis to assume that in some cases at least the suspended solids in a boiler water may at first have some stabilizing power, but will lose this property after some time in the boiling water. The rates at which different kinds of solid matter lose their foam-stabilizing powers will in all likelihood differ greatly. Let it be supposed then that in a given boiler a given type of solid matter is losing its foam-stabilizing property about as fast as it is being formed in the water. In such a case the solid will have little or no effect on the foaming. Another boiler using the same water may be operated at a lower pressure and consequently at a lower temperature with the result that the solid matter precipitated out of the water will not lose its stabilizing effects so fast and therefore will promote foaming. These are merely suggestions or working hypotheses that may in some cases lead to the explanation of an obscure case of wet steam.

Still another hypothetical situation might be suggested. Two boilers of identical design and using the same water are found to behave very differently. One foams over badly and must be blown down frequently while the other one tolerates a high concentration of both solids and dissolved matter. It might happen that one boiler is operating a reciprocating engine with a line for returning condensed steam. The scale or sludge in this boiler will then contain adsorbed oil making it more flotable, and giving it a high foam-stabilizing power, thus producing heavy foaming and priming. The other boiler of this hypothetical pair has no return line to carry in oil and consequently the water in it will not foam up as in the other case.

The above are purely hypothetical cases. The author cites them as part of an argument in favor of experimentation in glass vessels in the laboratory. Scores of such experiments can be made in a few days and the results stimulate the scientific imagination of the investigator engaged on a commercial problem, so that he will think of things that otherwise might not occur to him.

Effect of Solid Matter at Higher Pressures

The author's experiments referred to were all made at atmospheric pressure. There is also a growing list of papers on the effect of solids in experimental and commercial boilers operating at 150 lb. pressure or higher. Hancock (10) repeated some of the work of Joseph and Hancock and found again that finely divided solid matter had no effect on the moisture in the steam. Hancock generalizes as follows from these experiments: "It has been confirmed that at normal pressures (160 lb.) suspended solids have no influence on priming." This of course means only that no effect was obtained with the particular solids used and under the particular conditions employed. It is useless, however, to speculate about what might be the cause. The thing to do is to experiment under different conditions and in all cases seek to harmonize the experimental results with existing theory.

Other references on the effect of suspended solids in promoting foaming are as follows:

Chr. Eberle (12) states that in his experiments solid matter had a very marked effect in increasing foaming. His work was done in an experimental boiler operated at pressures as high as 150 lb.

The Water Service Committee of the American Railway Engineers Association, in its report for 1929 (13), gives data on the behavior of certain commercial boilers which show that solids greatly increased the water in the steam.

The preponderance of evidence is on the side of the opinion that suspended solids in the boiler water increases the moisture in the steam. In view, however, of the work of Joseph and Hancock and some of the work of the author, it is likely that there are exceptions. The author is willing, however, to go on record as saying that finely divided solids are still on trial for causing thousands of cases of wet steam, even if it can be proved in a few instances that the accused, though present, was not guilty.

Effect of Alkalinity

In 1927-1928 Mumford (14) made an extensive series of experiments at the Kip's Bay Station of the New York Steam Corporation and came to the conclusion that the hydroxyl-ion concentration played the chief role in the production of wet steam. He found a value for this concentration above which the production of dry steam was exceedingly difficult. For the boilers in question Mumford places this critical value at 220 to 250 p.p.m. The effect of this critical value of hyroxyl "was the same in boilers just filled with raw water as it was in boilers which had been on the line for weeks so that the effect of hydroxyl must have been independent of the concentration of suspended matter which must have varied under the above conditions." Finally it is pointed out that the particular critical hydroxyl-ion concentration in a given case is a function of the boiler design. The author naturally observed the following passage: "It may be said at this point, to forestall possible criticism, that several hundred concentrations of the raw water showed no organic matter when made acid and subjected to ether extraction, so that saponification is not the obvious reason for the action of hydroxyl in this case." Mr. Mumford adds that the findings make "a good question to lay at the door of the laboratory specialists in these subjects." The author takes this to heart, but is compelled to say that he has not yet had time to look into the parentage of this foundling on his door-step. That too will make a topic for future study if some other laboratory worker does not first adopt the child.

Mumford's article is outstanding in that it contains a wealth of engineering detail, which makes it especially interesting to chemists.

Effect of Organic Matter

No one seems to question the opinion that organic matter is often a cause of wet steam and recently there have been some investigations bearing directly on this point. Hancock (10) reports experiments in which he removed the organic matter from a surface supply (River Nile) and then restored the other constituents. The original water foamed badly, but after removal of the organic matter the foaming ceased. In connection with these studies Hancock makes the statement, "It is important that the organic matter be in solution." Many chemists believe that organic matter in colloidal suspension also causes foam.

Behrman (15) reports the case of a water that foamed badly on account of organic matter. This was proved by removing the organic material and then restoring the original alkalinity of the water. The foaminess was enormously decreased.

Smoothness of Boiling

Hall (16) in a paper entitled "Present Tendency of Boiler-Water Conditioning," states that calcium has a marked influence on smoothness of boiling, but gives no data. The following quotation indicates his point of view: "The fact must be recognized that a fully conditioned water does not boil as smoothly as one not conditioned; absence of calcium in the former is the cause." In other words, calcium promotes smoothness of boiling. The author has no other information on this point and can offer no theoretical explanation.

Some attention should be given to this problem of "smoothness of boiling." At present there are no available data; indeed there is not even a definition, so that few know just what the expression means. To the author the term means literally boiling smoothly, that is, uniformly and without bumping. Smoothness of boiling may and sometimes does accompany foaming. There has been some dabbling with the problem in the author's laboratory, but nothing definite is ready for publication. It might be added as a final note that solid matter frequently promotes smooth boiling.

Boiler Water Circulation

The author professes no knowledge of boiler-water circulation, that is, the rate and direction of the flow of steam with respect to the water. One of the experiences cited "An Unusual Cause of Water in Steam" suggests, however, that such circulation may have a pronounced influence on the production of wet steam Eberle (12) gives some interesting data obtained with one of his experimental boilers operated at atmospheric pressure, which show that the water in the steam increased with the depth of water in the drum through which the steam bubbles generated in the water tube were compelled to pass.

Conclusion

The author is impressed with the rapidly increasing interest in the subject of wet steam. During the last four or five years there have been as many experimental investigations bearing on the phenomenon as were made in the preceding 15 or 20 years. These investigations have increased the list of known specific conditions that affect the degree of moisture in steam and will consequently help in the solution of such problems in commercial installations. During the last few years there has also been advanced a theory of liquid film formation that is proving a helpful guide in researches on foaming. Those then who are interested in the foaming and priming of boiler water, whether for economic or scientific reasons, may feel that the curve of progress toward a better understanding of the subject is rising rapidly.

The author is more and more impressed with the complexity of the subject. The structural details of the boiler, the distance of the water from the steam outlet, and the physico-chemical properties of the water appear to be the controlling conditions. These factors do not, however, function independently, but rather in varying relations to each other. Indeed, these relations are such that in the experimental boiler used in the investigation entitled "An Unusual Cause of Water in Steam" it was shown that distilled water gave by far the wettest steam. Ordinarily the opposite would be true.

It is a pleasure to announce that the author's studies have been aided by a grant from the Boiler Feedwater Studies Committee. It is proposed to experiment with the effect of suspended solids of various kinds in experimental boilers of different design, operated at pressures of 150 lb.

Finally, the author asks the indulgence of his readers if any papers have been omitted. Necessity compelled the preparation of this review in a hurry, and hurry brings certain faults in its train. One paper by Müller (17) in 1927 was omitted because time did not permit access to it. It is entitled "The Present Status of the Question of Foaming and Priming of Steam Boilers."

Discussion

J. A. Holmes.[3] The theories and ideas advanced by Professor Foulk, in this and in previous meetings, have been the basis for many of our company's research problems on carryover and foaming.

In order to verify and elaborate on some of these suggestions, we recently constructed a small boiler with a capacity of 1 gal. of water and that could be operated at pressures up to 1000 lb., with sight glasses so that boiling characteristics could be observed. The rate of evaporation could be carried as high as 500 per cent.

More than 90 runs have been made in this boiler, using almost as many different types of treatment. Much information has been gained therefrom, but this discussion will simply point out a few of the results that are applicable to the points mentioned in the paper.

The physico-chemical theory of foam advanced by Professor Foulk has been adopted as a fact (since it has not been disproved), and research work has proceeded along this line. Since there are considerable data on the effect of pure chemical substances on the formation of foam, this work has been passed up, and only natural waters have been experimented with.

The dynamic foam meter has been used, and it is surprising how closely the measurement of the degree of foaming in this tube corresponds with plant experience. We have not only been able to measure the degree of foam, but in some cases have been able to measure the "explosiveness" or violence of bubble breaking.

Very little work has been done on anti-foam, except on the effect of suspended solids on carryover. This will be mentioned later.

Professor Foulk mentions the projection of droplets by bursting bubbles which would cause an increase in moisture in the steam. We have noticed one phenomenon allied to this. When operating our experimental boiler, as the pressure was increased to 450 lb. we could not see through the water, but could see through the steam by placing a light back of the sight glasses. Above 450 lb. there was a gradual clearing up of the water and a darkening of the steam, so that at 600 lb. pressure or above we could see through the water easily but could not see through the steam, which had a very black appearance. Until reading the paper we were at a loss to account for this change. However, we did notice that at the lower pressures there were a large number of steam bubbles in the water and that at 250 lb. pressure a foam was formed averaging $1^1/_2$ in. thick. As the pressure was increased, the number of steam bubbles passing through the water decreased, until above 600 lb. pressure there were practically none, and the water seemingly was boiling only at the surface, the thickness of the foam decreasing to less than $^1/_2$ in. The disappearance of the bubbles would allow us to look through the water and accounts for its being clear. Possibly the reduction of the thickness of the film of foam on the water, thereby eliminating a cushioning effect, and the boiling at the surface projected the small droplets mentioned in the paper and formed a sort of mist in the steam area, thereby causing it to appear dark. Condensed steam during this operation showed no carryover by chemical tests. Conductivity tests of the condensed steam were not made at that time.

The condition of varying bubble size described in Professor Foulk's experimental glass boiler has also been observed in ours and also in the dynamic foam meter. Also we have noted that different types of suspended solids can cause the same phenomena. This point should, we believe, be investigated further. Not only does the breaking of bubbles play an important part in the prevention of foam, but also possibly the formation of the bubbles may have some effect, although we are inclined to believe that there is less variation of bubble size at pressures encountered in boiler-plant operation.

Most of our work has pertained to the effect of suspended solids on carryover. Our experimental boiler was operated with various types of water and treatment, at a definite rating of 300 per cent and at 250 lb. pressure. Operation would continue until chemical tests of the condensed steam showed definite evidence of carryover due to foam. Most of the work was done on Chicago tap water, which varies but little in composition. In order to determine the effect of suspended solids on carryover, a series of runs were made using various chemicals commonly used in water treatment. The same amount of alkalinity was carried in the feedwater in each treatment, so that the alkalinity, chlorides, and sulphates of the boiler water would increase at the same ratio with each other and with the total dissolved solids. The major changes would be in the sludge—whether it was predominantly carbonate, phosphate, or aluminate. These runs showed that straight soda ash as internal treatment was the worst offender. Sodium bicarbonate was little better. As a comparison the concentration of dissolved solids at carryover with soda ash was considered as 100. Treatment with sodium bicarbonate showed carryover at 110, sodium diphosphate (no soluble excess) at 140, a combination of sodium aluminate and sodium phosphate 160, a combination of sodium bicarbonate and aluminate 195, a 15 per cent solution of sodium aluminate plus 20 per cent of caustic soda 205, and straight sodium aluminate with no excess caustic 275.

If the runs on the Chicago water, approximately 25, are plotted in the order of their increasing concentration, the percentage of alumina in the sludge, which varies from 0.5 per cent to 10 per cent, will rise in proportion to the dissolved-solids curve. The percentage of alumina in the sludge is a measure of floc formation which tends to absorb the more finely divided precipitates of carbonates and phosphates. These series of runs would tend to prove that the nature of the suspended solids had considerable to do with the point at which carryover resulted. A further experiment was made by using a water containing 3.5 grains of hardness and treating with disodium phosphate alone in sufficient quantities to carry an excess. Carryover resulted at 150 grains per gallon soluble solids. In a second run the water was treated with disodium phosphate and sodium aluminate, carryover resulting at 245 grains per gallon. A third treatment, a combination of sodium diphosphate, sodium aluminate, and magnesium sulphate, gave carryover at 355 grains per gallon or 225 per cent of the straight disodium phosphate treatment. Alkalinities, etc. were kept practically the same. Treatment with phosphates alone showed no coagulation, and the water was very difficult to filter clear. The treatment with phosphates and aluminate showed very little coagulation, but the water could be filtered fairly easily, whereas the treatment with phosphates, aluminate, and magnesium sulphate showed visible good floc formation and was very easily filtered. Here again only the nature of the suspended solids were changed, but a radical increase in the concentration that could be carried was noted.

Another experiment was made to verify the effect of aging of the sludge by continued boiling. This was done by operating the boiler to carryover and blowing down a sample for analysis. Operation was continued, keeping just below a concentration to give noticeable carryover in the condensed steam. In some cases by this aging process or nursing of the boiler we could increase the concentration at which carryover would result as much as 75 per cent. Professor Foulk mentioned the effect of continued boiling at atmospheric pressure, and our experiments would tend to indicate that such might be the case under pressure. However, in actual plant practice there must be a continuous supply of feedwater added to the boiler, which of course will be creating new suspended solids which have not been aged.

---

[3] National Aluminate Corporation, Chicago, Ill.

One experiment on the effect of alkalinity on carryover was made. Lake Michigan water was softened with lime and soda ash to 2.0 grains hardness with practically no excess alkalinity. Carryover resulted at 200 grains per gallon. Another run was made by softening the water to 0.5 grains per gallon, and a high excess of alkalinity was carried. Carryover then resulted at 275 grains, or an increase of 35 per cent. The alkalinity in the latter case or with the higher concentration was 390 per cent of the former. Therefore higher concentrations were carried with the high alkalinity and low hardness than with the high hardness and low alkalinity in the treated water. This would tend to indicate that the suspended solids were the prime cause for carryover and that alkalinity in this case effected foaming only as it contributed to the total amount of dissolved solids present.

It is also noted that in the runs on Chicago water the alkalinity increased in direct proportion to the dissolved solids, so that the higher the concentration at carryover the higher the alkalinity. If alkalinity was the prime cause of foaming, then the runs showing the highest concentration should have the lowest alkalinity, but the reverse was the case.

In conclusion, research work in regard to foaming in boilers should, as Professor Foulk states, be done with a clear understanding of boiler operation and conditions. Wet steam is not always caused by the formation of a definite foam, and consequently any work done along this line should definitely state and produce proper data to show conclusively whether foam is formed and what is its degree of stability, and all the conditions and analyses noted should accompany the experiments. Also experiments should be made in vessels so equipped that boiling, etc. can be observed and so that the tests will duplicate to some degree actual plant practice.

A. R. Mumford.[4] In offering discussion of the paper, the writer feels that it is better to submit additional data on the ways the quantity of moisture in steam has been reduced at the plants of the New York Steam Corporation than to offer imaginative descriptions of what might be taking place in commercial boilers to compare with what has been seen in the laboratory.

As operators of boilers we may set down three factors which we have found will influence the quantity of moisture in the steam:

1 The level of water indicated by the gage glass has a definite, although not a fixed, relation to the water level in the steaming drums, and all know that if the indication of the gage glass is too high we will have wet steam.

Boiler No. 5 at Kips Bay Station was thoroughly tested to determine the relation of water level to steam quality. The results of the tests are shown in Fig. 1, on which the temperatures indicated by each of four calorimeters are plotted against the average level indicated by the four gage glasses. One calorimeter was installed in a vertical run on each of the four steam outlets from the dry drun, and each of the two 60-in.-diameter steaming drums had a gage glass at each drum head. An examination of Fig. 1 and of Table 1 shows that as the average water level was decreased the temperatures indicated by the calorimeters rose until we were able to say that an indicated average water level of 2 in. would correpond to the calorimeter temperature which ought to result from dry steam. The operation of a boiler with only 2 in. of water showing in the glasses would require so much man power that it was impractical, and the water columns and gage glasses were lowered by providing lower connections. The check tests made after the columns were lowered are plotted as large open circles on the curves of Fig. 1. The ratings of the boiler varied about 15 per cent between some of the tests, the results of which are plotted in Fig. 1, but the data indicate that this variation did not influence the results.

TABLE 1 VARIATION OF CALORIMETER TEMPERATURES WITH AVERAGE WATER LEVELS

Test	Calorimeter temperature deg. fahr. East	E. center	W. center	West	Water level, in.	Conc. Cl, p.p.m.	Conc. OH, p.p.m.	Conc. sludge, p.p.m.	Rating 1000 lb. per hr.

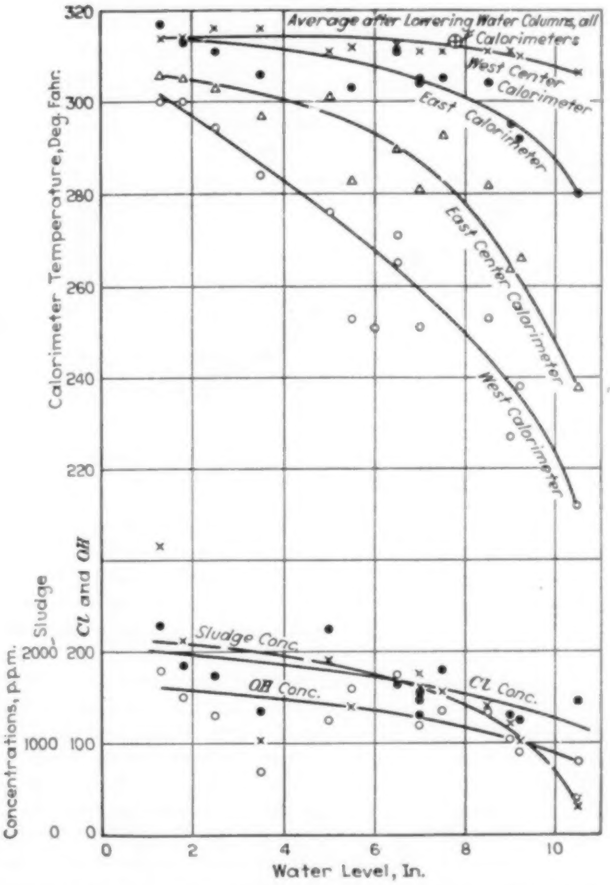

Fig. 1 Variation of Calorimeter Temperatures With Average Water Level

The new location of the water column brought forward an interesting problem in densities. An average level of 2 in. in the gage glasses at the old location would provide a safety factor in that the level in the drum would be sufficiently high to submerge all tubes if the fluid inside the drum were dense water. However, we all know that because the steam is formed beneath the water level the density of the fluid in the drum is less than that of dense water, and therefore the level in the drum will always be higher than that in the glass in a steaming boiler. In lowering the water columns it is necessary to know the average density in the drum in order to compute what level in the glass at the new

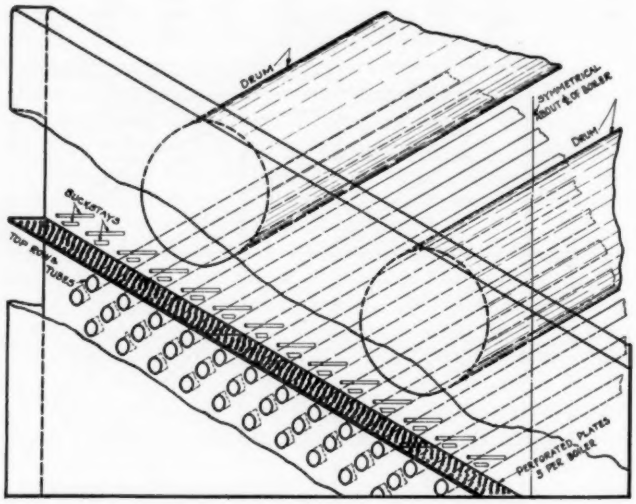

FIG. 2 INSTALLATION OF PERFORATED BAFFLE
(Water leg and horizontal water-tube boiler.)

location will correspond with a given level in the glass at the old location. No information was readily available on this point, so attempts were made to determine the density by studying the rate of concentrating the Cl ion. These tests indicated densities of from 10 to 50 per cent that of dense water and were suspended when the results began to cause loss of sleep.

At another station we found that the upper tubes in a horizontal water-tube boiler were sagging during a period of perhaps five years, probably due to lack of water. After comparing the circulation in this boiler with others of similar type on which the circulation had been studied, it was decided that the mixture of water and steam rising through the front water leg ought to be restricted so that some of the water would be deflected through the upper tubes to the rear water leg, while the steam with some water could pass on upward to the drums. For this purpose a perforated plate was installed in the front water leg at a point above that at which the upper tubes entered the tube sheet.

The presence of water in the upper tubes was determined qualitatively by inserting a sampling tube into several of the upper boiler tubes through a specially made cap. The character of the discharge from a throttling valve on the outer end of the sampling tube indicated qualitatively the amount of water in the tube.

The perforated baffle had little or no effect upon the amount of water in the upper tubes, but it did make it possible to operate the boiler at a high enough water level to increase materially the density of the fluid in the upper tubes and yet have no more moisture in the steam than at the low level without the perforated baffle. The data summarizing this investigation are given in Table 2, and a sketch of the installation is shown in Fig. 2.

In the foregoing the mechanical action of a perforated plate in the circulation was to reduce the effect of high water level on moisture in the steam so that full protection could be afforded to tubes which otherwise might have sagged over long periods due to the cumulative effect of occasional repeated overheating.

2 The second factor is the rate at which steam is generated in the boiler. Without any provision for the elimination of moisture in the steam, installed in the circulation or the steam path, we find that as the rating is increased a point is reached where moisture appears in the steam, and on further rating increase the amount of moisture increases as an approximate linear function of the rating. This condition is indicated by the curve in Fig. 3. This condition may be corrected by lowering the water level progressively with increase in rating, by installing moisture removing equipment, or by the installation of a mechanical means for rupturing the steam bubble films so that the bubbles may coalesce into larger ones from which the water may be more readily separated by gravity. We have found that the perforated baffle is incomparably more preferable to other means as reported herewith and as reported in the writer's paper quoted by Professor Foulk.

TABLE 3 CONCENTRATION AND TREATMENT FIGURES, NOVEMBER, 1931

1	Chemical added:	
	(*a*) To feedwater...........	NaOH, 11 lb. per million
	(*b*) To boiler water.........	Na_2HPO_4 and NaH_2PO_4 (10–1) To give pH value of 7.5 in 1% solution, 34 lb. per million) Na_2SO_4, 14.5 lb. per million
2	Boiler-water concentrations:	
	(*a*) (OH)	78 p.p.m.
	(*b*) (PO$_4$)	124 p.p.m.

	(*b*) Total,	5.7%

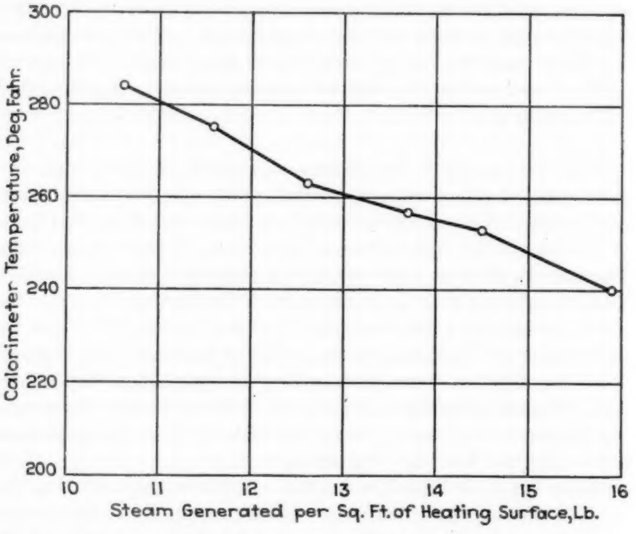

FIG. 3 CALORIMETER TEMPERATURE VARIATION WITH RATING
(No particular provision for moisture removal.)

The action of a perforated baffle is probably the mechanical rupturing of the bubble films, but this point can best be explained by Professor Foulk.

3 Within the limits of concentrations normally existing in our boilers we have not found any factor other than hydroxyl ion which specifically affects the quality of the steam. We know that there is a value of the concentration of hydroxyl ion, for those of our boilers which we have studied, above which the producton of dry steam is practically impossible, and we believe that a critical value of this concentration, which varies with the design, exists for all boilers. We understand that other investi-

gators have confirmed the existence of a critical value of the hydroxyl-ion concentration for their own boilers. Our efforts over the past three years have been directed to the adjustment and control of our feedwater treatment so that the normal building up of the hydroxyl-ion concentration would be offset by the neutralizing action of selected phosphate salts. We have not yet applied the maximum available neutralizing power, but all steps taken to date have been successful.

We find considerable variations in the sludge content of our boiler waters, and yet we find no noticeable variation in steam quality. Sludge or suspended matter may influence the permanence of steam bubble films, but in our boilers, if the sludge concentration is a factor, it is masked by other factors of more power.

We would like to call Professor Foulk's attention to the sampling error which influences reports from the power plants and which can be eliminated in the laboratory. In determining concentrations in boiler waters we select a sampling point which we have found by test to be fairly representative of average conditions, but we have not yet been able to find a sampling point which represents the average of several sampling points. The obvious conclusion is that uniform distribution of dissolved or suspended matter does not exist in our large boilers, and the corollary to that conclusion is that reported values of occasional samples cannot be depended upon for important conclusions.

In order that Professor Foulk may have figures representing what may be called normal concentrations, in Table 3 are given the average of daily tests of boiler waters at the Kip's Bay Station.

Summarizing the foregoing, we have indicated the relation of visible water level to quality of steam in one of our boilers. Whether the turbulence caused by the escape of steam from beneath the water level in the steam space when that space is restricted by too high a water level is the governing factor of this moisture relation or not is hidden from us by two inches of steel.

We have indicated that, as the rate of steam generation increases, the quality of steam decreases, unless a mechanical means for counteraction is provided. We believe that the perforated baffle is effective for this purpose, and we presume that its effectiveness is based on the rupture of bubble films.

We have not found as yet any other factor than hydroxyl-ion concentration which, under our conditions, will critically influence moisture, and we respectfully ask if Professor Foulk has ever met a foaming condition in an acid water.

Author's Closure

It is needless to say that the author is encouraged by the way that men in the commercial field are using his modest contributions to this subject of foaming and priming of boiler water. There are points in the discussions of both Mr. Holmes and Mr. Mumford which have suggested new laboratory experiments, and the author can assure these gentlemen that he probably got more out of their papers than they got out of his.

Mr. Mumford asks the specific question if the author has "ever met a foaming condition in an acid water." It can be said in answer, Not in a steam boiler, but then the author has had no experience with commercial boilers. In laboratory experiments in glass vessels acid solutions foam as readily as alkaline ones.

RP-54-6

Flow of Steam Through Square-Edged Orifices in a 4-In. Line

By W. W. FRYMOYER[1] and A. HERSCHEL,[2] FOXBORO, MASS.

W. W. Frymoyer

The flow of steam through square-edged orifices has little in the way of available data. Tests were therefore run to secure the necessary data on steam-flow measurement. The objects were to determine coefficients for steam flow through square-edged orifices under conditions favorable to securing basic coefficients; to determine effects of various types of disturbances, both upstream and downstream, on basic coefficients; to determine effects of straightening vanes with 0.5 pipe diameter from the upstream edge of the orifice plate on coefficients. The general statement of the results may be made that, for the disturbances covered in the report, and with the orifices installed with vanes $^1/_2$D from the upstream edge of the orifice plate, the actual coefficients will be near to 1 per cent of the 0.99 standard coefficient, for d/D ratios not over 0.75.

A. Herschel

THERE is little available in the way of accurate data on the flow of steam through square-edged orifices under the conditions met with in steam-flow measurements. Tests, therefore, were run to secure the necessary data for steam-flow measurement. Prof. J. J. Eames, in charge of the Steam and Hydraulic Laboratories of the Massachusetts Institute of Technology, made it possible for these tests to be run. The objects of the tests were as follows:

1. To determine coefficients for steam flow through square-edged orifices under conditions favorable to securing basic coefficients
2. To determine effects of various types of disturbances, both upstream and downstream, on basic coefficients
3. To determine effects of straightening vanes with 0.5 pipe diameter from the upstream edge of the orifice plate on coefficients.

It was soon found that tests near disturbances without straightening vanes produced serious and unpredictable results, so that these tests were confined almost entirely to conditions where straightening vanes were used. Furthermore, it is frequently necessary to install orifices where a large distance between the orifice and the upstream straightening vane cannot be maintained. All tests where disturbances were encountered were run with 0.5 pipe diameter between the vane and the upstream edge of orifice.

All work was done on flanges of the type shown in Fig. 1, as other comparative data applied to this type of flange.

It was originally planned to run tests covering the entire series of d/D ratios from 0.25 to 0.84. However, tests on the orifices under 1.6 in. in diameter (a d/D ratio of 0.420) gave wet steam on many of the flanges, so that they were omitted. On the 1.6 in. diameter, only high velocities were run to assure dry steam. On the larger orifice diameters only the lower velocities were run because of the limitation of the condenser capacities.

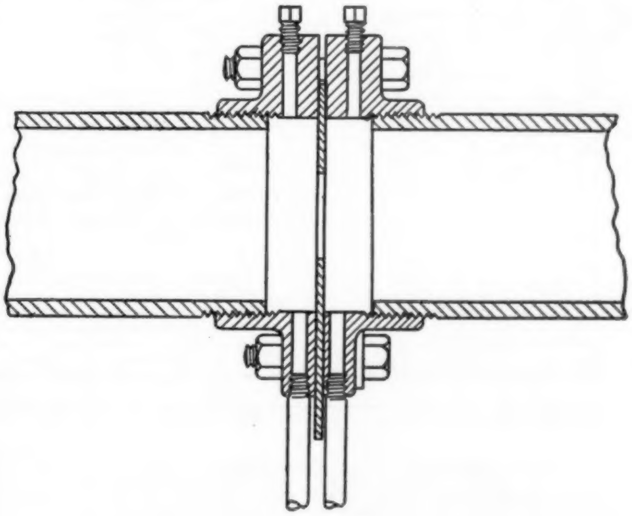

Fig. 1

In planning the program of tests it was decided to endeavor to maintain constant $(P_1 - P_2)P_2$ ratios for all pressures varying from 30 to 150 lb. per sq. in. At the lowest pressure only the largest $(P_1 - P_2)/P_2$ ratio (approximately 0.030) was run; at approximately double this pressure, $(P_1 - P_2)/P_2$ ratios of approximately 0.015 and 0.030 were run; while at four times the

lowest pressure, $(P_1 - P_2)/P_2$ ratios of 0.008, 0.015, and 0.030 were run.

EQUIPMENT USED IN THE TESTS

The 6-in. steam main, furnishing steam to the steam laboratory at 165 lb. and 100 deg. superheat, was available as a source of steam. One Alberger condenser of surface type with 1200 sq. ft. of condensing surface, with a Wheeler aftercooler, was available for condensing steam. Both condensers were carefully checked for tightness. All water trapped in the drip was collected in a long, slender pipe equipped with a gage glass and calibrated to give the measurement of water in pounds. The condensate was pumped to weighing tanks by a Worthington duplex pump.

The condensate was discharged into weighing tanks on Howe scales. The scales were checked for accuracy at the beginning of the test, once in middle of the test, and after completion of the tests. The discharge pipe had facilities for throwing the discharge from one weighing tank to another by simultaneous operating of two valves.

Control of flow was secured by pressure control at the entrance to the test piping and by a duplicate pressure control at the exit. The control was adjusted so that no surging occurred at any time. (See Fig. 2.)

Straightening vanes were made of $^3/_4$-in. tubing 4 in. long, welded into a tight unit. They were forced into the line, and a bead was turned up in front by means of a cape chisel to prevent movement during tests. They were inspected at regular intervals to determine whether any changes in position or appearance had occurred. (See Fig. 4.) All piping except orifice flanges were covered with 2 in. of 85 per cent magnesia. Condensers on meter lines were of the usual commercial standard fitted with the usual air vents, but with special gage glasses to show the water level. (See Fig. 3.)

Lines to the meters were a combination of steel and copper tubing. Both high- and low-pressure sides of each differential were tied adjacent to each other to insure temperatures as similar as possible. Differential gages were of inclined mercury type, calibrated while under actual conditions of liquid head by comparison with a water column. (See Fig. 5.)

Pressure gages were Foxboro standard steel-tube test gages, carefully calibrated at frequent intervals on a dead-weight tester. The thermometer wells were standard Foxboro thermometer wells, using a carefully checked mercury thermometer for measurement. The conditions under which the various orifices were tested are shown on the layout of the test line in Figs. 6 and 7.

Orifice No. 1 was preceded by a 16-in. straight pipe, a drip tee

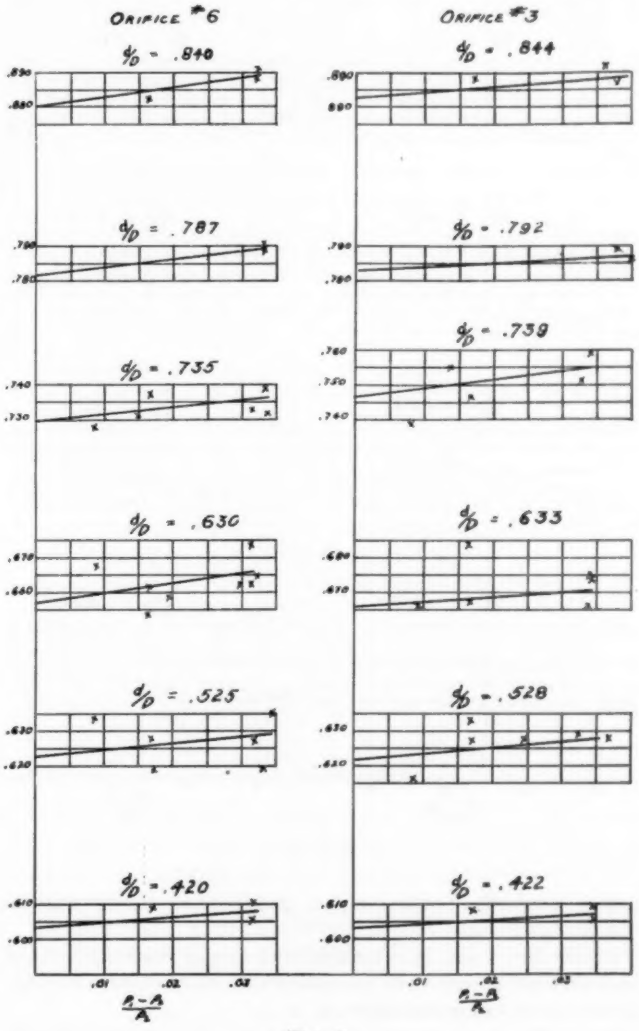

FIG. 9

into which the controlled valve of the pressure control discharged, and a gate valve open until the $1^1/_4$-in. valve in the bypass controlled the pressure. A straightening vane was installed 1.9 in. from the upstream face of the orifice plate. (See Fig. 6.)

Orifice No. 2 was preceded by a 16-in. straight pipe, a double-plane bend 21 in. on each leg, and another straight run of pipe. A straightening vane was also installed 1.9 in. from the upstream face of the orifice plate.

Orifice No. 3 was preceded by a 16-in. straight pipe and a single-plane return bend of about 25 in. radius. Following the orifice was a further 16-in. length, a drip tee going to the downstream controlled valve, and a gate valve. There was no straightening vane.

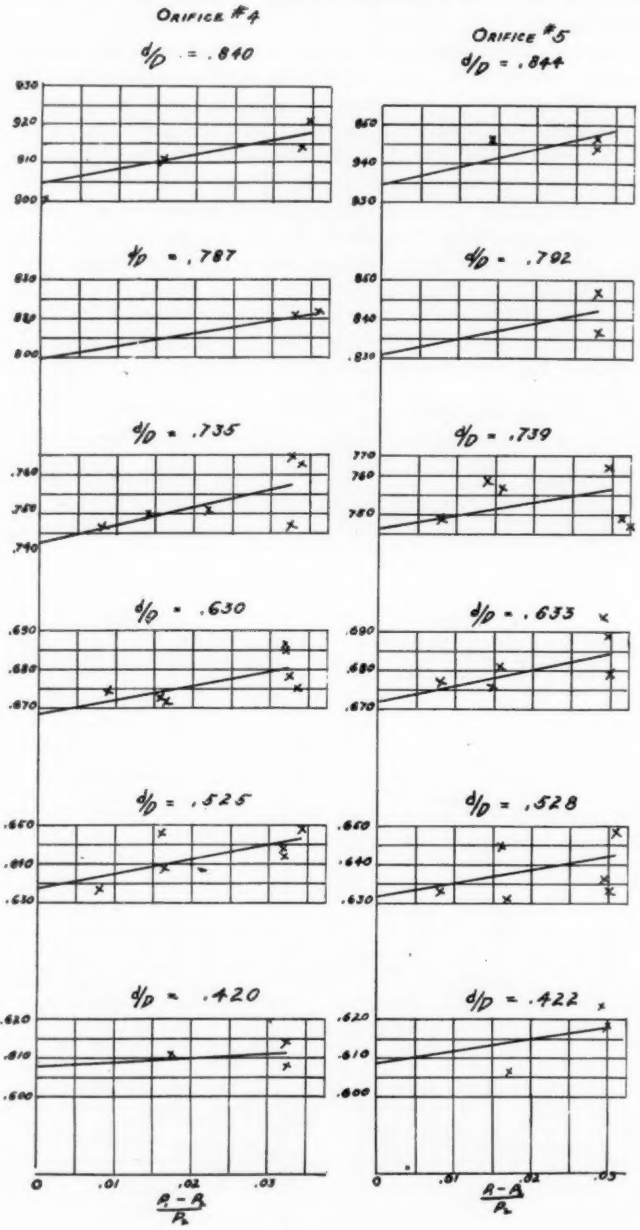

FIG. 10

Orifice No. 4 was in a straight run of pipe with $22^1/_2$ ft. of unobstructed straight run preceding and 11 ft. 6 in. following. There was no straightening vane.

Orifice No. 5 also was in a straight run of pipe with $22^1/_2$ ft. of unobstructed straight run preceding and 10 ft. 6 in. following. A straightening vane was installed 20 ft. ahead of this orifice.

Orifice No. 6 was preceded by a bend with 3 ft. radius and a 16-in. straight run. A straightening vane was installed 1.9 in. above the upstream face of the orifice plate.

METHOD OF RUNNING THE TESTS

In running these tests the gate valves at both ends of the piping were opened until something slightly less than the required quantity was passing. Further regulation was then secured by means of the pressure controllers. Steam was allowed to flow in the test line until for 30 min. no appreciable change in the temperature occurred. Then a minimum of 30 min. run was made on each type of set-up. At 10-min. intervals the condensate was checked to determine whether there had been any more than 0.5 per cent change in the weight flowing during any 10-min. interval. Where discrepancies larger than this occurred, further runs were made.

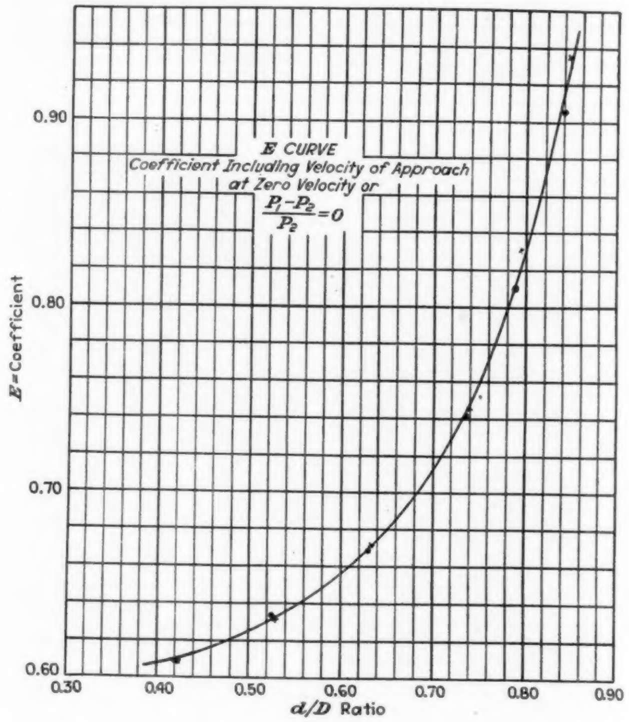

FIG. 11

The differential gages and the pressure gages were read at 2-min. intervals by two observers. The convenience in the arrangement of the gages and the arrangement of the scales to eliminate parallax enabled accurate readings to be made quickly. Owing to the use of pressure controls, the readings remained practically constant throughout any one run. Before each run, pains were taken to eliminate all air from connecting piping. A third observer made the readings of the thermometers while a fourth observer took care of the condensate tanks. The quantities were timed by the individual in charge who gave the signals for all observers.

MEASUREMENT OF ORIFICE PLATES

All orifice plates were checked by three observers with inside micrometers. The temperatures at which these observations were made were noted. Inasmuch as the greatest discrepancy between the averages of the three individual readings did not exceed 0.0003 in., and since the average of all readings in every plate was within 0.0001 in. of the nominal orifice sizes, comparisons between the various coefficients were greatly facilitated. The pipe used in the tests was carefully selected for uniformity of inside diameters and concentricity. The average dimensions of each of the pipes preceding and following the individual orifices were used in calculating the d/D ratios.

Discussion of Results

Preliminary tests showed that the thermometer wells placed five diameters downstream from the orifice plates had little effect on the coefficients. However, these tests gave the temperature gradient throughout the pipe line which was subsequently used in determining the temperature for the individual orifices at five diameters downstream.

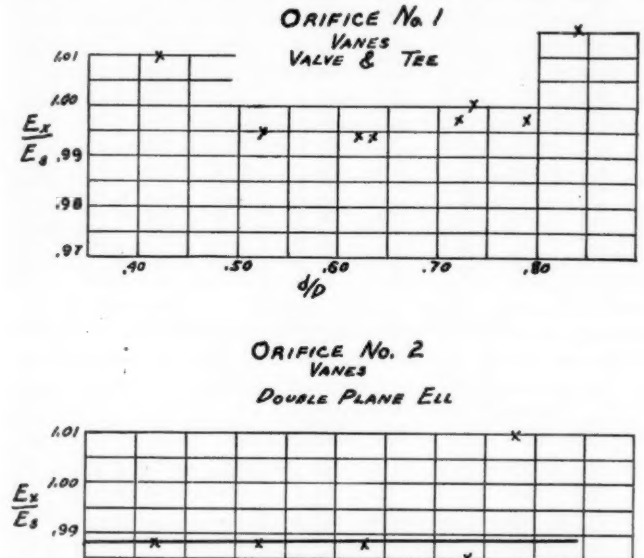

Fig. 12

Figs. 8, 9, and 10 show graphs of coefficients against $(P_1 - P_2)/P_2$ ratio. The lines are based on the average trend for the entire series of tests. Fig. 11 shows the E value based on plotting the coefficients of orifices 4 and 5 for zero velocity taken from Fig. 10. No effort was made to transfer these values into a graph of the coefficient of discharge, as the E graph gives information that the average user of orifices can conveniently use.

Fig. 12 shows the ratios of the coefficients of the various orifices under various types of disturbances as compared with the coefficient for the standard orifices 4 and 5. No attempt was made to plot a curve for this ratio for orifice 1, as two points at either end of the d/D ratio may have been produced by a large difference in the conditions existing when the two runs were made. For instance, during some tests the gate valves at either end of the piping were wide open; for others they were completely closed, with the entire flow being handled by the controlled valve in the bypasses. This analysis applies equally well to orifice No. 3. Furthermore, orifice No. 3 was installed without straightening vanes.

However, the general statement may be made that for the disturbances covered in this report, and with the orifices installed with vanes $^1/_2D$ from the upstream edge of the orifice plate, the actual coefficients will be within ± 1 per cent of the 0.99 standard coefficient, for d/D ratios not over 0.75.

Appendix

CALCULATIONS

The formula used in calculation of the E value was as follows:

$$E = \frac{W}{0.0997\, d^2 \sqrt{(h/v)}}$$

where

E = coefficient of discharge, including velocity of approach
W = weight of steam flowing in pounds per second
d = the diameter of the orifice in inches
v = the specific volume of the steam in cubic feet per pound
h = the differential in inches of water
E_s = the coefficient for standard conditions
E_x = the coefficient for any non-standard condition.

Inasmuch as the water in the legs of the differential gages was kept at nearly the same temperature, no corrections were made for differences in densities due to temperature. In the calculation of the coefficient, allowance was made for the effect of temperature on the dimension of the various orifice plates. No allowance was made for the 0.101-in. drain hole in the orifice plates. The density of steam was determined by using the values for v given in Keenan's Steam Tables.

It is desired to express appreciation for the interested cooperation, the many suggestions, and helpful criticisms of Prof. J. J. Eames and L. K. Spink, manager of Flow Meter Division, Foxboro Company, and for the assistance of H. D. Hibbard and A. B. Brand, students at Massachusetts Institute of Technology, and C. B. Ives, Research Department, Foxboro Company.

Discussion

George D. Conlee.[3] This paper is very interesting and the data obtained will prove of great value. The authors are to be congratulated on being able to condense so much information in a small space.

There is really very little known about the effect of various pipe fittings in front of an orifice or other differential medium. Various opinions are held by different engineers, but there is so

much divergence in opinion that they cannot all be right. In practice, it is customary to obtain all of the straight pipe possible in front of the primary element and hope for the best.

The data on the effect of bends are not conclusive, even in this paper. It is doubtful whether definite rules can be established that can be used to determine the correction to be applied under various disturbed conditions.

The data on straightening vanes are of much real value because of the indications that straightening vanes, immediately in front of a primary element, will affect the coefficient only slightly.

It has been generally believed that straightening vanes should be at least six diameters in front of an orifice, if accurate results were to be obtained. This opinion has made it necessary to place the straightening vanes in a flange some distance ahead of the one used for the measuring orifice and has often made it difficult to install vanes. The data obtained during these tests indicate that a straightening vane may be placed within one diameter of the measuring orifice without serious effect on the coefficient. This simplifies the problem greatly and will probably result in the use of many more straightening vanes in the future.

J. O. Feldmark.[4] The claim is made by the author that there is little of accurate data available on the flow of steam through square-edged orifices under the conditions met with in steam-flow measurement. From this statement the conclusion may be drawn that the object of their test was to secure the necessary reliable data which can be applied to the general measurement of steam flow under conditions actually met with in any industrial application.

However, such is not the case, as proved by the special type of flanges used for these tests. What was probably meant by the experimenters was to test only one particular application of steam-flow measurement. This becomes evident from the fact that no mention is made or consideration given to the "vena contracta" and "restoration taps," nor was any other form of flanges tested, such as commonly used in steam-flow measurement.

But such a conclusion can be reached only by men familiar with the various forms of flow metering. Hence, it is believed that, in order to avoid any possible misunderstanding, the paper ought to be corrected in such a way as to bring out clearly to the average reader that the results of these tests apply exclusively to the unique application shown in Fig. 1 and are not meant to cover the multitude of conditions met with in the wide field of steam measurements.

With this correction in mind, the present tests become valuable as a general contribution to that particular phase of metering and may serve as a base for comparison between coefficients used previously under identical conditions and those obtained by the present tests. However, for some reason nothing of this comparison is shown in this paper, so that it is impossible to determine whether the results differ from figures previously used under the same arrangement.

When one analyzes next the results of the other two intended objects, with regard to the effects of disturbances and straightening vanes on the basic coefficients, he finds the condition in such a shape that it is hard to reach the same conclusion that the experimenters did.

In the first place, there is very little given in the paper, either in the form of tables or curves, to show what happens when an orifice plate is installed near disturbances. Furthermore, no mention is made nor does the test diagram show of any disturbances on the downstream side, as intended according to the outline of object 2, while those on the upstream side are done away with quickly at the very beginning with a statement reading as follows: "It was soon found that tests near disturbances without straightening vanes produced serious and unpredictable results, so that these tests were confined almost entirely to conditions where straightening vanes were used."

Such a statement, important as it may be, is hardly what the metering industry would expect from experimenters. If serious and unpredictable results were obtained, why not show them, in order to demonstrate the disadvantage of such orifice locations or the beneficial effect of straightening vanes? Otherwise, an entirely different picture may be drawn, based on a comparison of the coefficients *E* gathered from the printed tables.

However, in order to facilitate any comparison between the results of the various orifice locations with and without straightening vanes, there is listed in Table 7 a condensation of the average coefficients *E* for each ratio, as given in Tables 1 to 6 in this paper. These are arranged in Table 7 in numerical order of orifice ratios.

Comparing, for instance, the results of orifices No. 3 and No. 6 to No. 4 orifice, located in a straight run of pipe, $22^1/_2$ ft. upstream and $11^1/_2$ ft. downstream, and taken as a standard, one finds that orifice No. 3, although located after a sharper bend than No. 6 and without a straightening vane, comes closer to the results of orifice No. 4 than orifice No. 6, located with a vane after a bend of a greater radius.

If one is to draw any conclusions from this comparison, he may be inclined to consider the presence of the straightening vane as detrimental or at least unnecessary. This certainly was not the object in the experimenters' minds.

In the same manner, one could attribute the differences between No. 4 and No. 5 orifice coefficients to the restriction created in the pipe area by the presence of a straightening vane. A rough calculation shows that close to 30 ${}^3/_4$-in. tubes are required to make up the vane. The walls of those tubes occupy an area of approximately 1 sq. in., which introduces an error of 0.7 per cent in the pipe area. Slight as this may be, the effect is nevertheless there and may explain why the coefficients are different in the two cases, although both are located in ideal straight lengths of pipe.

However, notwithstanding the few shortcomings mentioned, the authors deserve the thanks of the metering industry for their valuable contribution to the field of steam-flow measurement.

Optimum Conditions in Journal Bearings

By ALBERT KINGSBURY,[1] PHILADELPHIA, PA.

This paper presents in practical, serviceable form the most important results obtainable from the hydrodynamic theory of the oil film. The general theoretical treatment is supplemented by numerical evaluations whereby the conditions for the maximum load and for the minimum friction are determined for the ideal bearing; and these results are reduced to apply to practical cases by means of approximate methods. Tables and graphs are given, by means of which the loads, the losses by friction, and other characteristics of specified bearing forms may be determined, and special consideration is given to the optimum conditions for more or less arbitrary bearing proportions.

I—INTRODUCTORY

NO ABSOLUTE criterion of bearing safety has thus far been derived from practice, experiment, or theory. It is well known that bearings under laboratory conditions may be operated with speeds and loads far exceeding those applicable in practice; the latter remain, and probably must always remain, matters of judgment and experience. Nevertheless the mathematical theory offers valuable aid for attaining satisfactory results in practice.

Under running conditions, the minimum thickness of the oil film is the obvious feature determining safety. It does in some way fix the degree of safety, but it offers no possibility of establishing a definite "factor of safety," since danger of failure occurs only when contact of the metals occurs; and even then failure may be obviated by plasticity and good heat conductivity in the bearing metal. The most that can be said on this point is that the greater the minimum film thickness, the greater the safety. The film thickness is difficult to measure, even under laboratory conditions; but it is hoped that the present discussion may be of assistance in determining suitable practical values for this important quantity.

With a complete film and clean oil, there is no wear under running conditions; but when starting and stopping under load, there is inevitably more or less wear, depending upon the load, the area, and the properties of the oil, as well as upon surface conditions and upon the rates of acceleration. In many cases, bearings must serve as brakes for the ultimate stopping of rotating masses of great inertia. In general, reduction of wear is obtainable by increasing the viscosity or the area, or both; but either of these steps involves increased power loss when running. Here, again, there is no absolute criterion; the permissible loading must be based upon experience and judgment. It may, however, be said that the small wear occurring under the moderate journal loads of current practice does not in general cause increased friction or reduced safety under running conditions; it may have the contrary effects, as shown by the known beneficial effects of "running in" newly fitted bearings.

The present discussion is based primarily upon the minimum film thickness as a critical quantity, by whatever means its value appropriate to a given set of conditions may be determined; whether directly by physical conditions at the point of nearest approach of the metals when at speed, or indirectly by the limitations of loading imposed by starting and stopping conditions. No attempt is made to establish a law for the values of permissible film thicknesses. The general method of procedure in the research is as follows:

(*a*) Formal integration of the differential equations for pressure, load, and friction, in films between both plane surfaces and cylindrical surfaces, for the hypothetical condition of "infinite width" (or "no side leakage") and assuming uniform viscosity

(*b*) Determination of film forms giving respectively maximum load capacity and minimum coefficient of friction, for a given minimum film thickness, by means of trial numerical substitutions in the integral equations of (*a*)

(*c*) Approximate determination of the factors necessary for modifying the results of (*a*) and (*b*) to apply to bearings of finite widths; that is, covering the effects of "side leakage" and of varying viscosity

(*d*) Preparation of tables and graphs for convenient practical use, with special reference to the predetermination of optimum conditions, rather than the analysis of any arbitrarily chosen conditions.

The procedure thus outlined has been applied to three types of conditions of fit and of loading, as follows:

Class A Journal Bearings: Those in which the direction of the load and the clearance, that is, the difference of the radii of the journal and the bearing, are not arbitrarily conditioned, but are determined completely by the requirement of a maximum load or of a minimum coefficient of friction, for a given minimum thickness of the oil film, and for one direction only of rotation

Class B Journal Bearings: Those in which the clearance is assumed as zero, that is, journal and bearing of exactly the same radius, and the center of pressure is determined by the requirement of maximum load or of minimum coefficient of friction, for one direction of rotation and for a given minimum thickness of the oil film. This class also includes plane surfaces, considered as journal bearings of infinite radius and zero bearing angle, yet of finite arc length; but these are most readily treated as in Section II

---

[1] President, Kingsbury Machine Works, Inc. Mem. A.S.M.E. Mr. Kingsbury studied mechanical engineering at the Ohio State University and Cornell University, receiving the degree of M.E. from the latter institution in 1889. He was instructor in mechanical engineering and physics at New Hampshire College during the following year, after which he became mechanical engineer for the H. B. Camp Co., Cuyahoga Falls, Ohio. In 1891 he returned to New Hampshire College as professor of mechanical engineering, remaining until 1899, when he was appointed professor of applied mechanics at Worcester Polytechnic Institute. In 1903 he joined the Westinghouse Elec. & Mfg. Co. as mechanical engineer, remaining there until 1910. Since that year he has practiced as consulting engineer and headed his present organization. He has been a frequent contributor to the transactions of engineering societies on bearings, lubrication, and other mechanical subjects.

Contributed by the A.S.M.E. Special Research Committee on Lubrication and presented at the Annual Meeting, New York, N. Y., Nov. 30 to Dec. 4, 1931, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

Class C Bearings: Those in which the loading is symmetrical, that is, the center of pressure is at the center of the bearing arc, and the clearance is determined by the requirement of a maximum load or of a minimum coefficient of friction, for a given minimum thickness of the oil film; rotation to be in either direction.

The foregoing procedure appears to be the best method available at present. Exact calculation for practical bearing conditions in general has not been accomplished; certain solutions for plane bearing surfaces have been made by Michell (1),[2] by Martin (2), and by Duffing (3); and for fitted journal bearings by Boswall (4); but no mathematical results for the important case of journal bearings with running clearance have been obtained.

The latter case, along with others, is fairly well covered by the approximate experimental method of Kingsbury (5). In view of the great difficulty of mathematical solutions, the only hope of reducing theory to practice at present lies in approximate solutions. Those offered in the present discussion appear to be as nearly exact as are justifiable at present, in view of the uncertainties as to the actual film thicknesses and temperatures in practice, dependent as they are upon the circumstances of workmanship, of wear, and of distortion of the metals by heat and by pressure.

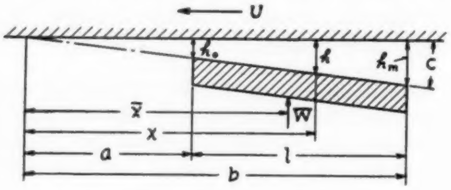

FIG 1

Mathematical analyses for the cases of the "infinitely wide" bearings are in general only qualitatively applicable in practice, although some of the results, such as the line of action of the load, the required volume of oil supply, and the nominal adiabatic heating of the oil, are directly usable for good practical forms of bearings without serious error. The main importance of such analyses is that they determine the maximum capacities theoretically attainable, and furnish the most convenient starting points and bases of reference for solutions for bearings of finite widths, whether these solutions be analytical or experimental.

Throughout this discussion the term "length" (l) is used for the dimension of the bearing surface in the direction of the motion, and the term "width" (w) at right angles to the motion; all bearing surfaces being assumed rectangular, either actually or as developed, with edges respectively parallel to the motion and at right angles thereto. The quantities calculated refer only to the active portion of the whole surfaces involved, taking no account of actions in enlarged clearance spaces and oil-supply channels; and all conditions are assumed as steady. Unless otherwise specifically stated, the film thickness is assumed to vary only in the direction of the motion, not in the transverse direction. The friction, being small compared with the pressure, is neglected as affecting the amount and direction of the load.

The oil supply is assumed sufficient to maintain the film, and any small pressure of the supply is neglected as affecting the film pressures. The viscosity of the oil in the film is taken as uniform at an average value, unless otherwise noted.

II—Theory of Plane Bearing Surfaces of Infinite Width

This case was first treated[3] by Reynolds (6). A more extended treatment is given by Boswall (4), including cases of varying viscosity. Although it does not exactly represent any case in practice, its mathematical simplicity and ease of calculation render it useful in furnishing qualitative results, applicable in kind to practical cases.

Fig. 1 shows the geometrical notation.

U is the velocity of the moving surface
c is the small angle of inclination of the planes
μ is the coefficient of viscosity, assumed constant
p is the pressure in the film at any value of x, above atmospheric pressure
h is the film thickness at any value of x
W is the resultant pressure, or load, per unit of width, and is taken normal to the moving surface
f is the shear stress in the oil at the moving surface
F is the integrated shear stress, opposed to U, per unit of width, and
λ = F/W is the coefficient of friction.

The differential equation of Reynolds (6), neglecting the transverse flow, is

$$\frac{d}{dx}\left(h^3 \frac{dp}{dx}\right) = -6\mu U \frac{dh}{dx}$$

or, since $h = cx$,

$$\frac{d}{dx}\left(x^3 \frac{dp}{dx}\right) = -\frac{6\mu U}{c^2} = -C \ldots\ldots\ldots\ldots [1]$$

By integration

$$x^3 \frac{dp}{dx} = -Cx + K_1 \ldots\ldots\ldots\ldots\ldots\ldots [2]$$

Again integrating,

$$p = Cx^{-1} - \frac{K_1}{2} x^{-2} + K_2 \ldots\ldots\ldots\ldots\ldots [3]$$

For determining the integration constants K_1 and K_2 we have the conditions $p = 0$ when $x = a$ and when $x = b$, whence, by substituting these values in [3],

$$K_1 = 2C \frac{ab}{(a+b)} \qquad K_2 = -C\left(\frac{1}{a+b}\right)$$

From [2],

$$\frac{dp}{dx} = \frac{C}{(a+b)}\left[\frac{2ab - x(a+b)}{x^3}\right] \ldots\ldots\ldots\ldots [4]$$

Inspection of [4] shows that $dp/dx = 0$ and that the pressure is therefore a maximum where $x = x_1$ and $h = h_1 = cx_1$, and

$$x_1 = \frac{2ab}{a+b} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots [5]$$

Differentiating [4] and writing $d^2p/dx^2 = 0$ shows that dp/dx has a minimum value, and therefore the pressure curve has a point of inflexion, at a point where $x = \dfrac{3ab}{a+b} = \dfrac{3}{2} x_1$; and therefore, from [5], this can occur only if $b > 2a$ as shown in Section V. If h_0 and l be considered constant, the value of W [8] is a maximum when $b = 2.189\,a$, and the value of λ [13]

---

[2] Numbers in parentheses refer to items in bibliography at end of paper.

[3] In Reynolds' original paper, this short section, covering less than two pages, contains ten misprints of subscripts and exponents, in addition to a real error in neglecting the part of the friction attributable to pressure. All these defects are reproduced in his "Collected Papers."

is a minimum when $b = 2.533\,a$; thus for either of these conditions the pressure curve has a point of inflexion near the leading edge, but this point would not be apparent in a graph except by large-scale plotting of exactly calculated pressures.

Substituting for K_1 and K_2 in [3],

$$p = \frac{C(b-x)(x-a)}{(a+b)x^2} \qquad [6]$$

The maximum pressure, from [5] and [6], is

$$p_1 = \frac{C(b-a)^2}{4ab(a+b)} = \frac{Cl^2}{4ab(a+b)} \qquad [7]$$

The load per unit of width is

$$W = \int_a^b p\,dx = C\left[\log_e \frac{b}{a} + 2\,\frac{(a-b)}{(a+b)}\right] \qquad [8]$$

and the line of action of W is at

$$\bar{x} = \frac{\int_a^b px\,dx}{W} = \frac{\dfrac{b-a}{2} - \dfrac{ab}{(a+b)}\log_e \dfrac{b}{a}}{\log_e \dfrac{b}{a} - 2\,\dfrac{(b-a)}{a+b}} \qquad [9]$$

The shearing stress in the oil at the moving surface is

$$f = \frac{\mu U}{h} + \frac{h}{2}\frac{dp}{dx} \qquad [10]$$

which reduces to

$$f = \frac{\mu U}{c}\left(\frac{3x_1}{x^2} - \frac{4}{x}\right) \qquad [11]$$

The total shearing resistance per unit width is

$$-F = \int_a^b f\,dx = \frac{\mu U}{c}\left[4\log_e \frac{b}{a} - 6\,\frac{(b-a)}{(a+b)}\right] \qquad [12]$$

The negative sign with F corresponds with the fact that F is opposed to U.

The coefficient of friction is

$$\lambda = \frac{F}{W} = \frac{c}{6}\left[\frac{4(a+b)\log_e \dfrac{b}{a} - 6(b-a)}{(a+b)\log_e \dfrac{b}{a} - 2(b-a)}\right] \qquad [13]$$

III—THEORY OF JOURNAL BEARINGS OF INFINITE WIDTH, WITH RUNNING CLEARANCE

Fig. 2 shows the geometrical notation. The axes of the cylindrical surfaces are assumed to be parallel, and at a distance $c\eta$. η is the difference of the radii (the radial clearance) and c is the eccentricity factor. With the exception of the angles α and β, all angles are measured from the line of centers, positive in the direction of rotation.

U is the linear velocity of the journal surface
h_m is the greatest thickness of the film
h_0 is the least thickness.

Neither h_m nor h_0 falls necessarily in all cases at the extremity of the bearing arc.

h_1 is the film thickness at the point where the pressure is a maximum
μ is the coefficient of viscosity of the lubricant, taken as constant
p_0 is the unit pressure referred to the projected area of the journal, and is equal to $W/2a$.

Reynolds' differential equations

$$\frac{d}{dx}\left(h^3\frac{dp}{dx}\right) = -6\mu U\frac{dh}{dx} \qquad [14]$$

and

$$\frac{dp}{dx} = 6\mu U\left(\frac{h-h_1}{h^3}\right) \qquad [15]$$

apply to this case, by writing $a\theta$ for x, $\eta(1 + c\cos\theta)$ for h, and $\eta(1 + c\cos\theta_1)$ for h_1. For convenience the negative sign in [14] is disregarded. [15] thus becomes

$$\frac{dp}{d\theta} = \frac{6\mu Uac\,(\cos\theta - \cos\theta_1)}{\eta^2(1 + c\cos\theta)^3} \qquad [16]$$

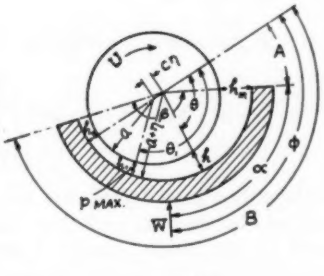

FIG 2

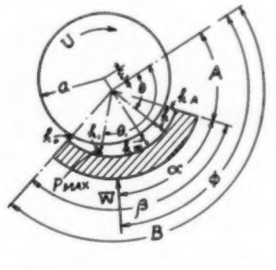

FIG. 3

The integral of [16] may have various forms; the form here employed is that of Harrison (7):

$$\begin{aligned} p = C + \frac{6\mu Ua}{(1-c^2)^2\eta^2}\Bigg[&\frac{c\sin\theta}{(1+c\cos\theta)^2}\left\{-(1-c^2)(1+c\cos\theta) + \frac{1}{2}(1+c\cos\theta_1)(1-c^2+3[1+c\cos\theta])\right\} \\ &+ (1-c^2)^{-1/2}\left\{2(1-c^2) - (1+c\cos\theta_1)(2+c^2)\right\}\tan^{-1}\left\{\sqrt{\frac{1-c}{1+c}}\tan\frac{\theta}{2}\right\}\Bigg] \qquad [17] \end{aligned}$$

C is here a constant of integration.

For further procedure, the following abbreviations for quantities in [17] are convenient:

$$\left.\begin{aligned} S &= (1-c^2) \\ M &= (1+c\cos\theta_1) \\ T &= (1+c\cos\theta) \qquad T_A = (1+c\cos A),\ \text{etc.} \\ K &= \frac{6\mu Ua}{(1-c^2)^2\eta^2} \\ D &= (1-c^2)^{-1/2}\tan^{-1}\left(\sqrt{\frac{1-c}{1+c}}\tan\frac{\theta}{2}\right) \\ D_A &= \text{the value of } D \text{ when } \theta = A,\ \text{etc.} \\ E &= \frac{c\sin\theta}{T^2}; \qquad E_A = \frac{c\sin A}{T_A{}^2},\ \text{etc.} \end{aligned}\right\} \qquad [18]$$

By the substitution of these expressions, [17] becomes

$$p = C + K\left[E\left\{-ST + \frac{M}{2}(S+3T)\right\} + D\left\{2S + M(S-3)\right\}\right] \qquad [19]$$

For finding C and θ_1, thus far unknown, we have the conditions $p = 0$ when $\theta = A$ and when $\theta = B$. The substitution of these conditions in [19] leads to

$$M = \frac{S[2(D_B - D_A) + E_A T_A - E_B T_B]}{\frac{E_A}{2}(S + 3T_A) - \frac{E_B}{2}(S + 3T_B) + (S - 3)(D_A - D_B)} \quad \ldots\ldots\ldots [20]$$

$$C = -K\left[M\left\{\frac{E_A}{2}(S + 3T_A) + D_A(S - 3)\right\} + S(2D_A - E_A T_A)\right] \ldots\ldots\ldots [21]$$

and from [18],

$$\cos\theta_1 = (M - 1)/c \ldots\ldots\ldots\ldots\ldots\ldots [22]$$

The definite integral for the pressure at any value of θ thus becomes, from [17], [20], and [21],

$$p = K\left[M\left\{-\frac{E_A}{2}(S + 3T_A) - D_A(S - 3)\right\} + S(E_A T_A - 2D_A) + \frac{EMS}{2} + ET\left(\frac{3M}{2} - S\right) + D\left\{S(M + 2) - 3M\right\}\right] \ldots\ldots\ldots [23]$$

In this equation M, S, and the subscripted factors are constant for a given film of assumed dimensions, and thus the constant terms may be replaced by the single symbol L for convenience in numerical substitutions and for further integrations: thus

$$p = K\left[L + \frac{EMS}{2} + ET\left(\frac{3M}{2} - S\right) + D\left\{S(M + 2) - 3M\right\}\right] \ldots\ldots\ldots [24]$$

The quantity L is in fact the value of $-C/K$, C being the constant of integration in [19], [21].

For finding W, the load per unit of width, and the angle $\phi = A + \alpha$, Fig. 2, the procedure is that of resolving the pressures p into components respectively normal to the line of centers and parallel thereto, and integrating for the respective components of W. Briefly indicated,

$$\left.\begin{aligned} W_V &= a\int_{\theta = A}^{\theta = B} p\sin\theta\, d\theta \qquad W_H = a\int_{\theta = A}^{\theta = B} p\cos\theta\, d\theta \\ W &= \sqrt{W_V^2 + W_H^2} \qquad \tan\phi = \frac{W_V}{W_H} \end{aligned}\right\} [25]$$

Omitting here the somewhat extensive details of the integrations indicated in [25] and writing only the final results,

$$W_V = Ka\left[{}_{\theta = A}^{\theta = B} - L\cos\theta + \frac{MS}{2c}\left\{\frac{c\sin\theta}{1 + c\cos\theta} - \theta + \frac{2}{\sqrt{S}}\tan^{-1}\left(\sqrt{\frac{1 - c}{1 + c}}\tan\frac{\theta}{2}\right)\right\} + \left(\frac{3M}{2} - S\right)\left\{-\sin\theta + \frac{\theta}{c} - \frac{2\sqrt{S}}{c}\tan^{-1}\left(\sqrt{\frac{1 - c}{1 + c}}\tan\frac{\theta}{2}\right)\right\} + \left\{\sqrt{S}(M + 2) - \frac{3M}{\sqrt{S}}\right\}\left\{\left[-\tan^{-1}\left(\sqrt{\frac{1 - c}{1 + c}}\tan\frac{\theta}{2}\right)\right]\left(\frac{1 + c\cos\theta}{c}\right) + \frac{\theta\sqrt{S}}{2c}\right\}\right] \ldots\ldots\ldots [26]$$

$$W_H = Ka\left[{}_{\theta = A}^{\theta = B} L\sin\theta - \frac{MS}{2c}\left\{\log_e(1 + c\cos\theta) + \frac{1}{1 + c\cos\theta}\right\} + \left(\frac{3M - 2S}{2c}\right)\left\{\log_e(1 + c\cos\theta) - (1 + c\cos\theta)\right\} + \left\{\sqrt{S}(M + 2) - \frac{3M}{\sqrt{S}}\right\}\left\{\tan^{-1}\left(\sqrt{\frac{1 - c}{1 + c}}\tan\frac{\theta}{2}\right)\sin\theta + \frac{\sqrt{S}}{2c}\log_e(1 + c\cos\theta)\right\}\right] \ldots\ldots\ldots [27]$$

The algebraic value of W is not required for numerical computations, since the numerical value of W is most readily derived by [25], W_V and W_H being evaluated separately in order to find ϕ.

To find the frictional resistance per unit width at the surface of the journal, we proceed from Reynolds' equation for the shear stress in the fluid at that surface

$$f = \frac{\mu U}{h} + \frac{h}{2}\frac{dp}{dx}$$

Substituting $a\theta$ for x, and $\eta(1 + c\cos\theta)$ for h, this reduces to

$$f = \frac{\mu U}{\eta}\left[\frac{1}{1 + c\cos\theta} + 3c\frac{(\cos\theta - \cos\theta_1)}{(1 + c\cos\theta)^2}\right] \ldots\ldots [28]$$

The total friction per unit width at the surface of the journal is

$$F = a\int_{\theta = A}^{\theta = B} f d\theta$$

which upon integration becomes

$$F = \frac{\mu Ua}{\eta(1 - c^2)}\left[{}_A^B \frac{3Mc\sin\theta}{1 + c\cos\theta} + 2\left\{\frac{4(1 - c^2) - 3M}{\sqrt{1 - c^2}}\right\}\tan^{-1}\left(\sqrt{\frac{1 - c}{1 + c}}\tan\frac{\theta}{2}\right)\right] \ldots\ldots\ldots [29]$$

The coefficient of friction is

$$\lambda = F/W \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots [30]$$

The complete algebraic expression for λ would be complicated and would not facilitate numerical computation; F and W being computed separately, λ readily follows from their numerical values. In the numerical evaluation of the preceding equations, the quantities that determine the form of the film are assumed as known, and the following procedure avoids ambiguities and multiple values. (*a*) The radical factors are considered as positive throughout. (*b*) The angle θ is limited physically to a complete circle, that is, its whole range of values is limited to 2π, whatever its initial and final values, whether positive or negative. The whole range of $\theta/2$ is thus limited to π, and thus as θ varies throughout its range, $\tan\theta/2$ passes through all its possible values. Writing $y = \tan^{-1}\left(\sqrt{\frac{1 - c}{1 + c}}\tan\frac{\theta}{2}\right)$, the value of y is taken as that nearest in value to $\theta/2$; it equals $\theta/2$ when $\theta = 0$, π, or 2π. The film form being taken as known, there can be but one physically permissible solution for any of the equations. The solutions reached by the above considerations are checked by those obtained by the graphical methods of Howarth (13), based directly on the differential equations.

IV—Theory of Fitted (No-Clearance) Journal Bearings, Infinite Width

The geometrical notation for this case is indicated in Fig. 3. The differential Equation [15]

$$\frac{dp}{dx} = 6\mu U\left(\frac{h - h_1}{h^3}\right)$$

applies to this case also, by substituting $a d\theta$ for dx, and $\epsilon \sin\theta$ for h;

$$\frac{dp}{d\theta} = \frac{6\mu U a}{\epsilon^2}\left(\frac{\sin\theta - \sin\theta_1}{\sin^3\theta}\right) \ldots\ldots\ldots\ldots [31]$$

As in the preceding cases, h_1 and θ_1 here refer to the point where $dp/d\theta = 0$ and the pressure is a maximum.

Integration of [31] leads to

$$p = C + \frac{3\mu U a}{\epsilon^2}\left\{\sin\theta_1\left(\frac{\cot\theta}{\sin\theta} - \log_e \tan\frac{\theta}{2}\right) - 2\cot\theta\right\} \ldots [32]$$

To find the integration constant C and the unknown θ_1, we have the conditions $p = 0$ when $\theta = A$ and when $\theta = B$, leading to

$$\sin\theta_1 = \frac{2(\cot A - \cot B)}{\dfrac{\cot A}{\sin A} - \dfrac{\cot B}{\sin B} + \log_e \dfrac{\tan B/2}{\tan A/2}} \ldots\ldots [33]$$

and

$$C = -\frac{3\mu U a}{\epsilon^2}\left\{\sin\theta_1\left(\frac{\cot A}{\sin A} - \log_e \tan\frac{A}{2}\right) - 2\cot A\right\} \ldots [34]$$

For brevity we may write

$$\left.\begin{aligned} \sin\theta_1 &= M \\ \frac{3\mu U a}{\epsilon^2} &= K_1 \\ -\frac{C}{K_1} &= L \end{aligned}\right\} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots [35]$$

These substituted in [32] give the definite integral for the pressure at any value of θ

$$p = K_1\left\{L + M\left(\frac{\cot\theta}{\sin\theta} - \log_e \tan\frac{\theta}{2}\right) - 2\cot\theta\right\} \ldots [36]$$

The load W per unit of width, and the direction angle ϕ of its resultant, are found from the integrals of the components;

$$\left.\begin{aligned} W_V &= \int_{\theta = A}^{\theta = B} p \sin\theta \, a\, d\theta \qquad W_H = \int_{\theta = A}^{\theta = B} p\cos\theta\, a\, d\theta \\ W &= \sqrt{W_V^2 + W_H^2} \qquad \tan\phi = \frac{W_V}{W_H} \end{aligned}\right\} [37]$$

Omitting the details of the integrations,

$$W_V = K_1 a\left\{L(\cos A - \cos B) + M\left(\cos B \log_e \tan\frac{B}{2} - \cos A \log_e \tan\frac{A}{2}\right) - 2(\sin B - \sin A)\right\} \ldots [38]$$

$$W_H = K_1 a\left\{L(\sin B - \sin A) + M\left(\cot A - \cot B + \sin A \log_e \tan\frac{A}{2} - \sin B \log_e \tan\frac{B}{2}\right) + 2\left(\cos A - \cos B + \log_e \tan\frac{A}{2} - \log_e \tan\frac{B}{2}\right)\right\} \ldots [39]$$

For the shear stress at the surface of the journal, the equation

$$f = \frac{\mu U}{h} + \frac{h}{2}\frac{dp}{dx}$$

becomes, by the substitution of $a\theta$ for x, and $\epsilon \sin\theta$ for h,

$$f = \frac{\mu U}{\epsilon\sin\theta} + \frac{\epsilon\sin\theta}{a} K_1 \frac{\sin\theta - \sin\theta_1}{\sin^3\theta}$$

$$= \frac{\mu U}{\epsilon\sin\theta}\left(4 - \frac{3\sin\theta_1}{\sin\theta}\right) \ldots\ldots\ldots\ldots\ldots\ldots [40]$$

The total friction per unit of width, at the journal surface, is

$$F = \int_{\theta = A}^{\theta = B} f a\, d\theta = \frac{\mu U a}{\epsilon}\int_{\theta = A}^{\theta = B}\left(\frac{4}{\sin\theta} - \frac{3\sin\theta_1}{\sin^2\theta}\right) d\theta \ldots [41]$$

and by integration

$$F = \frac{\mu U a}{\epsilon}\left[4\left(\log_e \tan\frac{B}{2} - \log_e \tan\frac{A}{2}\right) + 3\sin\theta_1(\cot B - \cot A)\right] \ldots\ldots [42]$$

The coefficient of journal friction then is

$$\lambda = \frac{F}{W} \ldots\ldots\ldots\ldots\ldots\ldots\ldots [43]$$

V—Maximum Load Capacity and Minimum Coefficient of Friction for a Given Minimum Film Thickness

The natures of these relationships are typified in Fig. 4, which is calculated for the hypothetical case treated in Section II, for planes of infinite width and with constant viscosity. Assuming the length l as constant, h_0 as fixed, and h_m increasing from an initial value = h_0, the load per unit of width W reaches a maximum when h_m = 2.189 h_0; the friction per unit width, F, decreases continuously; and the coefficient of friction reaches a minimum when h_m = 2.533 h_0. Reynolds (6) showed the existence of such a maximum for W in his treatment of plane surfaces; and Boswall (4) has further shown the minima for λ with constant viscosity and with several assumed laws of variation of viscosity.

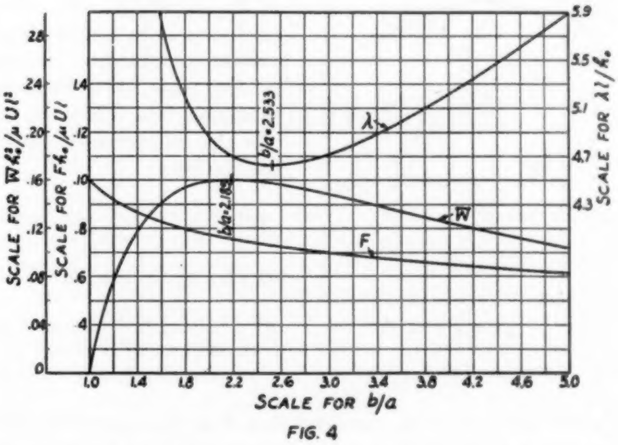

FIG. 4

It has been found that closely similar relationships exist in journal bearings, but the corresponding numerical calculations present far greater difficulty, as may be inferred from the complexity of the formulas relating to journal bearings. However, the calculations have been made for a number of cases, and the results are shown in the accompanying tables and graphs. The graphs relate only to the conditions of minimum coefficients of friction; these conditions differ but slightly from those for maximum loads.

The conditions for the minimum coefficient of friction, with a fixed minimum film thickness, are quite distinct from the analogous conditions based on a fixed running clearance in the hypothetical 360-deg. bearing, as treated by Sommerfeld (8) and by Harrison (7). A still different minimum is that obtained on a test of a partial bearing by increasing load, or by reducing speed, or by reducing the oil supply; a minimum found in this way depends largely on the accuracy of form and of finish of the bearing surfaces, and occurs when the film thickness is reduced to nearly zero at some point or points, and further reduction of speed or increase of load causes contact of the metals.

For plane surfaces, the maximum-load conditions and the minimum-friction conditions are readily obtained by numerical substitutions in Equations [8] and [13], varying the ratio b/a.

For clearance journal bearings, the general procedure for finding the conditions for the maximum load capacity is as follows: Referring to Fig. 2 as typical, a bearing arc β is chosen; then with a fixed value of $c = c_1$, Equations [26] and [27] are evaluated for various values of A and the dependent values of $B = A + \beta$, the factors μ, U, a, and η being constant. Three or more such calculations yield a curve 1, Fig. 5, which is found to be nearly a parabola with its axis vertical. To find the maximum W_1, a parabola is calculated, passing through the three points nearest the apparent maximum, and the exact vertex of this parabola is then calculated as giving the values of W_1 and A_1 corresponding to the particular value of $c = c_1$. The same procedure with other values of c yields values of W_2, A_2, W_3, A_3, etc. The next step is to reduce these several intermediate values to the basis of a common minimum film thickness, h_0. The general expression for W has the form

$$W = \frac{\mu U a^2}{\eta^2(1 - c^2)^2} f(c, A, B)$$

which may be written

$$W = \frac{\mu U a^2}{\eta^2(1 - c)^2(1 + c)^2} f(c, A, B) \quad \ldots. [44]$$

in which $\eta(1 - c) = h_0$, provided that B is not appreciably less than 180 deg., which is found to be generally true for optimum film conditions in bearings with running clearance. Since h_0 is to be the same for all values of c, it follows that η must vary inversely as $(1 - c)$. Thus for reducing the values of W_1, W_2, etc. to the same h_0 as that of W_3, the products $W_1 \left(\frac{1 - c_1}{1 - c_3}\right)^2$, $W_2 \left(\frac{1 - c_2}{1 - c_3}\right)^2$, etc. furnish ordinates for the curve 4; this curve, treated by the parabolic method, gives W_4, the maximum load capacity for the given bearing arc β and a given h_0; also the value of A_4 corresponding thereto. The axis of the parabola 4 intersects the curve $W_1W_2W_3$ at a point corresponding to c_4, the required eccentricity ratio; the value of c_4 is obtained by interpolation. The values of $W_4 \frac{h_0^2}{\mu U a^2}$, A_4, and c_4, together with other non-dimensional quantities consistent therewith, derived from the formulas in sections III and IV, are shown in plates I, IV, and VII.

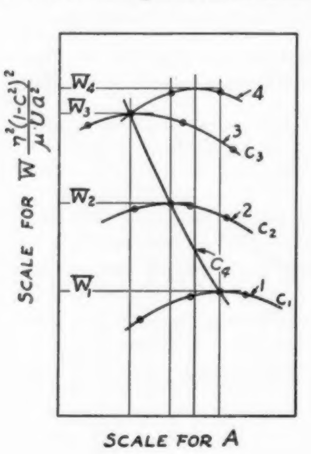

FIG. 5

For the condition of a minimum coefficient of friction, the procedure is analogous to that just described. The results of the calculations are shown in plates II, III, V, VI, VIII, and IX. These conditions differ but little from those for maximum load.

A comparison of the infinitely wide bearings of three chosen cases, for various angles subtended by the bearing arc, is shown in Fig. 6. It is seen that class A is superior to classes B and C for the same N and h_0, except that it is practically the same as class B up to about 85 deg. Under these optimum conditions for infinitely wide bearings, plots of the pressure curves show that with atmospheric pressure at the ends of the bearing arc, no subatmospheric pressures occur in any case, even when there are divergent films of large arc length. But experimental integrations (5), as well as numerous direct tests of bearings, show that when there is side leakage, as in all practical cases, the divergent films, if of sufficient length, cause negative pressures. Examples of this are shown in Figs. 7, 8, and 9, in which the curves show the average pressures for the respective widths, derived by the electrical method (5); w being the axial width, and l the arc length $a\beta$.

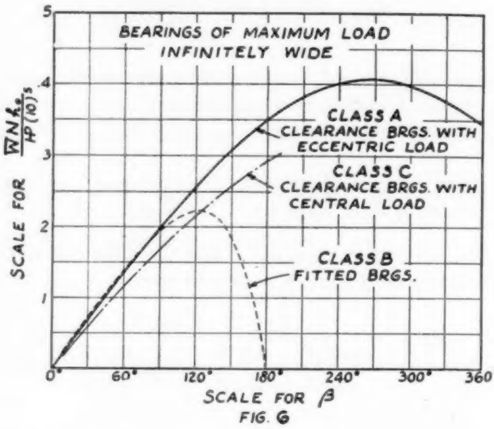

FIG. 6

These average pressures include the effects of the theoretical negative pressures, which may be considerable in amount; yet in practice these pressures are uncertain, and may not go below absolute zero, owing to the lack of tensile strength of the lubricant. In the present discussion, however, the theoretical load factors, Fig. 10 and plate X, are derived as if the theoretical negative pressures actually existed; hence some small uncertainties occur with large arcs and small widths.

In all that precedes Figs. 7, 8, and 9, the formulas and the calculated constants are based upon ideal conditions, including constant viscosity and the absence of side leakage. Under practical conditions, the pressures are in all cases materially less than those that have been derived; and all other quantities are changed, although to a less extent than the pressures, in general. Up to this time no exact general method of mathematical treatment of practical journal-bearing films has been developed; and in view of the complexity of the subject there is no prospect of such a method. It is evident that the derivation of constants and of simple rules for practical use can be accomplished only through approximate methods, with due regard to the relative importance of the factors involved, and necessarily with disregard of factors that may be considered as of secondary influence. The remainder of this paper is devoted to the derivation of approximation methods, with the minimum film thickness as the primary critical factor; with the allowable pressure per unit of projected area of the journal as a secondary critical factor; and with special reference to the conditions for minimum power loss by friction.

VI—Effects of Side Leakage on Pressure

Fig. 10 shows the results of calculations that have been made to date, reduced to a common basis, namely, the ratio L_1 of the mean load per unit width to the load that would be carried by the same film if there were no side leakage, with varying ratios of length to width; all with the assumption of uniform viscosity.

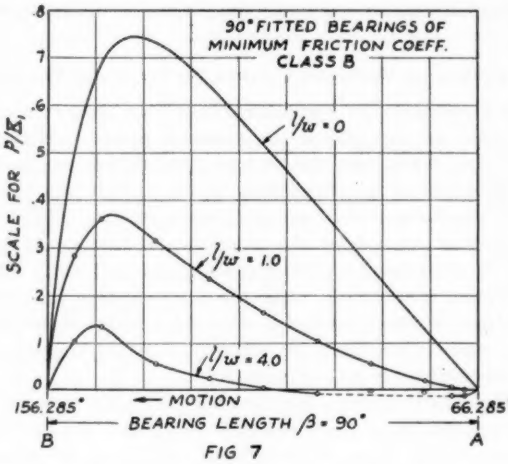

FIG 7

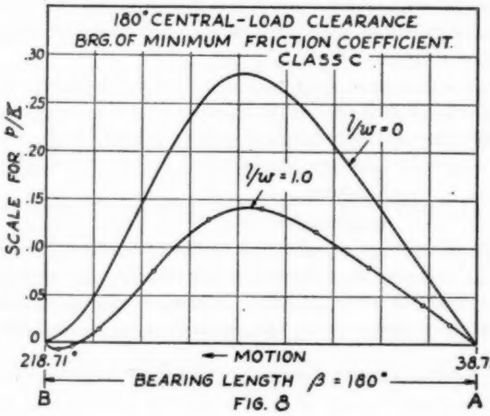

FIG. 8

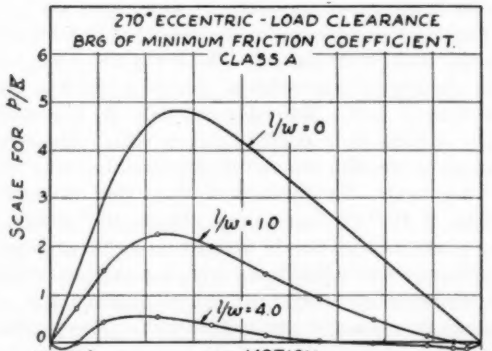

FIG. 9

The film forms for all the cases shown are either those giving the minimum coefficients of friction or not far therefrom, under the assumption of infinite width. The plot shows an average curve; in what follows, this curve, shown for greater convenience in Plate X, is used for approximate correction for the values of W in bearing films under nearly optimum conditions for load or for friction. An application of this kind has been made by Karelitz (9) on the basis of Michell's (1) and of Martin's (2) calculations for plane surfaces.

VII—Effect of Side Leakage on Friction

In the general differential equation for the shear stress at the moving surface

$$f = \frac{\mu U}{h} + \frac{h}{2}\frac{dp}{dx}$$

the first term on the right corresponds to a state of uniform shear across h, without reference to the flow corresponding to the pressure gradient, and is independent of the width of the bearing. The second term, being dependent on the pressure gradient, thus depends on the effect of side leakage upon the pressure and therefore upon the width of the bearing.

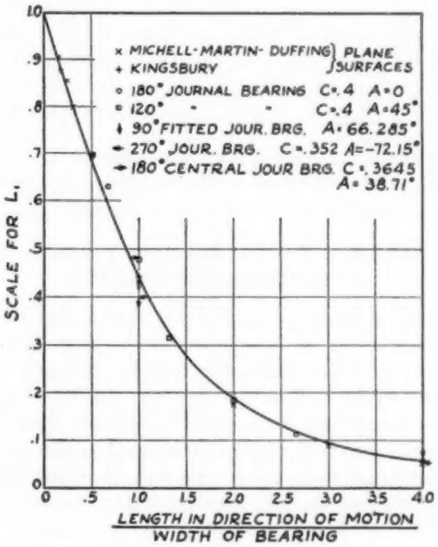

FIG. 10

The integrals for the separate terms on the right have been calculated for the film forms for minimum coefficient of friction, for the ideal bearings of infinite width. There is no great variation in the proportions of the total friction per unit of width due to shear and to pressure, respectively, for the several bearing arcs of infinite width.

Examination of cases of finite widths that have been integrated experimentally in detail (5) (180-deg. and 120-deg. bearings of finite widths) shows that the part of the friction due to pressure per unit of width is closely proportional to the pressure total per unit of width, whatever the width may be. Thus taking an average value for the friction due to simple shear as 84 per cent of the friction in the infinitely wide bearings, and the ratios L_1 in plate X as applying to the part of the friction due to pressure, plate X shows also the factors F_1 for reducing the friction of the infinitely wide bearing to apply to cases of finite length/-width ratios. For finite widths, the correction factor L_1 is hereafter used with the W of the "infinitely wide" theory, and the factor F_1 with the F of the theory.

The ratios L_1 and F_1 are further combined in plate X, giving a factor L_1/F_1, which is convenient for use in correcting for the coefficient of friction and quantities dependent thereon. Thus in what follows, plate X is used throughout as giving the approximate correction factors for W, F, and λ, for all bearings of Classes A, B, and C.

In the dynamical tables and curves, plates I to IX, inclusive, the numerical coefficients are for the infinitely wide condition. Thus for correction for bearings of finite width and given l/w ratio, these coefficients are to be multiplied by the proper factor from plate X, as below:

Tabular Dynamical Quantity	Multiplying Factor for Coefficient
W	L_1
F	F_1
$\lambda\left(\text{or } \frac{F}{W}\right)$	$\frac{F_1}{L_1}$
HP	F_1
$\frac{HP}{W}$	$\frac{F_1}{L_1}$
$\frac{W}{HP}$	$\frac{L_1}{F_1}$
$\lambda \Big/ \sqrt{\frac{\mu N}{p_0}}$	$\frac{F_1}{\sqrt{L_1}}$

With these operations, the quantities resulting from the tabular formulas all relate to actual loads, frictions, etc., including the "pressure per unit of projected area of journal," p_0.

VIII—Effect of Side Leakage and Viscosity Change on the Center of Pressure

Various calculations (1, 4, 5) have shown that one effect of increasing the ratio of length to width, thus increasing the relative amount of side leakage, is to shift the center of pressure toward the trailing end of the bearing surface. On the other hand, both theory and experiment (10) show that there is an increase in temperature of the oil in passing through the film, with a consequent reduction of viscosity; and one effect of this viscosity change is to shift the center of pressure toward the leading end. An exact account of these opposing influences would be difficult, if not impossible, and in any event would introduce complications. Experiments with pivoted-block thrust bearings show that the friction is not greatly affected by shifting the center of pressure by moderate amounts; they even operate well if the center of pressure coincides with the center of figure, which is theoretically impossible on the assumptions that the viscosity is constant and that the surfaces are plane.

For the foregoing reasons it is assumed that the optimum positions of the center of pressure, calculated as for infinite width and for constant viscosity, may be taken as fair averages for the ordinary practical conditions of finite width and varying viscosity.

IX—Effect of Side Leakage and Viscosity Change on the Optimum Ratios of h_m/h_0

The following results of calculations for the hypothetical rectangular plane surfaces may serve to show the relatively small effects:

$\frac{\text{Length}}{\text{Width}}$	Viscosity change	h_m/h_0 for $W_{\text{max.}}$	h_m/h_0 for $\lambda_{\text{min.}}$
0	0	2.189	2.533
0	2:1	2.22	...
1	2:1	2.325	...
2	2:1	2.335	...

In the first two of these cases, the results were obtained through exact integrations; in the third and fourth the integrations were effected by the electrical method (5).

These figures indicate that both the side leakage and the viscosity change require that for a maximum W the ratio h_m/h_0 should be somewhat greater than that calculated for infinite width and constant viscosity; and the same appears to be true as regards the minimum λ. But for ordinary bearing proportions, the required increase in h_m/h_0 is not great; and taking the view that similar conditions exist in journal bearings, it is assumed that the calculated values of h_m/h_0 for minimum coefficients of friction are actually very close to optimum conditions.

X—Effect of Viscosity Change on Load and Friction

It has been shown by Boswall (4) that for a moderate change in viscosity, for example, if the viscosity at the outlet end is one-half that at the inlet, the load and the friction may be fairly well approximated by calculating as for a constant viscosity taken as the mean of the inlet and outlet values. This conclusion has been verified by the experimental method of Kingsbury (5) in the case of a plane surface of square form. Thus in what follows, a numerical value for the coefficient of viscosity implies that an average value is assumed. Exact uniformity in practical cases is inconceivable, although it might be approached in water-cooled bearings, for example.

For the reasons given above (sections VI-IX), it is assumed that the geometrical quantities given in plates I–IX, defining the forms of the films for maximum loads and for minimum coefficients of friction, for the infinitely wide bearings, may also be used without great error for bearings of ordinary finite widths. These quantities are non-dimensional, and may be used with any system of units.

The dynamical groups in plates I to IX, inclusive, are also non-dimensional, but the units employed in deriving the tabulated constants are the English units—pound, inch, second—with N = revolutions per minute and HP = frictional horsepower. The ratio $\frac{\text{load}}{\text{horsepower}}$ is the same for the whole bearing as for unit of width. Application of the dynamical constants in plates I–IX requires that the geometric relations for eccentricity, clearance, and center of pressure be complied with, since these conditions form the basis for the dynamical tables and graphs.

XI—Experimental Check on the Preceding Theory

An approximate check of the theory, as regards the 360-deg. bearing, is furnished by the author's tests (11) of an air-lubricated journal 6 in. in diameter and 6.25 in. wide, load, 50.5 lb. In this case, the negative pressures in the upper 180 deg. are roughly similar to the positive pressures in the lower 180 deg.; and for this reason the l/w ratio is taken as that of a 180-deg. bearing, that is $3\pi/6.25 = 1.51$. Referring to plate X, this ratio determines $F_1 = 0.88$, $L_1 = 0.273$, $L_1/F_1 = 0.31$. The temperature of the air in the film was not determined, but was approximately 20 deg. cent.; the viscosity of air at this temperature is taken as 2.62×10^{-9} (in-lb-sec.), or 1.81×10^{-4} poises. The differences of the measured radii were by no means uniform; the average difference was 0.00079 in., with a maximum of 0.00163 in. and a minimum of 0.00062 in.; for the middle 5 in. of the width, the mean clearance was 0.000694 in. The journal was "out of round" by 0.00025 in., and the bearing by about 0.00012 in. By assuming the effective clearance as $\eta = 0.000705$ in., the experimental load and friction conform exactly to the theoretical values at 247 r.p.m.; but the experimental eccentricity ϵ at this speed was 0.0003 in. ($c = 0.426$), while the theory requires $\epsilon = 0.000258$ ($c = 0.366$). This discrepancy is 6 per cent of the nominal clearance, or 0.000042 in. Thus in the above respects the experiment agrees reasonably with the theory; but owing to the elasticity of air, the pressure distribution and the several critical angles differ considerably from those indicated by theory. These latter points have been discussed by Harrison (7).

The experiment illustrates the difficulties of determining effective film thicknesses in experimental bearings; and where heat and pressure affect the surface forms, the film dimensions are even less closely determinable than in the experiment described, in which these effects were negligible. With non-uniform clearance, both η and h_0 of the formulas must be regarded as nominal or effective values only, for purposes of calculation.

XII—Optimum Bearing Proportions

Plates XI, XII, and XIII are plots showing the values of the non-dimensional group WNh_0/HP as affected by side leakage, with the film forms for the minimum coefficient of friction, for bearings of the three principal classes.

The derivation of the curves is as follows: The curves marked $w = \infty$ are plotted directly from the constants for WNh_0/HP for the several values of β, plates III, VI, IX. The curves marked with finite values of w/a are derived from the curves $w/a = \infty$ by multiplying their ordinates by the proper values of L_1/F_1, plate X, for the various ratios of $\beta a/w$, that is, l/w. In each case these curves for finite values of w/a are tangent to that for $w = \infty$, at the origin. For a given w/a, the group WNh_0/HP has a maximum value at a certain value of β, which is therefore considered as an optimum value of β for the given w/a; and the curve H connecting the several maximum points, comprises all such optimum values of β for values w/a. An additional curve J is drawn, connecting the optimum values of β from the curve H with the corresponding values of w/a, with a linear scale for the latter at the right. If fixed values for N and h_0 be assumed, plates XI, XII, and XIII furnish direct measures of the relative merits of different proportions for bearings. While W and HP by themselves relate to unit width of the bearing, their ratio is the same as for the whole load and the whole power loss. To attain the desirable end of making this ratio high, with given values of N, h_0 must be made small, while fulfilling the geometrical conditions, as well as providing the required viscosity. The number and variety of the circumstances that affect the permissible values of h_0 render it impracticable to derive a general rule for it from theory alone.

If, however, h_0 be supposed to vary with N, β, w, or a, or all of these, according to some more or less arbitrary law, corresponding curves may be drawn, which will indicate optimum forms differing from those shown. But since h_0 ultimately remains to be fixed by experience and judgment, as well as mechanical skill, the simplest method at present is to use plates XI, XII, and XIII with chosen values of N and h_0.

XIII—Examples

Example 1. Required, a bearing of Class A, of minimum friction, to support a load of 25,000 lb. at 1500 r.p.m., with $h_0 = 0.003$ in., and with 200 lb. per sq. in. on the projected area of the journal. This requires a projected area of 125 sq. in.

Referring to plate XI, assume for this example that $w/a = 3$. The projected area being $2a^2(w/a) = 125$, it follows that $a = \sqrt{(125/6)} = 4.564$ in. This radius may or may not be sufficient for strength in bending or in torsion, or both; but it will be assumed that it is sufficient. The least power loss is incurred when $\beta = 153.6$ deg. (2.68 rad.), for which the factor (L. H. Scale) is 16,900; hence the ratio of load to power loss being the same for the whole width as for unit width,

$$\text{Power loss} = \frac{25{,}000 \times 1500 \times 0.003}{16{,}900} = 6.66 \text{ hp.}$$

As previously noted, this does not include losses in the clearance spaces outside of the arc β.

The clearance η (plate II, curve 7) for $\beta = 153.6$ deg. is $\eta = 1.72\, h_0 = 0.00516$ in.

The bore of the bearing is therefore larger than the 9.128 in. diameter of the journal by $2 \times 0.00516 = 0.01032$ in., or 0.00113 per inch of diameter.

The arc length of the bearing surface is

$$l = 2.68 \times 4.564 = 12.23 \text{ in.}$$

The width is

$$w = 3.00 \times 4.564 = 13.69 \text{ in.}$$

The ratio l/w is therefore 0.893. By reference to plate X, this determines the several correction factors,

$$L_1 = 0.487 \qquad F_1 = 0.916 \qquad L_1/F_1 = 0.532$$

The required mean viscosity in the oil film may now be determined from plate III, curve 10. For the infinitely wide bearing and $\beta = 153.6$ deg., curve 10 gives the factor 0.117. The actual mean load per unit of width is

$$\frac{25{,}000}{13.69} = 1826 \text{ lb.} = L_1W$$

hence

$$W = \frac{1826}{0.487} = 3749 \text{ lb.}$$

and therefore (10)

$$\mu = \frac{3749 \times 0.003^2}{0.117 \times 1500 \times (4.564)^3} = 2.022 \times 10^{-6} \text{ (in-lb-sec.)}$$

With the conversion factor 69,000, this viscosity is 0.1395 poise, which is that of a light machinery oil at about 130 to 140 deg. fahr. (12). The coefficient of friction (plate III, 12) is

$$\lambda = \frac{F_1}{L_1} \times 2.00 \times \frac{h_0}{a} = \frac{2.00 \times 0.003}{0.532 \times 4.564} = 0.00247$$

Inspection of plate XI indicates that by increasing the ratio w/a, other things being equal, the relative power loss will be reduced; this is shown more specifically in the following example. The extent to which w/a may be increased must be limited eventually by considerations of space, cost, and the strength or elasticity of the journal.

In the present example, the angle β might be increased, securing thereby a somewhat greater bearing area; but this would involve a relatively greater friction loss, as is obvious on inspection of plate XI.

Example 2. In Example 1, suppose that w/a is taken as 4 instead of 3, the other data remaining unchanged. We then have, referring to the same plates,

$$a = \sqrt{\frac{125}{8}} = 3.953 \text{ in.}$$

$\beta = 180.8$ deg. $= 3.155$ radians, for the least power loss.

$$\text{Power loss} = \frac{25{,}000 \times 1500 \times 0.003}{20{,}700} = 5.435 \text{ hp.}$$

Clearance $\eta = 1.622\, h_0 = 0.004866$ in.
$= 0.00123$ in. per inch of diameter.
Length $l = 3.155 \times 3.953 = 12.47$ in.
Width $w = 4 \times 3.953 = 15.81$ in.
Ratio $l/w = 0.789$

This determines

$$L_1 = 0.533 \qquad F_1 = 0.924 \qquad L_1/F_1 = 0.577$$

$$\frac{25{,}000}{15.8} = 1581 \text{ lb.} = L_1 W \qquad \therefore\ W = 2967 \text{ lb.}$$

$$\mu = \frac{2967 \times 0.003^2}{0.1517 \times 1500 \times (3.953)^3} = 1.90 \times 10^{-6} \text{ (in-lb-sec.)}$$
$$= 0.131 \text{ poise}$$

The coefficient of friction is:

$$\lambda = \frac{F_1}{L_1} \times 1.762 \times \frac{h_0}{a} = \frac{1.762 \times 0.003}{0.577 \times 3.953} = 0.002318$$

The procedure for examples under classes B and C is similar, having reference to the appropriate plates corresponding to those referred to in Example 1.

Conclusion

In the preparation of the material for this paper, the large amount of necessary detail work has been carried out by Mr. S. J. Needs.[4] The analytical work was for the most part performed independently by Mr. Needs and by the author, and identical results were obtained. Mr. Needs alone carried through the numerical evaluations leading to the tabulated results; the experimental integrations by the electrical method (5); and the preparation of the tables and graphs.

The numerical evaluations for the infinitely wide bearings were in all cases carried to at least six figures; the tabulated results are given to the nearest unit in the fourth place, which is believed to be amply accurate for any present or future purposes. For bearings of finite width, all results are based on the approximations indicated in plate X. Owing to the lack of complete and precise test data, the degrees of approximation cannot be estimated closely, but the present indications are that the method does not involve errors of serious practical importance.

Discussion

Georg Duffing.[5] The author's work will be a valuable help to the engineer in designing power plants. These well-arranged tables give indeed a clear view of the whole matter.

Although the results presented are widely supported by experimental research and the experience of the author, many engineers may nevertheless desire to perform the mathematical work themselves, which can easily be done by making use of Equations [17] et seq. of the paper.

The calculation will be simplified by making the substitution[6]

$$\sqrt{\frac{1-c}{1+c}}\tan\frac{\theta}{2} = \tan\frac{\eta}{2}$$

where η is a new variable (not the η of [16], which is equivalent to the writer's Δ). Then

$$\tan\theta = \sqrt{1-c^2}\,\frac{\sin\eta}{\cos\eta - c};\quad \cos\theta = \frac{\cos\eta - c}{1 - c\cos\eta};$$

$$\sin\theta = \sqrt{1-c^2}\,\frac{\sin\eta}{1-c\cos\eta};\qquad 1 + c\cos\eta = \frac{1-c^2}{1-c\cos\eta}$$

and [17] will be transformed into

$$(1-c^2)^{3/2}\frac{p}{6\mu U}\frac{\Delta^2}{a} = \left[1 - \lambda\frac{2+c^2}{1-c^2}\right]\eta - c\left[1 - \frac{4\lambda}{1-c^2}\right]\sin\eta - \frac{\lambda}{2}\frac{c^2}{1-c^2}\sin 2\eta + K$$

where

$$\lambda = (1-c^2)\,\frac{\eta_1 - \eta_2 - c(\sin\eta_1 - \sin\eta_2)}{(2+c^2)(\eta_1-\eta_2) - 4c(\sin\eta_1 - \sin\eta_2) + \frac{1}{2}c^2(\sin 2\eta_1 - \sin 2\eta_2)} = \frac{1}{2}\frac{h_1}{\Delta}$$

η_1 = value for $\theta = B$; η_2 = value for $\theta = A$.

It follows, then, that

$$(1-c^2)^{3/2}\frac{W_v}{6\mu U}\left(\frac{\Delta}{a}\right)^2 = \left[\left(\frac{1-c^2}{c} - \frac{2\lambda}{c}\right)\eta + 2\lambda\sin\eta\right]_{\eta=\eta_2}^{\eta=\eta_1}$$

$$\frac{(1-c^2)^2}{c}\frac{W_H}{6\mu U}\left(\frac{\Delta}{a}\right)^2 = \left[-\left(\frac{1-c^2}{c} - \frac{2\lambda}{c}\right)\cos\eta - \frac{\lambda}{2}\cos 2\eta\right]_{\eta_2}^{\eta_1}$$

$$(1-c^2)^{3/2}\frac{F\Delta}{\mu U a} = \left[(4 - 4c^2 - 6\lambda)\eta + 6\lambda c\sin\eta\right]_{\eta_2}^{\eta_1}$$

For example, referring to Plate VII, Class C (page 17), for $\beta = 180°$ and $c = 0.3437$, there result the following values:

Given, $\theta_2 = 37°\,50'$, $\theta_1 = 217°\,50'$

then $\eta_2 = 26°\,56'$, $\eta_1 = 232°\,14'$, $\lambda = 0.3800$

$K = -0.1330$

$h_0 = 0.6563\,\Delta$

Further,

$$\frac{W_v}{6\mu U}\left(\frac{\Delta}{a}\right)^2 = 0.3936;\quad \frac{W_H}{6\mu U}\left(\frac{\Delta}{a}\right)^2 = 0.3009$$

$$\frac{W}{6\mu U}\left(\frac{\Delta}{a}\right)^2 = 0.4954;\quad -\tan\phi = 1.3080;\quad \phi = 127°\,24'$$

$$\frac{F}{\mu U}\frac{\Delta}{a} = 4.3636;\quad \frac{Wh_0^2}{\mu N a^3} = 0.1340;\quad \frac{Fh_0}{\mu N a^2} = 0.2998$$

in accordance with the paper.

The tables given in the paper save a lot of labor, not only in common use, but if for any reason the most favorable conditions of the paper cannot be realized.

H. A. S. Howarth.[7] For about four years Mr. Kingsbury has been intensively engaged in investigations, the important features of which were presented to the Society in December, 1931, and in the present session.

Now that these analyses are available, it is necessary that practical problem after practical problem be solved and that test after test be interpreted, in order to demonstrate the practical utility of the families of curves to which we have now been introduced.

We must now acquire new habits of thought about oil-film bearings. Many of us are perhaps still playing with such children's toys as Morin's coefficients and the thumb rule of $PV = C$. If so, we ought to put them away. They have been passé for several years among engineers who have closely followed progress in the field of bearings and lubrications. We should therefore make a supreme effort to get abreast of the times and become "optimum conditions" minded. This is not said lightly. Up-to-dateness is a habit that may be acquired by hard work, provided one is still young-minded enough to accept something new.

G. B. Karelitz.[8] During the past several years there has been exerted a continuous effort to bring the hydrodynamical theory of lubrication to a state where it could be conveniently applied to design of bearings. The present paper is an important step in the logical development of the oil-film study. It really consists of two parts. The first gives the analysis and methods for choosing a bearing which, under given working conditions, will provide the maximum load-carrying capacity or the minimum friction for a desired oil-film thickness, this analysis treating bearings of infinite width. Means of taking into account finite width of bearings are discussed in the second part.

From daily contact with practical designers it seems to the writer that they are still quite reluctant to consider actually built bearings in the light of the hydrodynamical theory. Apparently there is doubt as to how closely the actual performance of a bearing is described by this theory, and the various methods of experimental verification of this question may be discussed to advantage.

The most common method used by experimenters has been that of exploring the pressures in the oil film over the bearing surface. It can be readily seen that this method cannot be reliable. Indeed, no matter what the distribution of pressures in the oil film of a partial bearing may be under normal conditions, the resultant of all the pressure forces will always be equal to the load carried by the bearing. The pressures at the inlet and the outlet edges of the bearing, as well as those at the bearing ends, must be equal to the atmospheric pressure. Under these circumstances, the maximum pressure will always be of the order from two and one-half to three and one-half times the average pressure over the projected area of the bearing. The shape of the pressure curve can only be compared with the theoretical curve, and any deviations from the latter can be very well charged to inaccuracy of observations.

The location of the journal center in the bearing clearance has been observed by a number of experimenters. Generally speaking, the location of this center, otherwise the minimum thickness of the oil film, checks quite well with the calculated values when the end leakage is taken into consideration. This circumstance is rather gratifying since it justifies the application of the hydrodynamical theory to an analysis of safety of bearing designed. It emphasizes once more the importance of the present paper.

[8] Associate Professor, Columbia University, New York, N. Y. Mem. A.S.M.E.

Experiments were completed recently at the laboratory of the Westinghouse Company by the writer and Mr. S. E. Amos, during which the end leakage was measured in a 6-in. × 10-in. partial bearing under different conditions of load, speed, and inlet oil temperature. The end leakage observed was of the same order as that which could be approximately estimated on basis of the hydrodynamical theory. The results have been submitted in the form of a preliminary report to the Lubrication Committee. It appears that, on the basis of all the experimental information available at present, there can be no doubt that the hydrodynamical theory represents the phenomena in the oil film correctly.

In connection with correction factors for bearings of finite length, Fig. 10 of the paper is very interesting. It will be noted that the values of the ratio L_1 giving the effect of finite length lie very close to an average curve, whether a plane bearing or a journal bearing be considered. This justifies the application of conclusions arrived at, when analyzing one kind of bearing, such as a plane bearing, to any other kind, such as partial journal bearings, and vice versa. This is particularly important with the present trend toward shorter journal bearings.

In conclusion, the writer wishes to call attention to the tremendous amount of work, analytical, numerical, and experimental, which is involved in the preparation of the paper and the tables given in it. Part of the work was made possible only by the ingenious device for experimental integration of the hydrodynamic equation of an oil film invented by Mr. Kingsbury and reported before the Society last year. This device, consisting of an electric analogy, will be used, no doubt, extensively in laboratories concerned with the mechanism of fluid lubrication. It must be remembered that there are numerous questions to be solved yet, such as the oil-film performance under a rotating load, the behavior of oil films in bearings under shock loads, oil flow in bearing clearances, etc.

M. Stone.[9] In this paper the author has provided the engineer interested in designing bearings beforehand rather than explaining phenomena in an existing bearing, with procedures for creating optimum conditions that he has hitherto lacked. The important influence of side leakage has been quantitatively introduced. Throughout the paper attention has been called to the importance of knowing what the minimum film thickness is, and that this be the prime consideration in bearing design. Some three years ago, the writer had occasion to study the dynamic stability conditions in a bearing oil film, with the purpose of determining the actual motion of the shaft in the bearing during rotation and at different speeds.

The measurements made were extremely accurate—down to 10^{-5} in.—specially developed coupled transformers being used, with the shaft acting as the movable armature. The results—the actual motion of the shaft, plotted inside the clearance circle—are shown in Fig. 11. The tests were made in a 10,000-hp. generator running at 900 r.p.m. and having a 9-in. diameter 90-deg. partial bearing, with a projected-area pressure of 102 lb. per sq. in. From these plots, by graphing the equilibrium position of the shaft center, we can obtain two important verifications of the hydrodynamical theory: (1) minimum oil-film thickness vs. ZN/P, and (2) locus of shaft center as a function of shaft speed.

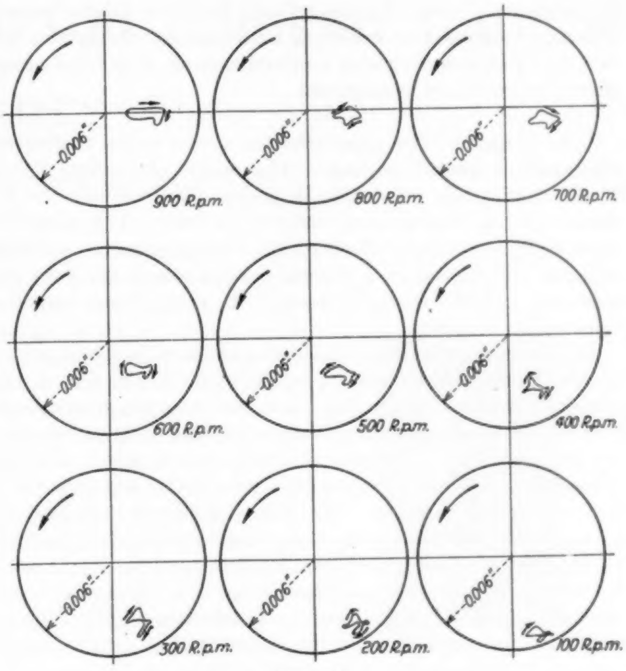

Fig. 11

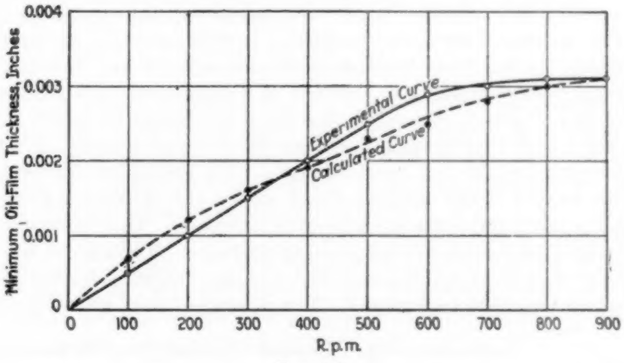

Fig. 12

The first curve is shown in Fig. 12, where it is compared with the theoretical one calculated by G. B. Karelitz in his paper "Charts for Studying the Oil Film in Bearings" [Trans. A.S.M.E., vol. 47 (1925), p. 1101], slightly modified to include side-leakage effects. This indicates that the major design premise in bearings—the minimum oil-film thickness—has every assurance of experimental justification for all types of practical bearings.

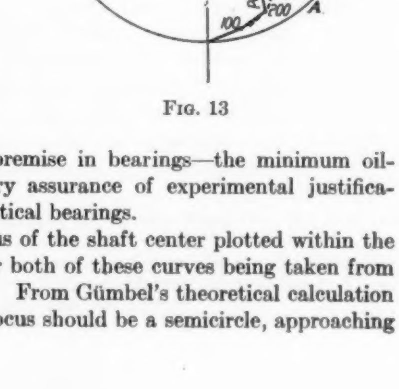

Fig. 13

Fig. 13 shows the locus of the shaft center plotted within the clearance circle, data for both of these curves being taken from results shown in Fig. 11. From Gümbel's theoretical calculation for total bearings, this locus should be a semicircle, approaching the geometrical center for theoretically infinite rotational speed. The departure from the semicircle is accounted for mainly by the fact that we are dealing with a partial bearing, with side-leakage effects that may not be neglected.

---

[9] Development Section Engineer, Power Engineering Dept., Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa.

I. A. TERRY.[10] The paper presents a very useful theoretical treatment of journal bearings. The results of Sections VI to X are particularly interesting in giving quantitatively the influence of side leakage and variable viscosity. The summary given in Plate 10 of the effects of side leakage upon the carrying capacity and friction of a journal bearing makes the data immediately available for use in design if the value of minimum film thickness h_0 is known.

Three classes of bearings have been considered in the paper, all of which have been based upon an initial knowledge of the minimum thickness of oil film. A fourth class which represents a large portion of the bearings used on rotating electrical machinery has conditions as follows: A definite load is to be carried by a bearing at a certain speed with a minimum journal diameter and a given oil viscosity. The journal diameter may be fixed by torque requirements or mechanical limitations. It is required to find the bearing proportions for minimum loss or, stated in different terms, minimum temperature rise. This set of conditions has led in recent years to a reduction of the ratio of length in an axial direction to journal radius (w/a), with a somewhat corresponding increase in unit pressures because of the fact that the coefficient of friction λ decreases faster than the unit pressure p increases. It has also led to a study to determine the optimum clearances for such a journal bearing. One procedure for this study has been to use the curves of Mr. Howarth's paper[11] corresponding to the type of bearing used, that is, complete or partial, then, with the given conditions of speed, viscosity of oil, and assumed pressure, the loss in a bearing for different clearances has been obtained. The results are similar to the λ-curve of the author's Fig. 4, except the ordinate is loss in kilowatts and the abscissa is bearing clearance. This shows some latitude in the selection of running clearance. Tests which have been made on large journals with various clearances have given rather unsatisfactory results. In a number of cases where curves showed that an increased clearance would give a lower loss, the bearings were bored out and the operating temperature was actually decreased. In other cases where the curves showed that a reduced loss should be obtained on increased clearances, enlarging them made practically no difference. Evidently other factors than those considered by Mr. Howarth enter the problem, and perhaps the effects of side leakage is one of the more important theoretical ones. Probably the greatest difficulty in the whole study is the fact that small differences in journal and bearing surfaces seem to make rather radical differences in bearing operation. It would be interesting to know if the author considers that the curves given by Mr. Howarth could be modified by means of Plate 10 to form a basis for a more complete theoretical study of this problem.

AUTHOR'S CLOSURE

The simplification offered by Professor Duffing effects an appreciable saving in the labor of calculation. The small discrepancies between his numerical results and those shown in the paper appear to be due to less exact calculation from his formulas.

Professor Duffing has also pointed out that in Equation [27] of the paper, the logarithmic terms cancel out, and therefore may be omitted, with a helpful saving in numerical work. This work is at best a serious burden, as suggested by Professor Karelitz; and any and all means for reducing it will aid progress in the study of the subject.

Referring to Mr. Terry's question regarding the graphical solutions of Mr. Howarth [13]: The graphical work has been checked at numerous points by the analytical forms of the present paper, and no appreciable discrepancies have been found. It may therefore be said that the graphical results are trustworthy, and may be used instead of the analytical solutions for the "infinitely wide" bearings. As to their application in connection with plate X of the present paper, this figure is derived only for the conditions of eccentricity etc. that are assumed to be the "optimum" ones. For other conditions of eccentricity etc. the effects of side leakage indicated in plate X, especially as regards the load factor L_1, could not be expected to apply closely. In fact, recent researches by Mr. Needs, using the electrical method, indicate that the L_1 curve itself should be regarded as a first approximation, not as a finality; but its use gives load values that are on the safe side. The F_1 curve does not appear subject to as great corrections.

Pressure Distribution in Oil Films of Journal Bearings

By S. A. McKEE[1] and T. R. McKEE,[2] WASHINGTON, D. C.

S. A. McKee

T. R. McKee

One fact which is becoming widely recognized by users of journal bearings is that under proper conditions of operation the load applied to a journal bearing is supported by the hydrostatic pressures built up in a film of lubricant wedged between and completely separating the journal and bearing. This paper describes an investigation at the Bureau of Standards the purpose of which was to determine the distribution of pressure in the oil film of a full journal bearing for various conditions of operation and of bearing construction. A specially designed apparatus provided a means for measuring the film pressures at practically all points on the surface of a bearing when operating under different conditions of load, speed, and viscosity of the lubricant. The results of nine tests made under conditions involving changes in clearance, load, speed, and viscosity are presented graphically in the form of pressure-distribution curves. In conclusion the characteristics of the film-pressure distribution are summarized, and further steps toward a better understanding of the pressure distribution are outlined.

ONE method of procedure in the design of a journal bearing suitable for a given machine and operation is based upon the hydrodynamic analysis of the load-carrying oil film. This analysis originated in the work of Tower, Reynolds, and Sommerfeld, and was made more complete by Kingsbury, Harrison, Howarth,[3] and others.

Another method, originated by Hersey,[4] is based upon certain general relations derived by dimensional analysis, and may be used for the planning of experiments and for the interpretation of the data obtained.

While in principle the former method requires no special experiments, the mathematical treatments are in general approximations involving simplifying assumptions which may not be applicable to an actual bearing. Both methods are therefore dependent to a considerable degree upon direct experiments. With the former method it is necessary to check the correctness of the assumptions and in the latter to obtain suitable coefficients for the dimensionless relations developed.

The problem may be attacked experimentally by observing the effects of changes in the construction of the bearing and in the conditions of operation upon (1) the friction developed in the bearing, (2) the minimum thickness of the oil film, and (3) the hydrostatic pressures developed in the film.

Each of these factors is a variable dependent upon construction and operation, and it is probable that a thorough knowledge of all three will be necessary to eliminate guesswork in bearing design. The first, the friction developed, provides a convenient means for studying the economic question of power losses in bearings, the heat developed, and with proper correlation of data may be used for the determination of the carrying capacity of bearings. It is of special use also in the study of bearing performance when conditions of operation are such that a complete film of lubricant is not maintained between the rubbing surfaces. The second, the minimum thickness of the oil film, is of special significance in the determination of the carrying capacity or factor of safety. The third, the hydrostatic pressure distribution in the film, possibly offers the most direct means for comparison with analytical studies based upon the principles of hydrodynamics. Notable progress in the study of the problem from this standpoint has been made in a recent development by Kingsbury[5] in which the number of cases where solutions to the analytical treatment are possible has been greatly increased by an ingenious experimental method of making electrical measurements upon enlarged models of the film.

The bearing herein described provides a means for the study of

this third factor—namely, the hydrostatic pressures developed in the oil film under various conditions of actual operation.

THE APPARATUS AND ITS OPERATION

The apparatus as originally designed was built in 1926. At that time, however, it was capable of measuring the film pressures only at the longitudinal center of the bearing. Changes in design were made in 1930 to permit determinations of the film pressure at practically any point on the whole bearing surface.

A photograph of the complete apparatus set up for use is shown in Fig. 1, and a drawing showing the arrangement of the principal working parts in Fig. 2.

The hardened and ground steel test journal (*A*, Fig. 2) is provided with a Morse taper for attaching to a vertical spindle mounted on the frame of a portable drilling apparatus and driven through belt and pulleys by an electric motor. This special drive is not essential, since an ordinary power drill press may be used if convenient. The actual working surface of the journal is 1 in. long and is located at the extreme lower end.

The bearing consists of two parts which can be rotated relative to each other around the axis of the bore. One part includes the bearing proper *B*, the oil bath *C*, and the thermometer well *D*. The bearing proper is a bronze bushing 2 in. long with a $^7/_8$-in. bore provided with the pressure tap *E* (a small hole 0.025 in. in diameter) at its longitudinal center and radial to its axis. The other part includes the yoke *F* and the adjustable nut *G* for connecting a horizontally mounted spring balance (see Fig. 1) used for applying the load. The yoke is held in place longitudinally by the collars *H* and *J*. The pressure tap is connected by copper tubing, manifold, and needle valve to a small combined vacuum and pressure gage (—15 to 100 lb. per sq. in. gage) mounted on the thermometer well. The weight of the bearing is supported by a horizontal table through the ball *K* set in the socket at the base of the oil bath. Counterweights are provided on the oil bath and yoke so that the gravitational forces are symmetrical about the ball. By this means unknown gravitational moments are eliminated and the sole force acting on the bearing surfaces is that caused by the pull of the spring balance.

By means of this apparatus the film pressures over practically the entire working surface may be observed with one pressure tap and gage. The angular location of the tap relative to the line of application of the load may be changed by releasing the wing bolt *L* and revolving the bearing within the yoke, the thermometer well acting as a convenient handle. Marks on the upper collar at 6-deg. intervals from the pressure tap in conjunction with a mark on the yoke at the center of load provide an indication of the location of the tap. The location of the tap relative to the ends of the working surface of the bearing may be changed as desired by moving the journal up or down in the bearing. This is accomplished by the "feed" on the portable drilling apparatus, a locking device with screw adjustment being attached for maintaining the journal in a given position. A mark on the upper part of the journal together with a special scale for fitting to the top of the oil bath provide a means for determining the longitudinal position of the tap. The nut *G* and the adjustable table (see Fig. 1) for holding the spring balance provide a means for centering the load for any position of the journal. A mark on the nut and a scale on the yoke are used for indicating the position of the load. These adjustments may be used also for making tests with the load off center.

The level of the lubricant in the bath is kept above the top of the working surfaces. The hollow arms from the bath to the thermometer well allow for circulation of the lubricant and prevent any pressure being built up in the lower portion of the bath other than that caused by the slight head of oil. By the use of the vertical journal and bath lubrication, oil is at all times automatically admitted to the proper point on the periphery of the bearing

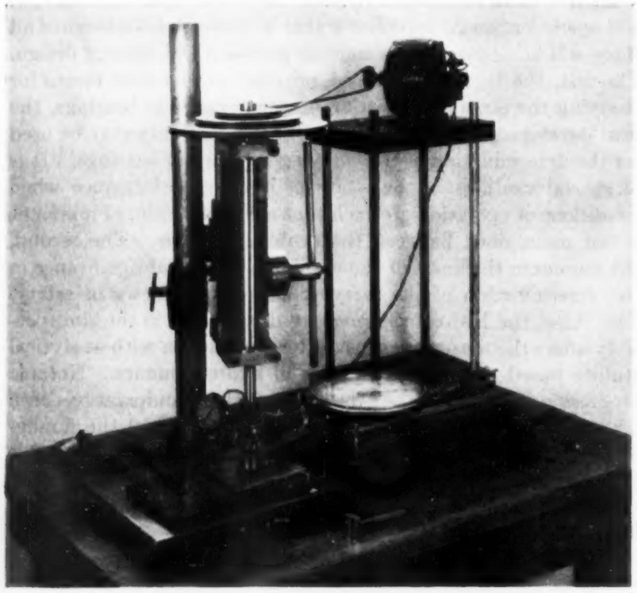

FIG. 1 JOURNAL-BEARING FILM-PRESSURE APPARATUS, GENERAL ARRANGEMENT

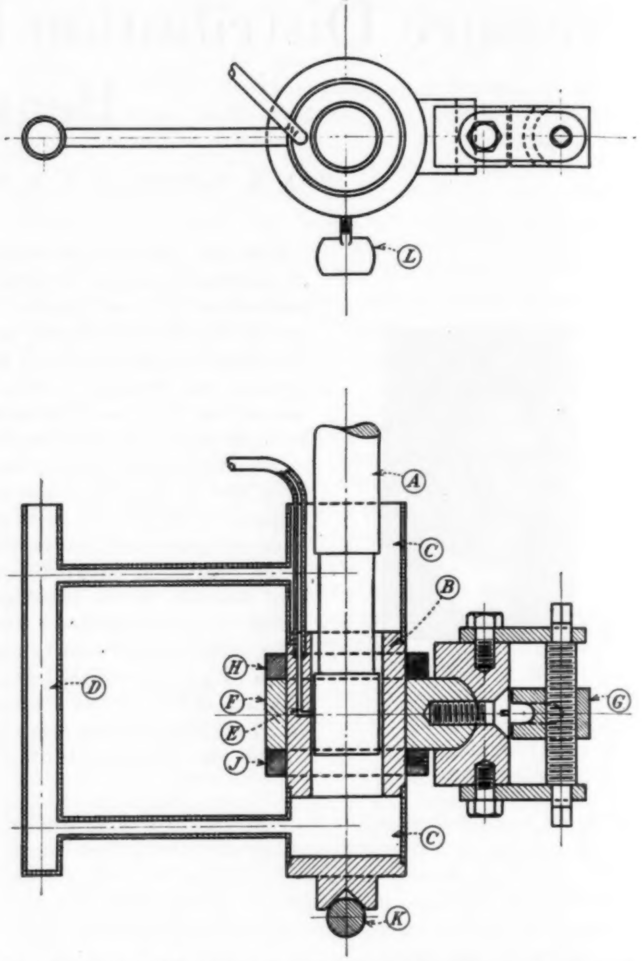

FIG. 2 JOURNAL-BEARING FILM-PRESSURE APPARATUS, ARRANGEMENT OF PRINCIPAL WORKING PARTS

The time required for the gage to indicate the pressure in the film at the bearing tap is kept small by making the pressure connections as short as convenient and by evacuating the air from gage and connections and filling with lubricant.

Trial runs indicated that accurate alignment of the load and the journal was necessary for obtaining a symmetrical longitudinal pressure distribution. It was found more convenient to secure the proper alignment by observing the pressure at certain points rather than by ordinary mechanical methods. A suitable screw adjustment for tilting the journal in relation to the line of the load was attached to the portable drilling frame. (If a regular drill press had been used, an adjustable table would probably have been more convenient.)

Since it is necessary to release the load and stop the journal in order to change and observe the longitudinal position of the pressure tap, it was found more convenient to make all the observations around the periphery in a given plane perpendicular to the journal before changing the longitudinal position of the tap. In each of the tests conducted with a given load, speed, and lubricant, observations were made in 11 different planes perpendicular to the length of the bearing surface.

Test Conditions

Of the tests made, each gave an indication of the distribution of pressure in the oil film for a particular condition of operation or construction. The factors changed were clearance, viscosity, speed, and load. Changes in the clearance were made by using two journals, one having a clearance (difference of diameters) of approximately 0.005 in. and the other of 0.002 in. Viscosity changes were made by the use of two lubricants, one having a viscosity of 125 sec. Saybolt Universal at 100 deg. fahr. and the other of 73 sec. Saybolt Universal at 100 deg. fahr. Large changes in speed were made by using pulleys of different sizes, and speed regulation was provided by a rheostat in the motor circuit. The load was limited to a certain extent by the range of the pressure gage used on the apparatus, and with the exception of one test a load of 25 lb. was applied. No attempt was made to control the temperature of operation, which was measured by a thermometer inserted in the well. However, the apparatus was allowed to come to steady conditions at a given load and speed before pressure readings were started.

The conditions of operation and construction in the respective tests are given in Table 1.

TABLE 1 TEST CONDITIONS

(Diameter of bearing, 0.8753 in.; length of bearing, 1 in.)

9.......	0.8733	0.002	25	553	20.0	389	0.1 in. off center

Symbols and abbreviations used for expressing the various factors pertaining to the bearing and its performance are as follows:

D = journal diameter, inches
C = diametral clearance (difference between bearing diameter and journal diameter), inches
L = bearing length, inches
P = bearing pressure (total load/DL), pounds per square inch
Z = absolute viscosity lubricant, centipoises
N = journal speed, revolutions per minute
p = hydrostatic pressure in film, pounds per square inch
θ = angle to point where p is measured as shown in Fig. 3. θ is measured in the direction of rotation of the journal and expressed in degrees.

Graphical Presentation of Results

The results obtained in test No. 1 are shown graphically in Fig. 4.

The circumferential pressure distribution is given in *A*. These curves are obtained by plotting the observed pressures against the circumferential location of the tap as measured by the angle θ. Each curve is for a different position of the tap along the journal axis as indicated in terms of decimal parts of *L*, the bearing length. The curve labeled 0.5*L*, for example, indicates the pressure distribution around the circumference of the bearing on a plane perpendicular to the axis of the journal and at the longitudinal center of the bearing surface.

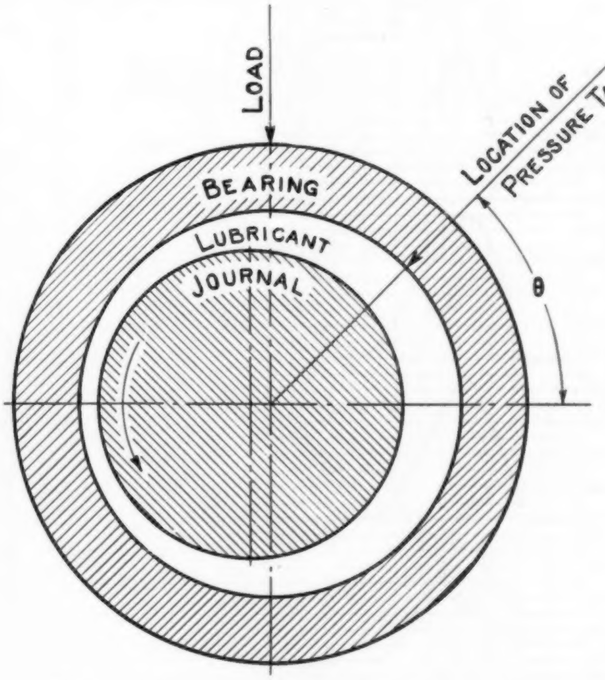

Fig. 3 Diagrammatic Representation of Bearing

(Angle θ, measured in the direction of the rotation of the journal, is used to indicate any particular circumferential position of the pressure tap.)

Curves showing the longitudinal distribution are given in *B*. These are made by plotting the observed pressures against the position of the tap relative to the length of the bearing for the given angle θ as noted below each curve. For example, the curve labeled $\theta = 90$ shows the pressure distribution along an element of the bearing passing through the point where the load is applied.

An isobaric plot of the film is shown in *C*. In this figure the bearing surface is developed into a plane with a length equal to the circumference (πD) and width equal to *L*. Upon this, isobars (loci of points of equal pressure) are plotted for gage pressures of 0 (atmospheric), 20, 40, 60, 80, and 100 lb. per sq. in. The shaded portion indicates roughly the region where the film pressures are negative (below atmospheric). Except for this region of negative pressure, the entire area outside the zero isobar is at atmospheric pressure.

Fig. 7 Curves Showing Distribution of Pressure in Oil Film of Journal Bearing

(Diameter of journal, 0.8703 in.; length of bearing, 1 in.; clearance, 0.005 in.; load, 20 lb.; speed 244 r.p.m.; viscosity of oil, 34.4 centipoises; $ZN/P = 368$.)

shown in *D*. These curves are similar to those shown in *A* except that those labeled 0.05*L*, 0.1*L*, 0.2*L*, 0.3*L*, and 0.4*L* in *D* are the arithmetic means of curves 0.05*L* and 0.95*L*, 0.1*L* and 0.9*L*, 0.2*L* and 0.8*L*, 0.3*L* and 0.7*L*, and 0.4*L* and 0.6*L*, respectively, in *A*. In other words, the curves in *D* represent the circumferential distribution at the respective planes along the length of the bearing if the pressures along any element at two points the same distance from each end had been equal and also the arithmetic mean of the pressures observed at these points.

The curve in *E* is obtained by plotting the mean effective pressures for the various values of θ against the diameter of the journal. The mean effective pressure for any value of θ was obtained by integrating with a planimeter the curves in *B*. The area inclosed by this curve is therefore a measure of the resultant of all the pressures acting parallel to and against the load imposed on the bearing. The area indicated by the shaded rectangle is a measure of this load; thus a comparison of the areas inclosed by the curve and the rectangle, respectively, gives an indication of the accuracy of the pressure observations.

Similar curves showing the results of tests 2, 3, 4, 5, 6, 7, 8, and 9 are given in Figs. 5, 6, 7, 8, 9, 10, 11, and 12, respectively.

Discussion of Results

Comparison With Hydrodynamical Equations. From the mathematical analyses by Sommerfeld or by Harrison it can be shown that in a complete journal bearing free from end leakage and operating under steady conditions such that a complete film of the lubricant separates the journal from the bearing, the

journal will take up some such position as is shown by the exaggerated cross-section in Fig. 3. In a given bearing of this type, the coefficient of friction, the eccentricity, and when the load is constant the pressure distribution all are dependent upon the operating variable ZN/P. Since there is no end leakage, the pressure will be constant along any element of the bearing; thus a single curve will represent the circumferential pressure distribution for a given bearing operating under a given load and at a given value of ZN/P.

A comparison of the pressure distribution for such a bearing and the pressures observed in one of these tests is shown in Fig. 13. In this figure curve A shows the circumferential distribution at the longitudinal center of the bearing obtained in test No. 6. Curve B represents the distribution as calculated from Harrison's equations for a bearing with no end leakage operating under the same conditions of load, speed, viscosity, and clearance and with the assumption that the lubricant is fed at atmospheric pressure to the point of minimum pressure on the bearing periphery.

From this figure it is apparent that the actual bearing has the pressure characteristics of a partial rather than a complete bearing. This fact together with the drop in pressure toward each end is the obvious explanation for the maximum pressure in curve A being so much greater than that of curve B.

Effect of Changes in Clearance. From Table 1, it is seen that the load, speed, and viscosity of the lubricant in test 3 are practically the same as in test 6, but that the clearance was much greater. Thus a comparison of the curves in Figs. 6*D* and 9*D* should give some indication of the effect of a change in clearance. These curves show that the pressure distribution in the bearing with the large clearance differs from that with the small clearance in the following characteristics: (1) The region of varying pressures extends over a greater arc, (2) the maximum pressure is greater and at a larger value of θ, (3) the rise in pressure as θ increases is more gradual and the drop more abrupt.

It should be noted that with the method used for supplying the lubricant, it is necessary for the oil to be drawn from the ends toward the center of the bearing. Thus a decrease in the width of the orifice through which the oil must flow might be expected to have a noticeable effect upon the amount of oil available to the bearing surfaces and may possibly be the reason why the area of varying pressure with the small clearance is less than that with the large. In some of the tests, however, an oil of lower viscosity was used. One reason for the use of this oil was the expectation that the lighter oil would flow more readily toward the center of the bearing and possibly give a comparative indication of the magnitude of this throttling effect. In this respect it is of interest to note that the pressure curves obtained with both oils with the same journal extended over approximately the same portion of the bearing surface.

Effect of the Value of ZN/P. Tests 6 and 7 were made with the same clearance and load and at practically the same value of ZN/P. In test 6 this value of ZN/P was obtained by a relatively low speed and high viscosity, while in test 7 a relatively high speed and low viscosity were used. A comparison of the curves shown in Figs. 9 and 10 for the respective tests indicates that the pressure distributions are practically alike. This is of interest in that it is what would be expected from dimensional analysis or the hydrodynamic equations.

Longitudinal Distribution. From the general trend of the longitudinal distribution curves it would appear that if perfect journal and bearing surfaces and perfect alignment had been attained the longitudinal pressure distribution at any value of θ in a region of positive pressure would have approximated a parabola symmetrical about the center of the bearing when centrally loaded. This of course assumes that the irregularities and scattering of observations as shown by the curves are caused by irregularities of the journal and bearing surfaces and by accidental misalignment in addition to experimental error.

Eccentric Loading. In tests 7 and 9 the conditions of operation were approximately the same, except that in test 9 the load was shifted to a point 0.1 in. from the longitudinal center of the bearing. A comparison of the pressure distribution curves for the respective tests shown in Figs. 10 and 12 indicates that the effect of eccentric loading is to increase the maximum pressure in the oil film and to move the point of maximum pressure away from the longitudinal center of the bearing in the same direction as the shift in the point of application of the load.

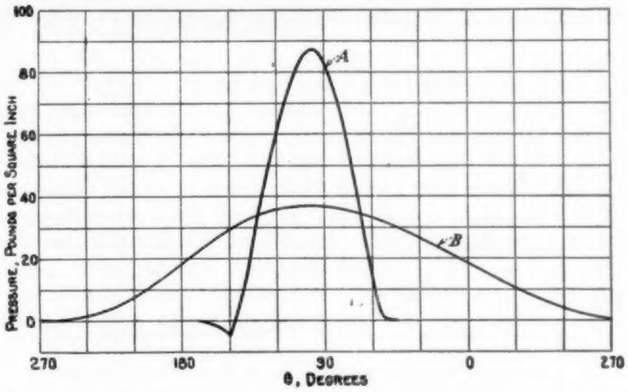

FIG. 13 COMPARISON OF EXPERIMENTAL AND CALCULATED DISTRIBUTION

(Curve A, circumferential distribution at center of bearing, test 6; curve B, circumferential distribution computed from hydrodynamical equations for same bearing under same operating conditions, but with no end leakage.)

SUMMARY

The characteristics of the film-pressure distribution indicated by this investigation may be summarized as follows:

1 The load applied to the bearing was in most cases wholly supported by the hydrostatic pressures in a film of the lubricant between the surfaces of journal and bearing.

2 In all the tests the pressure distribution was typical of a partial rather than a complete bearing.

3 The maximum pressure observed in the bearing for given operating conditions was usually considerably greater than the maximum pressure computed from hydrodynamic equations for a bearing with no end leakage operating under equivalent conditions.

4 The maximum pressures observed for the various conditions of operation were from two and one-half to four times the load per square inch of projected area.

5 The curve showing the longitudinal distribution along any element of the bearing in the region of positive pressure approximated a parabola in shape when the bearing was centrally loaded.

CONCLUSION

The results obtained in these tests of course apply only to the particular conditions present, and it would not be justifiable to predict that they are a reliable indication of the pressure distribution characteristics of bearings where the factors of construction or operation are markedly different.

Further steps toward a better understanding of the pressures developed in the oil films of bearings in actual service suggested by these tests are to determine the pressure distribution under various conditions favorable for a study of the following factors: the absolute size of the bearing, the bearing length, journal deflection, distortion, temperature gradients in the oil film, method of applying the lubricant, and partial or complete rupture of the oil film.

Discussion

D. P. Barnard.[6] From this work it seems evident that pressure-distribution studies represent the most effective tools for investigating bearing performance. Of particular interest to the writer are the virtually identical pressure distributions obtained at different speeds and oil viscosities, but at the same values of ZN/P. It would appear that as this work progresses it should lead to the deathblow for the time-honored pV-product or "rubbing factor," particularly for bearings operating at the higher rubbing speeds. Figs. 8 and 11 are of particular interest in that the longitudinal pressure gradients observed tend to corroborate the influence of ZN/P values on oil-pumping efficiency as observed by the writer several years ago.[7] Fig. 14 is a reproduction of the Fig. 2 presented at that time and shows an observed reduction in pumping efficiency from 0.3 to 0.2, which is about as might be expected by comparing the pressure contour diagrams in Figs. 8 and 11. The similarity of the pressure distributions observed in Figs. 9 and 10 also tends to verify this effect.

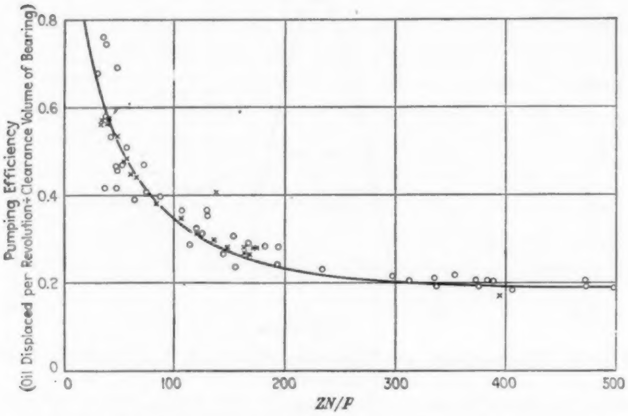

Fig. 14 Oil-Flow Characteristics of Complete Journal Bearing

(Oil-feed pressure, 10 lb. per sq. in.; diameter, 1 in.; length, 2 in.; ○ clearance of 0.0006 in.; ×, clearance of 0.0011 in.)

F. E. Cardullo.[8] The paper admirably serves to point out the great importance of end leakage in the hydrodynamic theory of journal bearings. The method used by the authors to obtain the pressure of the oil films at different points on the bearing surface is ingenious, but it necessarily produces hydrodynamic conditions different from those encountered in an ordinary bearing, and these conditions are unfavorable to lubrication.

In all practical bearings the oil is plentifully supplied by a longitudinal groove at a point where the pressure is such that the oil can readily enter the bearing and be swept into the region of maximum pressure by the revolving journal. In the case that the authors describe, such a groove is necessarily absent, and the oil has to find its way into the bearing through the clearance space. The conditions of pressure distribution which the authors have found therefore differ somewhat from the conditions of pressure distribution which would be found if an oil-distributing groove were provided. The large clearances used in the authors' tests are made necessary by the absence of such a groove.

It would be very interesting if the authors would add test results of the effect of length of bearing on the distribution of the pressure. All tests apparently were made with a fixed ratio of length to diameter.

In view of the forms shown by the circumferential distribution of pressure, it would be well for the authors to continue their experiments using a fairly wide distribution groove approximately opposite to the point of minimum of clearances, and to have available, not one, but a number of holes in the box, through which the oil pressure could be measured. The pressure could be read simultaneously or tiny valves be provided in the body of the box which would serve to connect any one of the several openings with the pressure gage. It would be a matter of great interest to compare the authors' results with the results obtained when an oil-distribution groove is used.

M. D. Hersey.[9] The A.S.M.E. Special Research Committee on Lubrication asked to have a limited number of experiments made with an oil-hole bearing also, reproducing conditions in the preceding investigation (effect of clearance and length). This was done, and showed agreement with dimensional analysis, also fair agreement with the submerged bearing. Can the authors supply particulars?

Dr. G. F. Rouse was asked by the committee to compute the hydrodynamic theory of the McKee test, neglecting circumferential flow instead of neglecting longitudinal flow, and found closer agreement than is shown by Fig. 13.

The writer believes the McKee data furnish the best expression available of full bearing characteristics, and therefore he questions the statement that tests agree better with partial bearing.

Dimensional analysis predicts the same relative pressure distribution for larger diameter bearings if strictly geometrically similar and running at the same value of ZN/P.

H. A. S. Howarth.[10] It seems that the authors "builded better than they knew" when they devised their testing machine. Their apparatus is beautifully simple and effective, and work upon it should be continued. A larger journal would have some obvious advantages, and higher unit loads should be tried. No amount of argument over the advantages of ZN/P will convince the layman so well as tests on a full-size model.

The authors are very modest in suggesting a limited practical value of such tests as they have conducted. They need not regret their inability to measure film thicknesses and friction. After all is said, are not the pressure distribution and loads safely carried the most important data of all for checking the hydrodynamical theory?

The exploration of pressure distribution by means of one hole has its advantages and its disadvantages. First, the resulting curves of recorded pressures will appear consistent, whether right or wrong, because the perfection or imperfection of the bearing surface about the hole will be present for every observation. Second, the bearing surface opposed to the journal is not the same for all axial positions of the one observation hole. A great degree of accuracy is necessary, therefore, in the bearing surface and also the journal.

The symmetry of the curves of "longitudinal distribution" of pressure indicates a fair degree of accuracy in the second respect. The θ-values below the curves of "circumferential distribution" of pressure, however, seem to indicate some defect in the bearing surface near the observation hole, which means that the first requirement is not fulfilled.

An examination of the curves of pressure distribution around the journal should enable one to place the position of the resultant with fair accuracy by inspection. The directions of such resultants appear to be about 10 deg. farther around the journal than the authors place their applied-load lines.

[10] General Manager, Kingsbury Machine Works, Inc., Philadelphia, Pa. Mem. A.S.M.E.

One cannot explain this by the turning of the bearing shell to balance the friction, because such turning would serve only to increase the apparent discrepancy. The only explanation that occurs to the writer is the presence of a bulge ahead of the observation hole, tending to reduce the gage pressure below the average pressures that actually existed along that element of the cylindrical surface.

Further evidence of the possibility of the presence of the defect mentioned is the moderate length of the arc between the zero and 20-lb. isobars in Figs. 4-*C* to 7-*C*, and the considerably reduced arc that appears in Figs. 8-*C* to 11-*C* for the case of smaller clearance. One would expect the smaller clearance to increase the range of the positive pressures. Also, if there were a bulge producing negative effect just ahead of the pressure-measuring hole, its influence would be more pronounced with the smaller clearance.

Now with regard to Fig. 13, the authors have in it taken their shot at the hydrodynamical theory, as it relates to a full bearing. Why bring that up? Unless an experimenter is able to produce a film with measurable pressures throughout the whole circumference of the journal, he should let the poor old full bearing alone. He should compare his test results with theoretical films that are really comparable with them. There are now plenty of data on theoretical oil films of partial bearings, especially if the influence of side leakage be neglected.

The practical value of tests of this kind is considerable, when we are sure our measured pressures give a fair picture of those in the film. The authors have shown, for example, the parabolic transverse distribution of pressures. One can therefore say that if side leakage did not take place, the test load could have been carried by pressures two-thirds as great as those measured. A reference curve could therefore be drawn with ordinates two-thirds as high as those found in the mid-plane of the bearing.

To this reference curve we could fit a theoretical pressure curve of a suitable partial bearing, produced by similar speed and viscosity. The eccentricity which this theoretical curve represented would be another reference point. We would know that the actual eccentricity was greater than this reference value, because if it were not greater, the test pressures could not have been produced.

One could go a step further in analysis of the test results, and assume, what is probably close to the fact, that the shape of the actual test film would be close to the optimum investigated by Mr. Kingsbury. One could therefore apply his charts to the tests and determine what was the probable film shape and minimum thickness. By doing this one would discover how closely the most fully developed theory will fit in with actual test conditions.

It is for these reasons that, as said in the beginning, the authors "have builded better than they knew." They have shown an easy way to obtain test data that can be used to determine the degree of reliability of the hydrodynamic theory as extended and interpreted by Mr. Kingsbury and other investigators.

Adolph A. Moline.[11] The authors have presented a very interesting method for determining hydrostatic pressures in oil films. It gives a very close approximation to the conditions in an actual bearing.

Comparing curves C, Figs. 4, 6, and 12, the lines indicating the higher pressures in C, Fig. 4, are fairly symmetrical about the center line of the load application, but are shifted a considerable distance away from the center line of load application in C, Figs. 6 and 12. Possibly this is due to a slight deflection in the shaft. Will the authors please comment on this point?

The writer has observed peak pressures of from two to three times the load per square inch of projected, which agrees with the results found by the authors.

On large machines, in order to reduce the starting torque, oil under high pressure is fed under the journal through a small opening in the bearing shell. If a gage is placed in this oil-feed line, the pressure indicated, after the starting period, is that near the peak load. Any lowering or fluctuating of this pressure would indicate trouble in the bearing. Some operating companies use this idea and claim it is superior to that of the more commonly used thermostat or thermometer.

S. J. Needs.[12] The idea of shifting the journal to make an entire exploration with one pressure hole is quite ingenious, but it has the undesirable feature that each different circumferential pressure reading is made at a different position of the journal in the bearing, hence on a different bearing. The effect of this on the pressure curves is probably slight at the loads and speeds under which the experiments were conducted, particularly if the bearing was round and of uniform diameter.

The general slope of the isobaric plots would seem to indicate that the axes of the bearing and journal were not parallel in the running position.

Apparently, convection is relied upon for oil circulation. The position of the thermometer would hardly afford an accurate indication of the bearing temperature. However, if there is no change during a run, knowledge of the temperature is not necessary except for comparison with other runs and theory.

In Fig. 13 the authors compare the circumferential pressure distribution at the longitudinal center of the bearing, as found in a particular test, with the calculated theoretical distribution curve. At first glance the theory appears inadequate. Curve *A*, however, represents the maximum pressure values found, while *B* represents the mean pressures, constant over the bearing width at a given value of θ. It would seem more reasonable to the writer to compare the mean of the test results with the theoretical mean, bearing in mind that the theory neglects side leakage. This the writer has done in Fig. 15. The curve *B* is taken directly from Fig. 13, while the curve *A′* represents the mean of the longitudinal distribution curves given in Fig. 9. The mean values were found by planimeter.

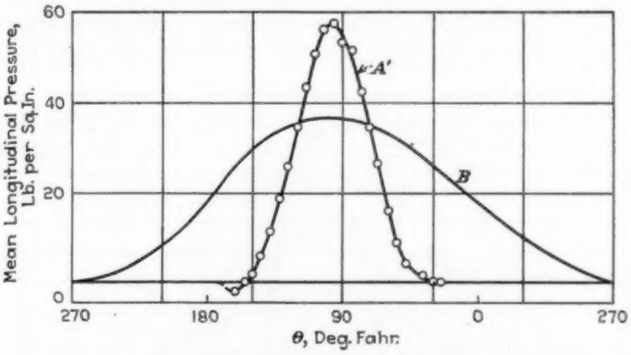

Fig. 15 Comparison of Calculated and Experimental Distribution

Neglecting side leakage, curves *A′* and *B* are now directly comparable, and their lack of similarity opens a most interesting field of discussion. The classical hydrodynamic theory appears inadequate, yet Professor Kingsbury's experiments on an air-lubricated bearing have established the theory on a rather firm foundation, at least for an incompressible lubricant. All the available test results on complete journal bearings, using an incompressible lubricant, indicate that the oil film has not the strength to resist the tension set up by diverging surfaces on the "off" side of the bearing. Hence, rupture and zero pressures. The greater the clearance and load, the shorter the useful or load-carrying arc of bearing. Possibly with reduced clearances and loads, the authors will find an increased angular length of bearing having positive pressures, the oil being introduced at the theoretical point of minimum pressure. This conceivably could be extended to a check of the hydrodynamical theory.

[11] Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa.

[12] Research Engineer, Kingsbury Machine Works, Inc., Philadelphia, Pa. Jun. A.S.M.E.

It is interesting to further examine the curves A' and B. The area under each represents their respective load-carrying capacity. A' from the test bearing, subject to side leakage, has an area of 2.70 sq. in. to a certain scale. B was computed from an equation uncorrected for side leakage. The area of B is 5.48 sq. in. to the same scale as A'. From A' the effective bearing arc is about 128 deg. This gives a length-to-width ratio of 0.977. The side-leakage factor for partial cylindrical bearings of this length-to-width ratio has been found to be 0.494. Correcting B by this factor gives $5.48 \times 0.494 = 2.71$ sq. in., about the same capacity as the test bearing.

It is the writer's belief that the classical theory is an unfailing guide when its requirements of film continuity are met.

A. E. Flowers.[13] It would appear from the omission of any mention of oil grooves in either the bearing or journal that no oil grooves were used. The authors might clarify this point and also answer the question as to whether they observed any experimental evidences of instability of the pressure readings.

It would also be of interest to know whether any of their test conditions approached the critical conditions for film breakdown and whether any checks were made of surface smoothness or efforts made to get the bearing well run-in before taking observations.

R. Plank.[14] The extensive research revealed in the paper means a significant progress in the knowledge of the phenomenon of lubrication, for there was until now but little known about the end leakage and the real distribution of the pressure in bearings. At the same time this research gives a new confirmation of the hydrodynamical theory, particularly if its results are supplemented by the observations of E. Schneider, who in my institute compared some years ago the coefficients of friction of real bearings with the results of the theory. Both papers are in accordance also in confirming better the theoretical equations of Gümbel than those of Sommerfeld, which disagree by different conditions of integration. According to the last research there are only very small negative pressures in the bearings, while the equations of Sommerfeld led to greater negative pressures. Indeed, the theoretical curve B in Fig. 13 runs only in the sphere of positive pressures, but it deviates more from the distribution of pressure experimentally ascertained than the values calculated according to Gümbel. The writer has prepared another Fig. 13 (see Fig. 16) which contains besides the former curves A and B a new one C following the equations of Gümbel.

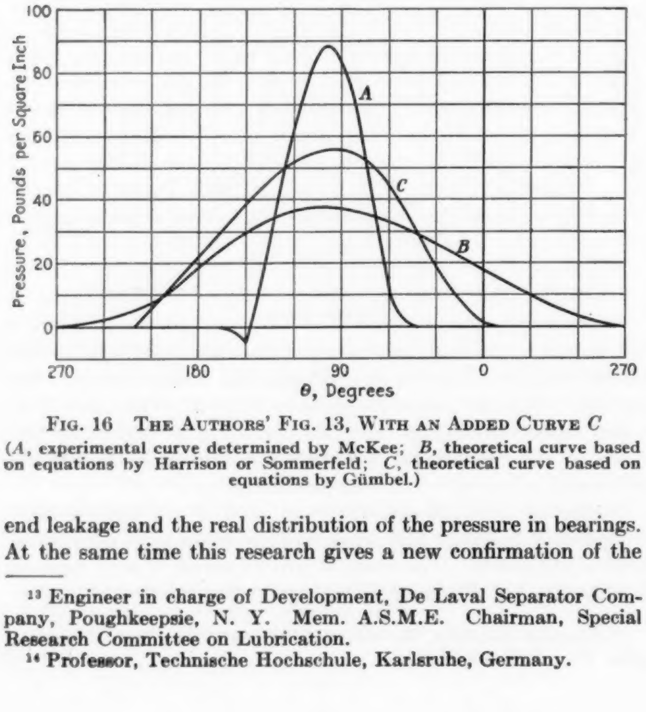

Fig. 16 The Authors' Fig. 13, With an Added Curve C

(A, experimental curve determined by McKee; B, theoretical curve based on equations by Harrison or Sommerfeld; C, theoretical curve based on equations by Gümbel.)

Henri Weiss.[15] The writer would like to ask the authors the following questions: (1) They have shown the existence of a region of negative pressure in the neighborhood of $\theta = 150$ deg. Is this in accord with the fact previously deduced from the study of the parabola of speed of liquid filaments—namely, that at the exit of the wedge of oil certain filaments of oil attain a speed greater than the peripheral velocity of the journal? This fact has been emphasized particularly in a paper by Brillié. (2) The study of the authors shows that the complete journal bearing acts as regards the distribution of hydrostatic pressures as foreseen by theory for incomplete bearings Does not this explain a result found by Mr. S. A. McKee in a previous paper in a study of frictional torque? With small clearance the frictional torque is greater than indicated by hydrodynamic theory; the more so, the less the clearance. Would not the fraction of the

[15] Director, L'École Nationale Supérieure du Petrole, University of Strassbourg, France.

torque indicated by the theory be produced by the oil between $\theta = 0$ deg. and $\theta = 180$ deg.? Would not the excess of torque be produced by the effect of the oil situated between $\theta = 180$ deg. and $\theta = 360$ deg., other things being equal, the influence being the greater the narrower the clearance. In other words, could not this phenomenon be thus explained, without including any effect of oiliness? (3) Given that the main fact put in evidence by the authors is that the distribution of pressure occurs as theory predicts for incomplete bearings, and given that the authors attribute this in all probability to the loss of oil at the sides. It would be of the greatest interest to confirm this explanation by a test. Would it not be possible for the authors to have constructed an arrangement where the loss of oil would be considerably reduced at one side without changing anything else in the apparatus? Perhaps that would permit seeing whether near this side the pressure was distributed in a less localized manner around the periphery of the journal, as Fig. 13 of the paper would indicate. A sketch of the proposed arrangement is given in Fig. 17.

A. Sommerfeld.[16] It is very interesting to see from Fig. 13 how markedly the actual pressure distribution deviates from the theoretical. Besides, the theoretical pressure distribution in my old work (Fig. 15) is not symmetrical about $\theta = 90$ deg., except at extremely high velocities, but is somewhat displaced toward larger angles; i.e., just as in Fig. 13 of the paper. It is especially noteworthy that the region of negative pressure, which can in fact also be indicated by the theory, can be found experimentally. It would perhaps be advantageous, even if somewhat difficult, to extend the theory to the case of a journal of finite length, in order thus to obtain the end effect also theoretically.

May the writer point out that his papers on friction of lubricants, together with papers of N. Petrow, O. Reynols, and A. G. M. Michell, are reprinted in Ostwald's "Klassiker" No. 218, Leipzig, Academy Press, 1927, price about 3 marks.

Authors' Closure

With reference to the discussion regarding the type of apparatus used, it should be noted that the design of a practical apparatus for measuring film pressures in a journal bearing must include some compromise between maintaining conditions as in actual service and obtaining sufficient data for a complete picture of the pressure distribution.

It was realized that with the apparatus used in these experiments the significance of the data was dependent to a considerable extent upon whether or not the journal and bearing were true cylinders, as was mentioned by Mr. Howarth. It was realized also that the lines of flow in the oil film were changed to some extent by the method of applying the lubricant. Its chief advantage, however, is that a sufficient number of observations could be taken to obtain a more complete picture of the pressure distribution than could be advantageously obtained with the two types of apparatus that have been commonly used in this kind of work—namely, the fixed bearing with numerous pressure taps and the swiveled bearing with several taps along the length.

Some indication that the method of applying the lubricant from the ends instead of at the center of the bearing might not materially affect the pressure distribution was obtained in the experiments mentioned by Mr. Hersey. In these tests pressure observations were taken at one point directly opposite the load ($\theta = 90, 0.5\, L$) at various loads and speeds on an oil-hole bearing of different diameter but of approximately the same L/D ratio. The results indicated that the ratio of film pressure at this point to the pressure on the projected area was of the same order of magnitude in both bearings.

It was not the intention of the authors to attempt either to credit or discredit any one of the various mathematical interpretations of the hydrodynamic theory. The chief reason for including curve B in Fig. 13 was to emphasize the fact that the observed film pressures (other than atmospheric) extended over only a portion of the bearing periphery, although from the standpoint of construction the bearing extended the full 360 deg. and had no oil grooves or relieved spaces.

With reference to curves C in Figs. 4, 6, and 12, it is believed that the differences in symmetry in the pressure lines in Figs. 4 and 6, noted by Mr. Moline, are due chiefly to differences in alignment. It was stated in the paper that the alignment between load and journal was obtained by observing the pressures at various points; thus it was chiefly a matter of "cut and try." It is quite probable that better alignment was obtained in test No. 1 (Fig. 4) than in test No. 3 (Fig. 6). With reference to Fig. 12, this test was run with the load off-center, and some of the lack of symmetry is possibly due to the fact that there was more surface available for carrying the load on one side of the center line of load than on the other.

Referring to Dr. Flowers' questions, there were no oil grooves in either the bearing or journal and the bearing was not run in before the tests. Also no evidences of instability of the pressure readings were observed. No attempts were made to check the surface smoothness. In one test, however, it was found that one part of the journal had become scratched to an extent hardly visible to the eye. This abrasion was discovered by noting the presence of the sharp "hooks" in the pressure lines shown in Fig. 7, curve C. These "hooks" were at the same position as the scratch relative to the length of the journal and did not occur in the tests that were made after the journal had been polished to remove the abrasion. With reference to the question of film breakdown, in test No. 4 (Fig. 7) there was evidence of abrasion, in test No. 8 (Fig. 11) the value of ZN/P was lower than in the other tests, and in test No. 9 (Fig. 12) a low-voltage lamp placed in series with journal and bearing gave an indication of film breakdown at some settings of the pressure tap. It is of interest to note that in curves E of Figs. 7, 11, and 12 the ratios of the area under the curve to the area of the rectangle are appreciably lower than in the other figures.

A possible explanation for the presence of negative pressures other than that given by Mr. Weiss is that the negative pressures were developed beyond the point of closest approach where there was a diverging rather than a converging wedge of lubricant. With reference to the question by Mr. Weiss regarding the frictional torque, the results of previous experiments[17] by the authors seem to indicate that end leakage or drop in pressure in the film toward the ends of the bearing is one possible explanation as to why the experimental friction curves should be higher than those indicated by the theoretical equations of Sommerfeld, since the observed increase in coefficient of friction is greater for the short than for the long bearings.

Fluxing of Ashes and Slags as Related to the Slagging Type Furnace[1]

Progress Report of the A.S.M.E. Special Research Committee on Removal of Ash as Molten Slag From Powdered-Coal Furnaces[2]

By P. NICHOLLS[3] and W. T. REID,[4] PITTSBURGH, PA.

This paper is presented as a report for the Special Research Committee on the Removal of Ash as Molten Slag From Powdered-Coal Furnaces. The primary object of the investigation was to obtain data on the fluxing of coal-ash slags to enable users of slagging-type boilers to increase the fluidity of the deposited ash should it not be possible to tap at available furnace temperatures. Studies were made using a platinum-wound furnace, supplemented by a gas furnace with a 32-in. by 28-in. hearth. A standard of fluidity desirable for easy tapping was established, and the results were expressed as the temperature necessary to produce this fluidity, designated the flow temperature. Values for flow temperature in terms of the chemical composition of the ash, or ash plus flux, were determined for a range of ashes found in American coals, and for additions of the following fluxes: iron ore, limestone, dolomite, fluorspar, saltcake, steel slags, and some less important minerals. It is deduced that limestone or dolomite would be the most economical material to use for slagging-type boilers as now built, and from a diagram the quantity of flux can be computed. The investigation was carried beyond present requirements for slagging-type boilers and to flow temperatures below 2400 deg. fahr. A complete diagram is given for coal ash-lime-iron showing the flow temperature plotted against composition.

Introduction

The work here reported may be considered as the Second Progress Report presented for the A.S.M.E. Special Research Committee on Removal of Ash as Molten Slag From Powdered-Coal Furnaces. The first report[5] covered a limited investigation at the Toronto Station of the Ohio Light and Power Company; the main object of that investigation was to study the slagging factor when burning coals, the ashes of which had higher fusion temperatures than that of the strip-mine coal used in the regular operation. In these tests it was not found possible to tap the furnace when using a semi-bituminous coal having an ash-softening temperature of 2700 deg.,[6] and a bituminous coal with an ash-softening temperature of 2470 deg. was on the border line.

P. Nicholls

W. T. Reid

At the time when these tests were made there was only one other station, the Huntley Station, Buffalo, N. Y., in which slagging boilers were in operation, although a number were being installed. The boilers at Toronto in which these tests were made had been converted from the dry-bottom type, and the installation was more or less experimental. While it was recognized that the furnace temperatures could be increased and the location of the tap hole and the method of tapping improved, yet it was felt desirable that there should be the added safeguard of the ability to add some material which would act as a flux and increase the fluidity of the bed so that the slag could be tapped at available furnace temperatures, or which could be used in emergencies. As a consequence, at the request of the committee, the Bureau of Mines undertook to make the study of fluxing the second phase of the investigations of this method of utilizing coal; from the bureau's standpoint this was a logical continuation of other studies of coal ash.

Presented at the Annual Meeting, New York, N. Y., Nov. 30 to Dec. 4, 1931, of The American Society of Mechanical Engineers.

OUTLINE OF PROBLEM

The original conception of what amount of work would be required and how far it should be carried was quite indefinite. The plan agreed to with the committee was to have three stages, as follows:

(1) *Small-scale laboratory tests*, by which the fluxing effects of admixtures were to be determined under the ideal conditions of intimate mixture and uniform temperature.

(2) *Large-scale laboratory tests* in a gas-fired furnace having a slag hearth $2^1/_2$ ft. by 3 ft. to check the conclusions arrived at from the small-scale tests and to study the mass action.

(3) *Plant tests*, to confirm the laboratory tests and to develop methods for adding the flux.

Whether they should be completed in the order given or should be overlapped was left to development, but it was desirable that some rough ideas of the possibilities of fluxing should be obtained as early as possible. Fortunately, the need for the use of fluxes has not arisen, and although two stations have asked for advice, yet so far as is known all stations have been able to raise the slag to the flow temperature, and lack of fluidity in the slag has not been a major difficulty. As a consequence, the expense involved in conducting full-scale tests at the stations has not been necessary.

The question arose early in the investigation, as to what limitations should be put on the order of fluxing required. Based on the experience at the Toronto Station, it could be said that if the fluid temperature of the deposited ash as determined by the standard cone test was 2550 or lower, then it could be tapped from a furnace the design of which permitted a temperature of the bed not less than that obtained at Toronto. This limited the immediate study to slags more refractory than the 2550 deg., and the fluxing to that necessary to reduce refractory ashes to fluidity at 2550 deg. It was evident, however, that a knowledge of the fluxing of coal ash was desirable for contingencies other than that of a general fluxing of the whole of the slag bed. The following possible applications were suggested:

(*a*) That a flux would be useful, and perhaps sometimes necessary, to make more fluid the portion around the tap hole.

(*b*) That a flux might be used occasionally over the whole bed to make it possible to drain the bed more thoroughly before the boiler was shut down for repairs; the use of a flux would permit this to be done without the risk of heating the permanent structure of the bed abnormally.

(*c*) That the slagging-bottom principle might be applied to smaller furnaces and boilers in which the furnace temperature was materially lower than is customary in larger furnaces.

(*d*) That a knowledge of the possibilities of fluxing coal ash was of importance in fields other than that of boiler furnaces.

In addition to the foregoing, it was early seen that the insight these studies gave on the properties of coal ash and their slags, and the reactions of other materials with them, would be very useful and would supply data on a subject on which knowledge was very meager. A direct application is the problem of absorbing the fly ash in the bed, and an indirect one the reaction between slags and refractories.

The investigation has therefore been broader than what were considered the immediate necessities, and studies have been made of slags having relatively low fluid temperature, the fluxing studies often being continued to fluidity at 2400 deg. and lower.

When this investigation was started there was very little information available, and this only of a general type. The most pertinent were the deductions which could be made from the fusibility of coal ash as determined by the cone method of test, a large number of values for which have been determined by the Bureau of Mines and others. These data have been, however, of little use unless accompanied by the chemical analysis of the ash, and relatively few analyses have been made. In addition, so far, no close relationship has been established between the chemical analysis and the fusibility; also, the only fluxing constituents in coal ash which vary over more than a few per cent are the lime and iron oxide.

Although many workers have studied slags associated with other industries, such as those of pottery, glass, iron, and other metals, yet each field is peculiar to itself, and data obtained for one are of little help to the others. The relationships between the properties of all types of slags are quite complex, and no general laws have been established. Also, determinations at high temperatures are time-consuming and expensive in apparatus, and if work is done on a truly fundamental basis the time may run into years. This is true where the slags studied have only three constituents, and would be more so for coal ashes which contain a larger number of constituents, independent of others which may be added as fluxes.

It has therefore been the endeavor to limit the work to the order of accuracy that would accompany its application and, as far as possible, to avoid investigations on the reactions or underlying causes. This was considered sufficient for the purpose since in no application of fluxes to slagging-bottom furnaces could the exact analysis of the deposited ash be known, and the composition and the temperature will vary over the area of the bed.

This does not mean, however, that a more thorough study of slags and their properties is not desirable and would not be useful to the operator, and the temptation has continually been present to extend the investigation into side lines. The following section briefly discusses some of the general properties of slags and may be helpful in the better understanding of the problem.

PROPERTIES OF SLAGS

All slags contain silica (SiO_2) or alumina (Al_2O_3), or both, together with other materials, depending on the industry the slags belong to; the distinction between a glass and a slag is merely one of name. A slag resulting from the fusing of a coal ash will show by chemical analysis iron, either as ferric oxide (Fe_2O_3), if the slag has been subjected to an oxidizing atmosphere, or as ferrous oxide, if reducing, and usually both; also metallic iron may be present if the atmosphere be highly reducing; lime (CaO), magnesia (MgO), and the alkalis (Na_2O and K_2O); small quantities of sulphur and phosphorus or their oxides; and also, perhaps, small quantities of oxides of other metals may be present, of which titanium oxide (TiO_2) is the more common.

A slag is not a mixture of these oxides, but some portions of them are combined, and form simple or complex minerals; some such compounds in coal-ash slags may be mullite ($3Al_2O_3.2SiO_2$) fayalite ($2FeO.SiO_2$), anorthite ($CaO.Al_2O_3.2SiO_2$), and many others. The determination of the minerals in a slag is directly accomplished by microscopic examination of the cold slag, which will show their crystals embedded in the matrix—that is, glass. The forms in which the oxides exist in the glass cannot be determined directly, but sometimes may be deduced; in general, the glass can be thought of as a solution of materials in each other, the materials either being in compound or simple form.

When a slag is heated, the crystals and glass do not necessarily melt at the same temperature, and consequently its softening (that is, its fluidity) may not change uniformly with increase in temperature. Also, new combinations may be formed and existing ones broken into simpler forms, and heat may be required or evolved for each such change. Little is known on this subject, and it becomes very complex as the number of oxides increase beyond two. It is of interest here only as it underlies the action of melting.

Slags in general soften and increase their fluidity gradually, and the relation of their increase in fluidity to increase of temperature differs materially. A small change in composition may cause a large change of the temperature to produce the earlier softening, but the effect of small change is less as the whole composition of the slag is more complex. Such small changes have less effect at stages of higher fluidity, such as that at which the slag will run freely.

Fig. 1 represents diagrammatically some forms of melting which different slags may have. The vertical scale represents fluidity; the axis 0 represents a solid material; the line marked Flow is the fluidity which was standardized for these tests as necessary to permit of easy tapping of the slag; the line Penetration is the fluidity necessary to permit a rod to be poked into a slag without too much effort; the line Oil is the fluidity of Mobiloil B at 68 deg., which is a rather heavy summer oil.

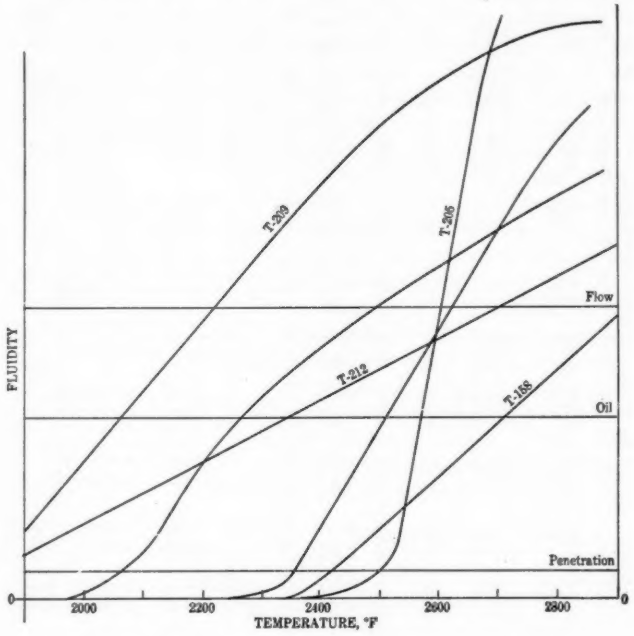

FIG. 1 DIAGRAM SHOWING HOW SLAGS MAY MELT

The melting curves are based on the values for Penetration and Flow obtained for some of the slags used in this investigation; the shapes of the curves are not based on definite data. They show how some slags may soften gradually and others rapidly; thus, T-212 starts to melt at 1520 deg., but does not flow freely till it reaches 2700; slag T-205 flows at 2590 deg., but the temperature only has to fall to 2505 for the slag to become stiff enough to make penetration difficult. These characteristics materially affect operation and tapping.

METHOD USED IN THE SMALL-FURNACE INVESTIGATIONS

The first problem in the small-furnace work was to devise a method for determining the temperature at which a slag, or slag with flux, would be fluid enough to flow when tapped; it therefore required the fixing of a standard fluidity (or viscosity) and a method for its measurement. Several methods previously used were considered, particularly the apparatus developed by Feild[7] for determining the viscosity in absolute units, but it was believed that a simpler method involving less expense would suffice. Fulton,[8] working on copper slags, states that he determined the flow point by stirring with a heavy platinum rod, but makes no statement on the order of accuracy he obtained. Such a method was tried, using a sirup for the liquid, and it was shown that two observers could closely duplicate their own and the other's results. This method was therefore adopted, because of its simplicity and promise of relatively rapid progress.

Fig. 2 shows the platinum-wound electric furnace as now constructed. It has no particularly novel features. The currents through the inner and outer windings are under full control, and the temperature at the outer winding can be measured and thus avoid burning out of the nichrome wire. Originally there were nichrome windings on the two flat ends, but these gave trouble and were abandoned.

The platinum crucible is shown in place. It is $^{3}/_{4}$ in. in diameter and $1^{1}/_{2}$ in. high; it has two sets of three buttons welded on, which center the crucible in the tube, the nominal diameter of which is 1 in. There are two crucibles to a furnace, so that one can be cleaned while the other is in use. A Tork clock has been used to switch the current on at some set time so as to heat up the furnace before the investigator arrived. A temperature regulator has also been used in some of the tests, but normally work can be advanced quicker by hand adjustment of the outside resistances.

The measurement of the temperature of the slag is an important factor. The straightforward method would be to insert a thermocouple into the slag. There are, however, a number of objections to this as a regular practice, as the temperature must be followed continuously; it would mean that the couple would be in all the time and would be in the way. The temperature was measured as shown in Fig. 2; a platinum, platinum-rhodium couple threaded through a $1^{1}/_{4}$-mm. inside and 2-mm. outside porcelain tube lay next to the inner wall, with the junction at the average height of the slag in the crucible. It follows that the temperature of the slag in the crucible would lag behind and be lower than that registered by the couple. The relationship between the two

[8] C. H. Fulton, "The Constitution and Melting Points of a Series of Copper Slags," Trans. A.I.M.E., vol. 44, p. 764, 1912.

temperatures was determined at intervals, so that the recorded value could be corrected to that of the slag.

Test Procedure With Small Furnace

It was first necessary to establish a standard of fluidity, which should be such that slag would run freely when tapping. The standard was based on a sample of a slag collected during the tests at the Toronto Station which gave satisfactory flow and the temperature of which was known at the time of tapping. Some of this slag was melted in the crucible, brought to the afore-stated observed temperature, and its "feel" when stirred studied. From this a standard feel was learned. The feel at which the fluidity reached the value determining the temperature at which the slag would flow was judged by the ease of stirring, the rapidity with which the slag flowed in behind a cold stirring rod drawn through the melt, and by the quantity of slag adhering to the platinum rod when withdrawn from the melt.

This in effect established a standard of fluidity and viscosity, but the method of test does not itself give numerical values. The corresponding viscosity was determined by an indirect method, and found to be 5 poises.[9] The determination was made by using castor oil, of which the viscosity-temperature relation is known. The 5 poises is the viscosity of castor oil at 83 deg.

In subsequent studies of slags the operation consisted of determining the temperatures at which each slag had the standard fluidity. This temperature is designated as the flow temperature.

In addition to the flow temperature for each slag, the temperature at which it showed the first softening was also noted. This point can be defined as the temperature at which the slag has a degree of softening which would allow the platinum stirring rod to penetrate the slag when using a pressure of 6 oz. This temperature is termed the penetration temperature; this determination has not the same exactitude as the flow temperature. In many melts a penetration point would occur at a certain temperature, and then the slag would harden again, and another penetration point would occur at a higher temperature.

In the initial work the temperature of the slag in the crucible was brought to as high as 2800 deg., but early failure of the furnace required this to be reduced and the maximum temperature to be used was fixed at 2630 deg., which limitation lengthened the period between failures to as much as five months' continuous use of the furnace when the wire was new. This limitation seemed logical because at that time it was thought that reasonable operation would require that a furnace could be tapped without having the average temperature of the slag exceed 2630 deg., although it was known that a higher temperature could be obtained by carrying a high rating for a long enough time.

All the slags and fluxing materials used in the electric-furnace tests were finely ground. Briefly, the general procedure was to weigh out a sample, usually of 10 grams, of ash or slag, add two-thirds of it to the platinum crucible, heat to the point where fluidity was obtained, cool, add the remainder of the charge, heat again to fluidity, and maintain at that temperature till all gas was evolved—generally 20 minutes. The melt was then cooled until solid. In reheating for determinations of points, a high rate was used until the approach of the penetration temperature was indicated by a stickiness of the slag surface, after which the heating rate was decreased to about 25 deg. per min. Further heating was continued at the same rate until approaching the flow temperature, when the rate was decreased to about 10 deg. per min. The melt was then allowed to cool, a similar heating

[9] A poise is that viscosity which a liquid possesses when a force of 1 dyne is necessary to cause two parallel liquid surfaces of unit area and unit distance apart to slide past one another with unit velocity. ("Outline of Theoretical Chemistry," Getman, p. 91, 4th edition.)

cycle made, and the average of the values for three such cycles taken as the penetration and flow temperatures for that slag.

When fluxing, each addition of flux was added to the cold solid-slag surface, the melt brought not more than 30 deg. higher than the flow temperature of the previous run, and the points determined in triplicate. The first flux addition, when the flow temperature of the slag had been determined in a previous run, was made by intimately mixing the finely ground slag or ash with the flux on glazed paper before transferring to the crucible. Obviously, this was not possible when the slag had once been melted down in the crucible.

Cleaning was accomplished by mechanically removing as much slag as possible while fluid; soaking in hydrofluoric acid for 36 hours at room temperature generally removed the remainder. Fusion with potassium pyrosulphate was resorted to in extremely stubborn cases.

Slags and Ashes Used

There was the option of making synthetic mixtures of slags or of using slags or ashes from boiler plants. The latter method was adopted, as it would give more direct data and also because of the size of the samples that would be required. Table 1 lists the slags and ashes which have been used; Table 2 is supplementary and gives their origin. They were selected to cover a range of fusibility from low to high. Since few slagging-bottom boilers were in operation at that time, those samples collected at the start of the investigation were from dry-bottom furnaces; it is not known how far the selective action in the combustion chamber may affect the composition of the ash deposited, but the ash from a dry-bottom furnace served equally well.

Table 2 shows that all the ashes and slags were from coals, except T-209, which was from a refuse incinerator, and T-211, T-212, and T-228, from oil sludges and coke. The samples designated by letters were obtained by ashing coals selected from a series previously used in a clinkering investigation.[10]

An examination of the chemical analyses illustrates the difficulties involved in classifying by composition; however, for the coal ashes, the three principal factors are the silica-alumina ratio, total iron as Fe_2O_3, and the CaO.

The silica-alumina ratio of the coal ashes listed in Table 1 ranges from 1.72 to 3.66, with the greater number having a ratio from 1.8 to 2; this is representative of ash in coals from the Eastern and Central states; no coals from the Pacific Coast states are included, but from the few analyses of their ashes which are available, it would appear that the silica-alumina ratio is much lower and sometimes as low as 0.7. The conclusions reached in this report must not be applied to such ashes.

Materials Considered for Fluxes

In considering possible fluxes the main consideration was the price. The use of a flux would be an additional cost, not only in its purchase and handling, but also in most plants in the increased weight of slag to be tapped and disposed of. The desirable characteristics can be listed as:

(1) Low price
(2) Well distributed to avoid cost of a long haul
(3) Effectiveness to be greater as the cost is higher
(4) Should not volatilize at furnace temperatures
(5) Should not be a fine powder so that the loss to the stack would be high
(6) Should not damage refractories
(7) Should store well, and preferably in the open
(8) Should be delivered preferably in the size to be used, and thus avoid crushing
(9) It might be an additional economic advantage if the flux were normally a waste material, but it should be obtainable without investment for its reclamation.

All known sources were consulted for information on materials that might be considered. The following are those which were given consideration, and are discussed without reference to their effectiveness:

Iron Oxide (Fe_2O_3). The forms in which this is obtainable are mill scale and iron ore. Mill scale, however, is not a regular article of commerce, and the steel mills reuse it; it would only be available in limited amounts and under special conditions, and would be more suited for experimental purposes than for regular use. What is known as the red ore would be more suitable as a flux because it is more friable than the black ore and would be ready for use as delivered. The Superior ore is about 74 per cent Fe_2O_3, with the remainder SiO_2 and Al_2O_3 in varying proportions and moisture.

It is quoted at $4.50 a ton at the lower lake ports; the cost per ton of Fe_2O_3 would therefore be $6.10, or, say, $7 delivered. Since a certain portion of the Fe_2O_3 will be required to satisfy the silica and alumina in the ore, the available effectiveness as Fe_2O_3 is still further reduced. A typical analysis of a Superior ore is:

Fe_2O_3	SiO_2	Al_2O_3	CaO+MgO	MnO	Moisture
74	10	2	1	0.6	11

An average cost per ton of available Fe_2O_3 can be taken as $7.20.

A slag formed in connection with the Aston process of manufacturing wrought iron has properties which should make it a quick acting flux when iron oxide is required. It contains about 85 per cent iron oxide, mainly FeO, and 10 per cent silica, so that the slag has about 40 per cent fayalite (Fe_2SiO_4). It melts at about 2150 deg. and is very fluid. It was not tested and it is likely that its cost would prohibit its use except for special purposes.

---

[10] Fieldner, Selvig, and Nicholls, "The Clinkering of Coal Ash as Related to Laboratory Fusibility Determinations," Trans. A.S.M.E., 1928, paper FSP-50-6, p. 53.

Limestone ($CaCO_3$). Only the CaO would enter into the slag, and the CO_2 would be driven off; the calcining absorbs heat; the heat used per pound of limestone would be 771 B.t.u. in addition to the sensible heat. Limestone is a material readily purchasable in all sizes and is good for handling and storage. The $^3/_4$-in. or $^1/_2$-in. screenings should be suitable; prices are variable, but in carload lots can be taken as 75 cents per ton at the quarry or as $1.50 delivered. The CaO forms about 55 per cent of the limestone, so that the cost per ton of CaO would be about $2.75.

Dolomite. Dolomite ranges from $CaCO_3.MgCO_3$ to deposits which contain only a small percentage of the magnesium carbonate. It is in the same class as limestone, and the relative availability of the two materials depends on the location; MgO forms 47.8 per cent of $MgCO_3$. The cost of dolomite at the quarry can also be taken as 75 cents, but the screenings tend to be somewhat cheaper. Assuming $1.50 delivered, the cost per ton of equivalent CaO.MgO would be about $2.95.

Lime. As calcined stone, whether as CaO or CaO.MgO, lime need not be considered, since it is not suitable for handling for use as a flux. There are, however, a number of industries which have lime waste as a hydrate or carbonate. Such industries are soda works, magnesia manufacturers, the sugar industry, and others. Some plants might be so situated that it would be economical to use lime in these forms.

Magnesite ($MgCO_3$). Magnesite is mined mainly in the West, and its cost is high compared with limestone and dolomite.

Fluorspar (CaF_2). Fluorspar is used as a flux in the steel industries. It is mined in Illinois and Kentucky and is quoted regularly in the trade journals at this time at from $17 to $18 per ton at the mine. It is also mined in Nevada and New Mexico, where it is quoted at $12 to $13 because of the location relative to demand. The greater part is shipped in gravel size; the ore averages about 95 per cent CaF_2; another grade with 85 per cent CaF_2 is quoted at $13. It melts at 2510 and has a flow temperature of 2600 deg.; its density when solid is 3.1, which is higher than that of coal-ash slags, and therefore it tends to sink in molten slag. It decrepitates when thrown in the furnace, and there is a tendency for the fluorine to combine with the silica to form SiF_4, which is a gas; these two properties introduce the possibility that the use of fluorspar as a flux may cause some slagging of the refractories of the walls.

Silica (SiO_2). If silica was found to be effective, it would not be necessary to use the pure grade employed in the glass industry, but rather sands high in silica. The composition of sands is very variable in different localities. It is desirable that the sand should be low in alumina, but the presence of iron would be an advantage. The percentage of silica in some molding sands is as high as 97; in sea sands 90 and in river sands 83 are average values. The cost of sand would depend on whether a suitable one were produced in the district. Quotations on building sands vary by location, but $1.50 per ton might be expected.

Low-Grade Clays. It was thought that low-grade clays high in iron were good possibilities, but no records were found except for clays too high in silica and alumina. There may be deposits better suited, but since they are of no value for other purposes they have not been investigated or mined. Two well-known clays used for glazing are the Albany and Michigan slips; the latter contains 6.5 per cent Fe_2O_3, 8.5 CaO, and 5.3 alkalies. These clays are, however, too expensive for consideration, and no clays were used in the tests.

Saltcake (Na_2SO_4). Saltcake is used in the soda and glass industries. It is obtained as a by-product of the manufacture of hydrochloric acid by the action of sulphuric acid on common salt. It does not volatilize, but melts at 1600 deg., is quite fluid, and being less dense than molten coal-ash slag, will float on the top of the bed. Its cost has been taken at $17 per ton delivered. The Na_2O is the fluxing constituent of saltcake and can be taken as 46 per cent of the weight of the saltcake.

Common Salt (NaCl). Salt was considered, but rejected as a possibility because of the ease with which it volatilizes, which would mean loss of flux and, in addition, possibility of added trouble in erosion. There is, however, some doubt whether these deductions are justified, and the salt might be added in such size that it would not volatilize as it does in small granules. The price of salt at the mines is given as $3 to $4 a ton, and in containers at New York as $12.

Borax ($Na_2B_4O_7.10H_2O$). Borax was considered because it is commonly used as a flux in laboratory work. Its cost is too high for use in service.

Steel Slags. The slags from the open-hearth process are high in metallic oxides and low in alumina. One, termed "tapping slag," is stated to be a waste product, and so its fluxing effect was studied. Representative analyses are given later, and it will be noted that it introduces two oxides not included in the foregoing fluxes—namely, those of manganese and phosphorus. No price can be assigned to this waste material, but to the cost of reclamation would be added that of crushing.

Coal-Ash Slags. The obvious solution of trouble caused by an insufficiently fluid slag from a given coal might seem to be to mix with that coal one having a low-fusion ash, or, as was done in the Toronto tests, to use the latter coal at intervals. The committee considered that this solution might be objectionable from an operating standpoint. The same end would be obtained by using as a flux the slag from a furnace burning the low-fusion ash coal, but again it is not likely that the two coals would be used in the same plant or that another plant using such a coal would be located within economic shipping distance.

TESTS MADE IN SMALL ELECTRIC FURNACE

The greater part of the work has consisted of determination of flow temperatures in the small electric furnace. A number of months were required at the start on more or less guess trials to obtain some preliminary knowledge of the fluxing effect of economically possible material on typical ashes. As data were accumulated it became possible to systematize the order of the tests to some extent, but it was not possible to completely cover the area of the field—that is, to try each flux with a complete range of possible ash compositions. As the work progressed it also became necessary to make side investigations to check previous results or to try to obtain explanations for disagreements, or for departures from the expected. The results obtained from the various tests will be dealt with independent of the order in which the tests were made.

RELATION BETWEEN FLOW TEMPERATURE AND ASH FUSIBILITIES

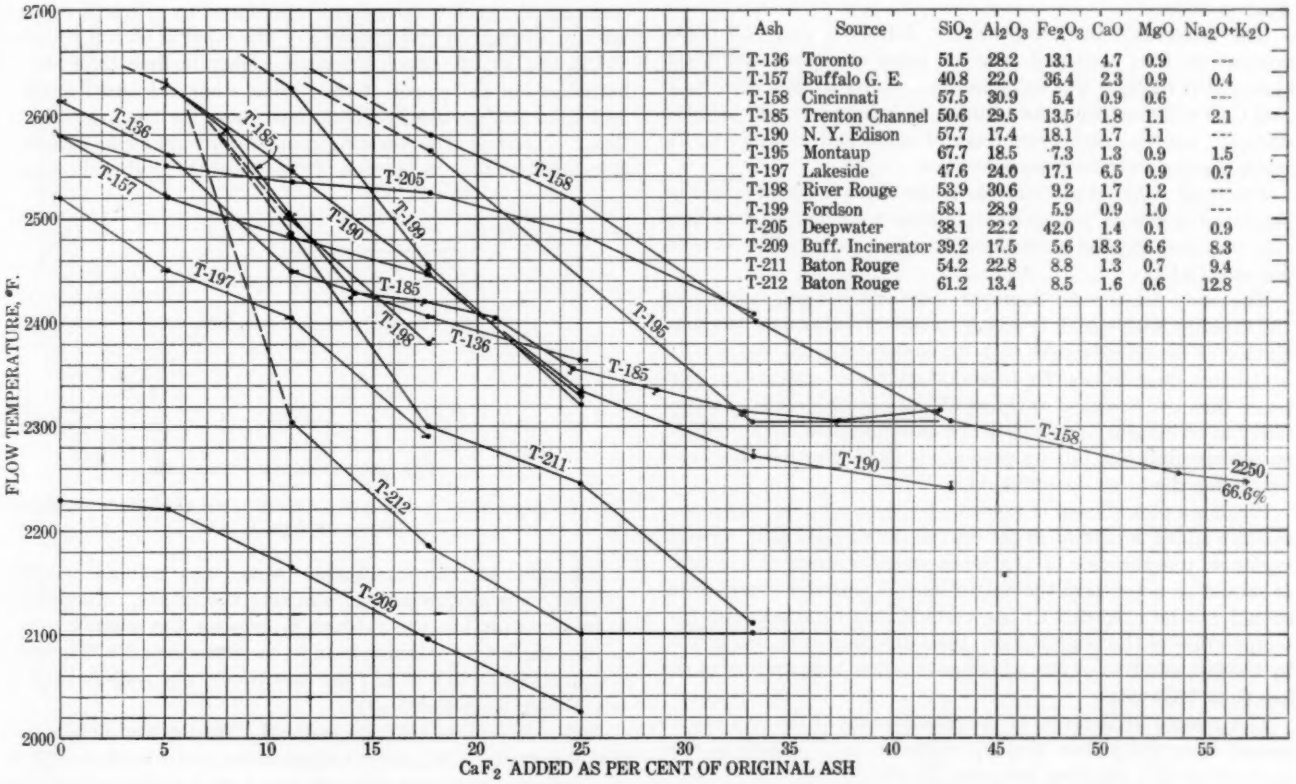
It would be convenient if one could predict the flow temperature—that is, the temperature the slag must attain for free flow—from the standard ash-fusion temperatures. Analyses of the values in Table 1 for items 4, 5, and 6 for the ash fusions and 7 and 8 for the measures used in this investigation do not show good relationships. That these relations cannot be predicted without a full knowledge of the properties of the slag can be understood from the discussion on Fig. 1. Although the fluid temperature of the cone test is nearer to the condition of the slag represented by the flow temperature, yet, because of the technique of the test method, neither it nor the initial temperature is as reliable a measurement as is the softening temperature, which is used in the comparisons shown in Table 3.

Table 3 includes all the ashes of Table 1 in which both values for the softening and flow temperatures are given; a number of the flow-temperature values of Table 1 are marked +2630, because to prolong the life of the furnace the temperature was

TABLE 3 COMPARISON OF FLOW AND SOFTENING TEMPERATURE

Ash	Flow temperature	Softening temperature	Difference	Fe_2O_3, per cent	Computed flow temperature
T-136	2615	2350	265	13	2505
T-66	2590	2360	230	14	2630
S	2285	1990	295	16	2290
T-197	2520	2210	310	17	2525
F	2565	2190	375	20	2550
K	2595	2210	385	22	2590
G	2450	2070	380	25	2405
T-102	2590	2080	510	28	2560
T-157	2580	2020	560	36	2620
T-205	2590	2320	270	42	..

not run higher. Table 3 shows that the flow temperature averages from 280 to 580 deg. greater than the softening temperature, which means that at the softening temperature the slag is far from the free-flowing state. Feild[11] experimented on a limited number of coal ashes and found that the viscosity represented by the softening temperature was about 20 poises, but he recognized that the state of the slag might not be the same in the two methods of test.



Ash	Source	SiO_2	Al_2O_3	Fe_2O_3	CaO	MgO	Na_2O+K_2O
T-136	Toronto	51.5	28.2	13.1	4.7	0.9	---
T-157	Buffalo G. E.	40.8	22.0	36.4	2.3	0.9	0.4
T-158	Cincinnati	57.5	30.9	5.4	0.9	0.6	---
T-185	Trenton Channel	50.6	29.5	13.5	1.8	1.1	2.1
T-190	N. Y. Edison	57.7	17.4	18.1	1.7	1.1	---
T-195	Montaup	67.7	18.5	7.3	1.3	0.9	1.5
T-197	Lakeside	47.6	24.0	17.1	6.5	0.9	0.7
T-198	River Rouge	53.9	30.6	9.2	1.7	1.2	---
T-199	Fordson	58.1	28.9	5.9	0.9	1.0	---
T-205	Deepwater	38.1	22.2	42.0	1.4	0.1	0.9
T-209	Buff. Incinerator	39.2	17.5	5.6	18.3	6.6	8.3
T-211	Baton Rouge	54.2	22.8	8.8	1.3	0.7	9.4
T-212	Baton Rouge	61.2	13.4	8.5	1.6	0.6	12.8

FIG. 3 EFFECT OF ADDITIONS OF FLUORSPAR ON FLOW TEMPERATURE OF VARIOUS COAL ASHES

The fifth column of Table 3 gives the iron in the ashes as per cent Fe_2O_3, and the table lists the ashes in order of increasing Fe_2O_3, which shows that the difference increases with increasing Fe_2O_3. A plot showed that the flow temperature is fairly closely given by the empirical equation: flow temperature = softening temperature + 60 + 15 (per cent Fe_2O_3).

The last column of the table gives the computed values, which are close to the experimental values considering the variations in the composition of the ashes. Ash G departs most, but it contains 17.5 per cent CaO. Ash T-205 (Deepwater) is entirely out of line, but it will be shown later that this ash is peculiar in all respects.

Tests of more ashes would be required to confirm the truth of this empirical formula, particularly for ashes having low iron; it should be noted that the softening temperature of the deposited ash must be used, and not of the ash of the coal burned, because that ash will not be of the same composition as the ash which is deposited on the slag bed.

Results Under Headings of Fluxes

The less important fluxes will be covered first. The difficulty of presenting data which cover as many variables as are included in the composition of the ashes and the fluxes will be recognized, especially as the material used as a flux may also be in the original ash, and as combinations of fluxes were also tried.

There are also two optional ways in which the proportions of the constituents of the ash and the flux may be expressed:

(*a*) To call the original ash 100 and to express the flux as "per cent of original ash."

(*b*) To express in any mix the ash plus flux as 100, so that each addition of flux is evaluated as "flux, per cent of total mix."

Method (*a*) is best suited to service application, but method (*b*) is the better to show relationships, especially when the material used as the flux is already in the ash.

There is a further complication when the flux contains material which is lost, such as $CaCO_3$, which loses its CO_2. Formulas for converting from one system to another will be appended to the report.

Borax. The tests with borax were limited to its use with ash T-212 (Louisiana). The flux was added as $Na_2B_4O_7.10H_2O$, but was calculated as the dry sodium biborate, $Na_2B_4O_7$. On this basis, two additions of flux were made, each being of 5$^1/_2$ per cent of the ash weight. The first addition did not produce fluidity at the limiting temperature of 2630; the second gave a slag fluid at 2425; but as doubt existed as to the absorption of the borax, the melt was maintained at 2590 for two hours. At that time a considerable quantity of borax had volatilized from the melt and condensed on the cooler parts of the furnace, badly slagging the porcelain protecting sheath around the thermocouple. A redetermination of the flow temperature showed it to have increased to 2545. This volatility of the flux showed that it would be unsuited for use in a furnace, and it was not studied further.

---

[11] A. L. Feild, "A Method for Measuring the Viscosity of Blast-Furnace Slag at High Temperature," U. S. Bureau of Mines Tech. Paper 157, 1916.

Feldspar. The feldspar used analyzed:

SiO_2	Al_2O_3	Na_2O	K_2O	CaO	MgO
67.4	20.0	10.03	1.04	0.5	0.20

Feldspar was tried early in the investigation with ash T-158 (Columbia), but with additions of feldspar up to 11 per cent the flow temperature was still higher than 2630. Later it was tried with T-197 (Lakeside), which had a flow temperature of 2520 deg.; however, each addition of the feldspar increased the flow temperature until, with 17 per cent added, the slag was no longer fluid at 2630.

The ashes used had, respectively, 5.4, 17.1, and 11.9 Fe_2O_3 content, so that a normal range of ashes was tried and it was shown that feldspar was not effective. Later studies with Na_2O and CaO will show that the addition of limestone would help the feldspar, but the high percentage of silica and alumina in the feldspar removes it from consideration.

Fluorspar. Although fluorspar is the mineral which would be employed in service, yet in the small-scale tests c.p. calcium fluoride was used because commercial fluorspar contains but 85 to 95 per cent CaF_2.

The early trials with fluorspar were encouraging because of the rapidity with which it acted, its effectiveness, and the continuity of the effectiveness with increasing amounts of flux.

Calcium fluoride has the disadvantage for investigational purposes that the chemical analyses of slags containing it are very likely to be in error; not only is the determination of the CaF_2 in such slags difficult, but its presence is likely to cause incorrect values for the other constituents.

Fig. 3 is a plot of most of the tests using calcium fluoride alone; the flux added is plotted as per cent of the original ash; for convenience, the analyses of the ashes are also given on the plot. It should be noted that the dotted lines in this and other figures should not be extended to the vertical axis to obtain the flow temperature of the original ash; their direction as shown is fixed by the last addition of flux which gave a flow temperature of not less than 2630 deg.

The general irregularity of the effectiveness of the flux can be judged from the jumble that the curves make. Attempts were made to obtain relations between the curves and the chemical composition of the ashes, but if there are direct relationships they are too complicated to express the flow temperature as a function of the composition.

The effectiveness of a flux in a plot such as Fig. 3 is shown by the slope of its curve, and is greater as the slope is greater. Considering the upper portions of the curves T-195, T-199, T-211, and T-212, all have steeper slopes, and all also have a higher silica-alumina ratio. T-158 and T-199 have the same iron and lime, but the latter has the higher ratio and the steeper slope. Little is known about the form the calcium fluoride takes in a slag, but it would seem that higher silica increases the fluidity for moderate additions of CaF_2, though with larger additions the curves show that each pair meets.

If one considers only the coal ashes and omits T-211, T-212, and the incinerator ash T-209, and also again excludes the Deepwater ash T-205, the best approximate rule that can be given from the tests—which are few compared with the number of variables—is:

The lowering of flow temperature by the addition of fluorspar up to 20 per cent is 12 deg. for each 1 per cent of fluorspar added for ashes having up to 2 silica-alumina ratio and 16 deg. if the ratio is 3.

The foregoing statement is based on using a commercial fluorspar containing 80 per cent calcium fluoride. Such a rule is very rough and presupposes a knowledge of the flow temperature of the ash. If the composition of the ash is known, one should be able to make a fair estimate from the data given in Fig. 3.

In all tests calcium fluoride was found to be quick acting, and its effectiveness tends to remain more constant with increase in the amount added than occurs with other fluxes. The additions for ash T-158 were continued to determine the lower limit of temperature, which was about 2200 deg. Calcium fluoride in excess of that required to give the standard fluidity gave a very fluid slag, indicating that this flux is useful for flushing the hearth.

Some tests also were made in which a mixture of fluorspar and limestone was used. These tests did not show any marked increase of effectiveness because of the combined flux. That the lowering of the flow temperature produced by either is not materially affected by the presence of the other is shown by ashes T-136 and T-197. Both these are higher in lime than the remainder, but the slopes of the curves when calcium fluoride is added do not materially differ from those for the ashes low in lime. Therefore, the lowering produced by fluorspar and limestone can be taken as the sum of the lowerings produced by each.

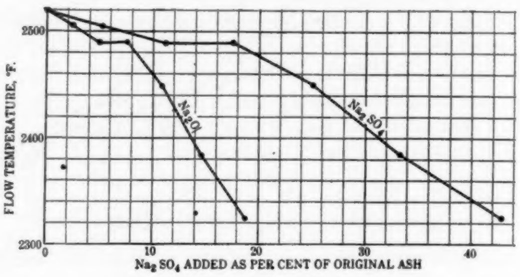


FIG. 4 EFFECT OF ADDITIONS OF Na_2SO_4 ON THE FLOW TEMPERATURE OF ASH T-197

Saltcake. In the small-scale tests, c.p. sodium sulphate (Na_2SO_4) was used in place of commercial sulphate. Commercial saltcake as used in the Leblanc process for the manufacture of sodium carbonate contains from 94 to 98 per cent Na_2SO_4, which is equivalent to 40.9 to 42.7 per cent Na_2O; c.p. sodium sulphate contains 43.6 per cent Na_2O.

Although sodium sulphate melts at 1700 deg. and does not decompose by itself at furnace temperatures, yet in contact with the slag definite reactions take place, the most notable one being the formation of sodium silicates by combination with silica. The speed with which this reaction takes place is dependent largely on temperature; below 2230 deg. no reaction occurs, and below 2460 deg. reaction is very slow. The rate of reaction between sodium sulphite and silica is greater at low temperatures than with sodium sulphate, so that in a reducing atmosphere or in contact with carbon higher reaction velocities will probably occur. This fact is made use of in the manufacture of glass, where charcoal or a high-grade coal is added to accelerate the saltcake-silica reaction.

From a knowledge of the system $CaO\text{-}SiO_2$, minimum viscosity

TABLE 4 SILICA-SALTCAKE

—Percentage composition—				
SiO_2	Na_2O	CaO	Molecular ratio	Flow temperature, deg.
74.6	25.4	..	$Na_2O.3SiO_2$	2490
72.6	27.4	..	$Na_2O.2.75SiO_2$	2430
70.6	29.4	..	$Na_2O.2.5SiO_2$	2380
66.0	34.0	..	$Na_2O.2SiO_2$	2360
57.2	29.5	13.3	$Na_2O.0.5CaO.2SiO_2$	2355
50.5	26.0	23.5	$Na_2O.CaO.2SiO_2$	2280
60.4	20.8	18.8	$Na_2O.CaO.3SiO_2$	2250

above the temperature for complete solution has been shown to exist at the compound $CaSiO_3$, and if similar conditions exist in the system Na_2O-SiO_2, minimum viscosity should occur at the compound sodium-disilicate ($Na_2Si_2O_5$).

Melts to indicate the reliability of this argument were made up; the flow temperatures were determined in the usual manner. Table 4 indicates the results.

Steadily decreasing flow temperatures are observed with each step toward the expected ideal composition. In a slag such combination may be difficult to obtain, but no doubt does occur when lime and alkalis are in the proper proportions to combine with silica not otherwise held in combination with other slag constituents. Attempts made to procure reaction between saltcake and limestone were unsuccessful.

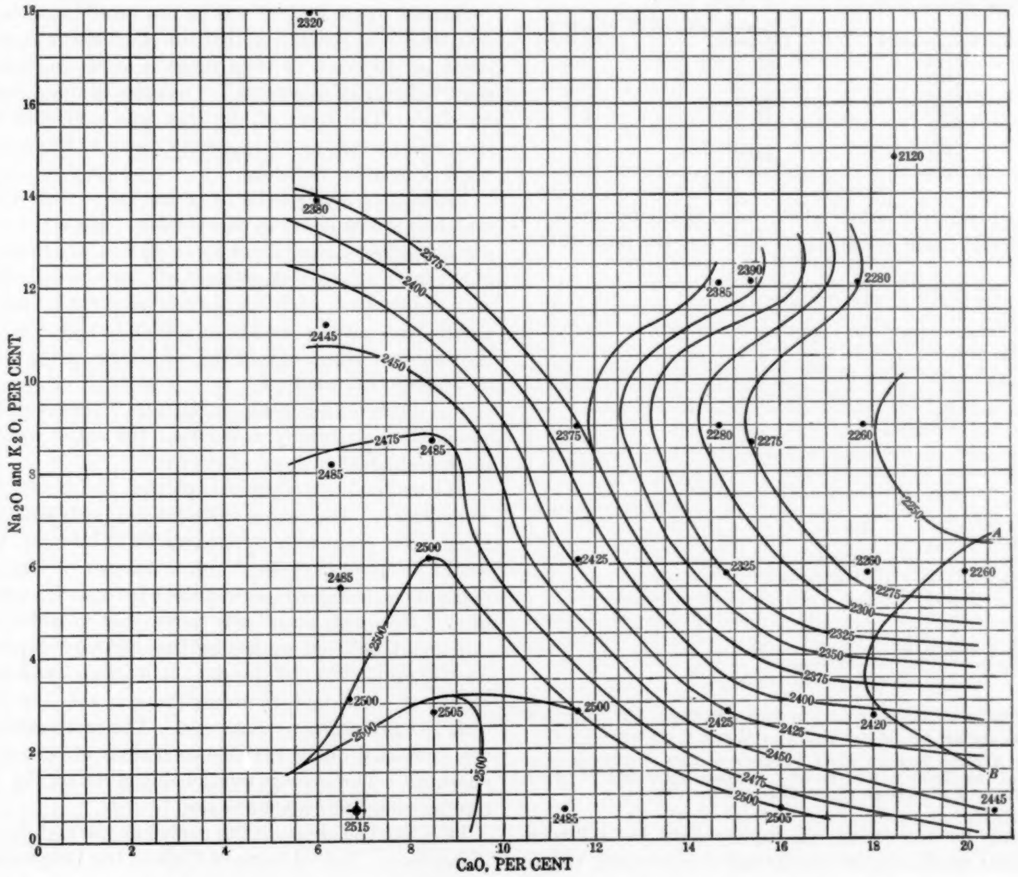

FIG. 5 PLOT SHOWING EFFECT OF CHANGE IN CaO AND Na_2O CONTENT FOR ASH T-197
(Having a constant ratio of SiO to Al_2O_3 to Fe_2O_3 of 2.78 to 1.40 to 1.00. SiO_2 + Al_2O_3 + Fe_2O_3 + CaO + Na_2O + K_2O = 100 per cent. MgO limited to less than 0.8 per cent; K_2O less than 0.4 per cent.)

Only a few tests were made using sodium sulphate alone. Fig. 4 shows the fluxing with ash T-197, in which the Fe_2O_3 was 17.1 per cent and the CaO 6.5 per cent; the flux added is expressed as per cent of original ash. The one curve shows the weight of sulphate added, and the other the effective part as Na_2O which combines with the slag.

The flux was effective from the start and maintained its rate for large additions. As a rough average, 1 per cent of Na_2SO_4 lowered the flow temperature 3.8 deg., or 1 per cent of Na_2O, 8.7 deg., which is not high compared with the cost of saltcake.

Since the effectiveness of sodium oxide appeared to be materially dependent on the lime present, a survey was made of the field (ash + Na_2O + CaO), the lime present varying from 6.4 to 20 per cent and the Na_2O up to 13 per cent. Ash T-197 was used. It contained initial 17.1 per cent Fe_2O_3 and 6.5 per cent CaO. The fluxes were used as Na_2SO_4 and $CaCO_3$.

Fig. 5 shows a plot of the results; the axes represent the percentages of Na_2O and CaO in the mix and therefore the percentages of the other constituents in the original ash, $SiO_2 + Al_2O_3 + MgO = 100 - (Na_2O + CaO + K_2O)$. The curves represent the mixtures which had the flow temperatures indicated by their markings. The test points are shown, and these were used in drawing the probable curves.

The method of plotting generalizes the data more than does plotting each set of tests in curves as in Fig. 3, and it will probably be better understood by most than would a trilinear plot. It should be clearly recognized that the curves in Fig. 5 show the percentages of the two fluxes which must be in the mix to produce a required flow temperature and not the percentages that must be added. Formulas for conversion are given in the appendix.

Such a set of curves show complex relationships which cannot be expressed in words. The position of the orginal ash is shown by a cross; assuming one wanted to flux to a flow temperature of 2450 deg., starting from the cross one has the choice of a number of relative proportions of the two fluxes which could be used and yet obtain the required flow temperature. In making a choice one desires that which would give the minimum cost for the total flux added.

An exact but simple method for determining the economic quantities is given as an appendix. Using that method, curve *AB* was found which represents the economic compositions;

the intersection of curve *AB* with each temperature line gives the economic composition for that flow temperature. The equivalent cost of CaO was taken as $2.75 per ton and the Na_2SO_4 as $17.

Because of the high cost of saltcake relative to limestone the economic curve *AB* comes at the high-lime end. As indicated in the appendix, a full consideration of economics would involve a consideration of the curves at the left of the diagram for flow temperature of 2500. With fluxing curves of the complex form of Fig. 5, a full knowledge of the whole area might result in material savings in cost of flux.

From the formulas 1 and 2 the weights of Na_2SO_4 and $CaCO_3$ were computed, and Table 5 shows the pounds of these fluxes required per 100 lb. of ash T-197 for a series of flow temperatures.

TABLE 5 WEIGHTS OF LIMESTONE AND SALTCAKE REQUIRED PER 100 LB. OF ASH T-197

	Flow temperature	Pounds per 100 lb. of ash Limestone	Pounds per 100 lb. of ash Saltcake
1	2425	29.3	3.2
2	2400	25.9	6.0
3	2375	25.2	7.6
4	2350	25.7	8.9
5	2325	26.2	10.3
6	2300	27.5	11.7
7	2275	28.4	13.1
8	2250	33.7	17.2

Fig. 5 is good only for ashes which have the same ratio of silica-alumina-ferric oxide as has ash T-197, but the lime in the original ash may be any value. Complete data for saltcake-limestone as fluxes would require similar sets of curves with ranges of ratios of silica-alumina-ferric oxide sufficient to cover all the possible compositions of coal-ash slags; this would require an amount of work which was not considered necessary at this time. That done was restricted to a determination of the effect of variations in the ferric oxide. To keep the determinations in the neighborhood of the economic mixture of the fluxes, a ratio of 1 Na_2O to 2.8 CaO (that is, 1 of saltcake to 2.17 limestone) was adopted for the flux and the ferric oxide varied. The results are shown in Fig. 6.

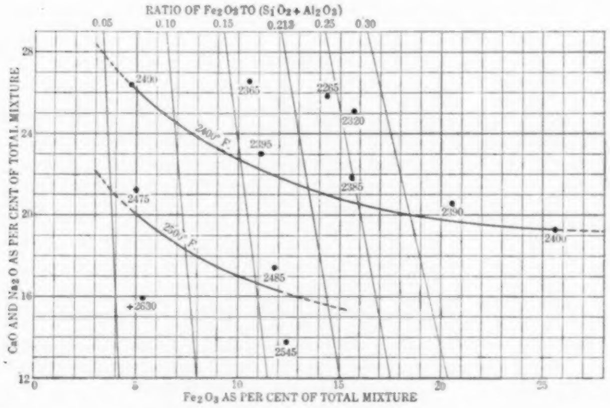

FIG. 6 PLOT SHOWING EFFECT OF CHANGE IN Fe_2O_3 CONTENT ON FLOW TEMPERATURE OF SLAGS FLUXED WITH CaO AND Na_2O

(Based on $SiO_2 + Al_2O_3 + Fe_2O_3 + CaO + Na_2O + K_2O = 100$ per cent. Average ratio CaO to $Na_2O + K_2O$ is 2.8. Average ratio SiO_2 to Al_2O_3 is 1.85. K_2O limited to less than 0.4 per cent.)

There are not enough values to plot many flow-temperature curves, but those for 2500 and 2400 show the trend of the effect of the quantity of iron in the mix. The sloping lines show the paths of composition followed by ashes having the Fe_2O_3 to (SiO_2 + Al_2O_3) ratios indicated for each line.

Fig. 6 gives a rough guide for estimating the percentages of Na_2O + CaO having a ratio by weight of 1 to 2.8 that would be required as dependent on the ferric oxide content of the original ash. Some computation would be necessary to obtain actual weights for a given ash, but tables could be constructed.

Iron Oxide and Limestone. Because the iron oxides and lime occur in all coal ashes, it is simpler to treat them together. Since the addition of iron oxides and lime did not add a mineral not already present in coal ashes, this phase of the investigation, in addition to being a study of fluxing, was also in great part a study of coal ashes themselves. The problem was, however, none the less complex because—

(1) The silica and alumina vary in quantity and in ratio

(2) The effect of the three possible forms of iron, Fe_2O_3, FeO, and Fe, had to be considered

(3) There are the minor constituents of magnesia, the alkalis, possibly titanium oxide and phosphorus, and always some sulphur.

Some of these factors will be discussed later, but as a fluxing problem it was considered that the effect of the minor constituents could be neglected as their range is small and somewhat of the same order in all coal ashes. The silica-alumina ratio was always watched. The form of the iron was neglected to a large extent, since additions were always made as Fe_2O_3 and the atmosphere was never reducing.

No tests on the special or incinerator ashes, T-209, 211, 212, and 228, are included in this section. Since the coal ashes gave a good range of equivalent Fe_2O_3 (5.4 to 42) to start from, most of the tests consisted in adding CaO, for which $CaCO_3$ was always used. Details of each set of tests need not be given, and Fig. 7 summarizes all the results in a plot having CaO and Fe_2O_3 as coordinates; this plot is of the same form as Fig. 5, the principles of which were discussed.

The limitations accompanying Fig. 7 are given in its title. It should be particularly noted that the ashes were selected with a silica-alumina ratio of 1.7 to 2.0.

The test points having been plotted, the curves to best fit them were drawn. The curves as drawn are fairly smooth and regular. If each test point were to be given its full weight, then the curves would be more irregular; also a number of the points conflict. Some of the possible causes of these irregularities will be discussed later. However, every new factor that is added introduces another variable that multiplies the difficulty of presentation, and for the application of the data it is of no avail to evaluate the effects of small factors unless there is also the ability to state exactly the conditions of service. The composition of slags from the same coal under variable conditions of burning will never be constant. The average relationship given by Fig. 7 should therefore be sufficient for general use.

Deciding the shape of the curves at the high-iron end involved difficulties. The addition of CaO to the Deepwater ash with its 42 per cent equivalent Fe_2O_3 should have given good points, but if all these had been used there would be big jogs in the curves. The points used were obtained by increasing the iron in T-102, which, however, had a high silica-alumina ratio, and 25 deg. was added to these indicated values when drawing the curves.

An inspection of the plot shows that the fluxing effect of the Fe_2O_3 decreases as the amount present increases, and that after 20 per cent it is negligible. This action is important, since it means that slags with high iron can absorb silica and alumina without reducing their fluidity.

To a less extent, the effectiveness of increase of CaO decreases with increase of Fe_2O_3. There is a material difference, however, in the fluxing requirements of a slag having high iron and of one having high lime. With high iron, the flow curves are far apart, so that large percentages of lime would be required. With high lime, they tend to gather together, and a small addition of iron will produce a large change.

It also will be noted that in the absence of lime the flow temperature cannot be reduced below about 2600 deg., however much the iron is increased.

No data were obtained for curves having a flow temperature higher than 2625 deg. One probably could plot two more without much error, but further work is required, as this area of the plot increases in importance with increase in furnace temperatures, and the curves should be carried to 2800 deg. at least.

To use the plot one must know the analysis of the original ash, reduce it to the form specified in the title, and locate the corresponding point on the diagram. An inspection will show whether an addition of lime or iron or a combination of the two will be more effective for that point.

In fixing the economics, the cost of the CaO, as previously developed, may be taken as $2.75 per ton, and of Fe_2O_3 as $7.25, or 2.6 times the cost of the CaO. To obtain the exact economic composition one would use the method of the appendix on the chart, but a good guess can be made by locating the point for the composition of the original ash and then judging by eye the point on the new flow-temperature curve which would require 2.6 times more CaO than Fe_2O_3.

The economic curves were determined, but were not added to the figure because of its crowded state. At a future time, when further data have been collected and the test points can be omitted, a more workable chart will be prepared.

For convenience, and as an indication of how such a chart should be used, the scales at the top and right-hand side have been added. These lines show the composition resulting from changes in one flux only; for instance, the line joining the 20 on the lower and the 20 on the upper scale gives at its intersection with the CaO horizontal lines the percentage of Fe_2O_3 in the mix corresponding to the CaO for all mixtures in which the ratio of Fe_2O_3 to $SiO_2 + Al_2O_3$ is 20 to 80—that is, when lime only is added to an ash the analysis of which falls on this line.

Unless Fe_2O_3 in some cheaper form than iron ore were available it would be desirable to use limestone alone, rather than introduce the complication of having the two fluxes to handle. Lime, however, becomes less effective as a flux as the iron in the slag is low, and the weight required may become large.

The question as to what would happen if the CaO was increased to large amounts in excess of what had been used arose when considering how it might affect the absorption of the flux at the surface of a slag bed when the flux was placed on the surface and the slag might become supersaturated with CaO.

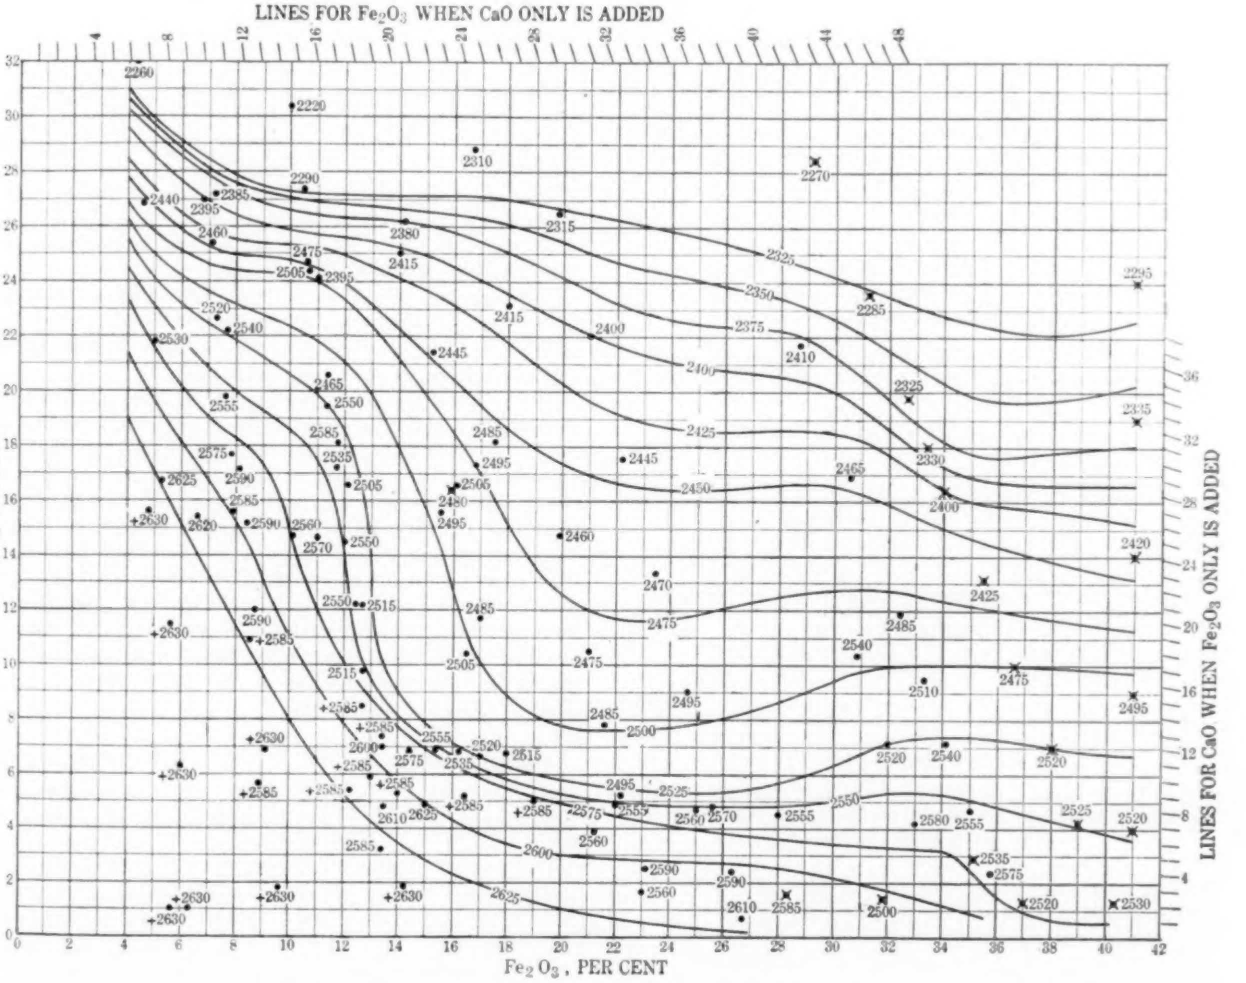

FIG. 7 PLOT SHOWING FLOW TEMPERATURES IN OXIDIZING ATMOSPHERES OF COAL ASHES HAVING A SILICA-TO-ALUMINA RATIO OF 1.7 TO 2.0, WITH VARYING CAO AND FE_2O_3 CONTENT

(CaO and Fe_2O_3 calculated on the basis of $SiO_2 + Al_2O_3 + Fe_2O_3 + CaO = 100$ per cent. Original ashes limited to a maximum of 2.0 per cent MgO. Points X have a silica-to-alumina ratio of 2.15.)

Fig. 8 shows the results from adding $CaCO_3$ to ash T-228 (Louisiana); this ash was chosen because at that time it was being used in the large gas furnace. Note that the percentage of flux added is shown as $CaCO_3$; the fluxing effect was uniform until 40 per cent $CaCO_3$ (22 per cent CaO) had been added; the flow temperature then remained at about 2190 deg. until 90 per cent $CaCO_3$ (50.4 CaO) was reached, after which the flow temperature increased at about the same rate as it decreased for the earlier additions.

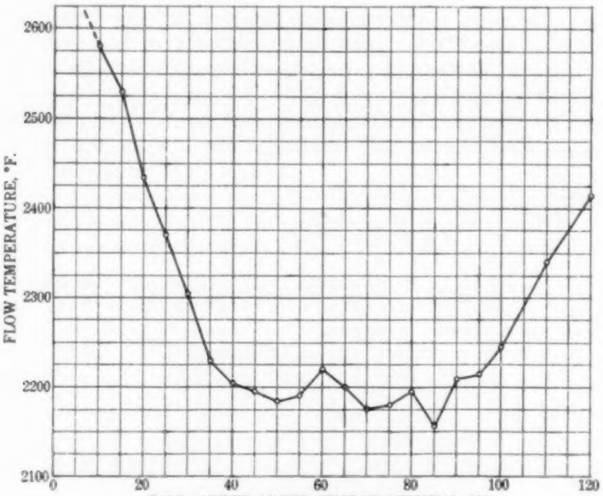

FIG. 8 PLOT SHOWING CHANGE IN FLOW TEMPERATURE OF SLAG T-228 WHEN FLUXED WITH CALCIUM CARBONATE ($CaCO_3$)

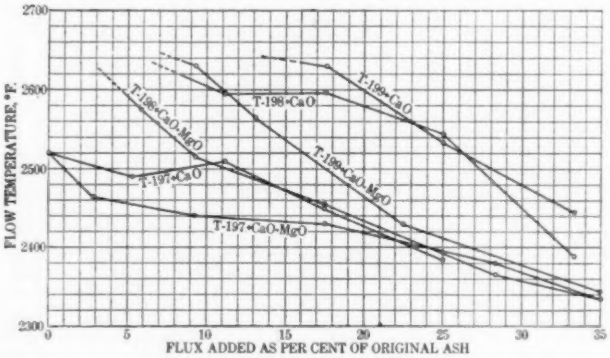

FIG. 9 PLOT SHOWING RELATIVE EFFECTIVENESS OF CaO AND CALCINED DOLOMITE (CaO.MgO) IN REDUCING THE FLOW TEMPERATURE OF THREE COAL ASHES

After about an 80 per cent addition of $CaCO_3$ the mixture began to have a crystalline feel. This test does not give a definite answer, because each addition was stirred in and not absorbed naturally, but it showed the limit of the fluxing effect of CaO.

Dolomite. Less work was done with dolomite than with limestone. In many districts dolomite and limestone are equally available and cost about the same, and it is therefore important to know the relative effectiveness of the two. There are several references in the literature in which opinions are expressed based on general observation. Bowles[12] discusses it in connection with metallurgical slags and points out the conflict of opinions.

Feild[13] made a series of tests on steel slags in which he changed the ratio of MgO to CaO within the limits of the MgO varying from 1.5 to 7.5 per cent of the total MgO + CaO and found that 5 per cent gave the greatest fluidity. The range he covered, however, is small compared with that of high-grade dolomite in which the percentage of MgO is 41.5 of the MgO + CaO.

Fig. 9 shows the effectiveness of dolomite and limestone on three ashes. The iron, lime, and silica-alumina ratios in the three ashes were:

Ash	Fe_2O_3	CaO	SiO_2/Al_2O_3
T-199	5.9	0.9	2.01
T-198	9.2	1.7	1.76
T-197	17.1	6.5	1.98

The figure shows that for ash T-199 the CaO.MgO was much more effective than the CaO, and for a flow temperature of 2600 deg. the weight of limestone required would be 1.7 times that for dolomite.

With ash T-198, dolomite had a still greater relative average effectiveness, and yet more for some portions of the curves for ash T-197. All three pairs of curves tend to converge, however, for large additions of flux, and even to cross.

The foregoing were all coal ashes. Fig. 16 shows a comparison of the CaO.MgO and CaO curves for T-212, an ash from oil sludges. The superiority of the dolomite is material, but not as great as for the other three ashes.

The evidence from these tests would appear to indicate conclusively that dolomite is decidedly superior to limestone, but it is not considered to be sufficient to generalize for ashes of all compositions; in particular, it has not been proved that it is true for the more refractory ashes when it is desired to lower their flow temperature a small amount, because the field of flow temperatures above 2630 deg. has not been studied.

An attempt was made recently to determine what percentage of MgO the dolomite should have to make it most effective. In these tests ash T-185, having 13.5 per cent Fe_2O_3, was used. Synthetic dolomites were made from $CaCO_3$ and basic magnesium carbonate. The compositions of the fluxes used, based on MgO + CaO = 100, were:

Number	1	2	3	4	5	6
MgO, per cent	0	7.2	14.6	22.2	32.0	41.9

Fig. 10 shows the results; they appear erratic and do not indicate as great a superiority for high MgO as is shown by Fig. 9. It is proposed to make further tests, and the results will

not be discussed further; however, in general, the curves show superiority for the high-magnesia fluxes.

Silica. The use of silica as a flux would be advantageous since it is obtainable generally and is of low cost. A comparison of ashes having high and low silica content and a given flux concentration usually showed a greater fluidity for the higher silica ashes. An example is ash S, having a silica-alumina ratio of 3.15 and a flow temperature of 2285 deg., whereas Fig. 7 indicates that with a ratio of 1.85 the flow temperature for the same lime and iron is 2450 deg. The difference of 165 deg. is evidently caused by the greater silica content of ash S.

The fluxing of ash P to the same composition as ash S by addition of silica, as well as iron and lime, lowered the flow temperature to 2355 deg. Similarly, fluxing to the same composition as S gave with ash T-185 a flow temperature of 2390 deg., with T-199 2380 deg., and with T-205 slag, where alumina was one of the added materials, 2370 deg. The average flow temperature for these four tests is 2370 deg., which is 80 deg. lower than indicated for a silica-alumina ratio of 1.85, but 85 deg. higher than the value for S. The reason that the flow temperature of S was not obtained may possibly be the inability of all the added silica to combine with the slag. In spite of prolonged thermal treatment, in which the slag, after addition of silica, was held at 2630 deg. for 2 hours, very small grains of silica were sometimes disitnguishable upon the slag surface.

The results of adding silica to ash T-205 are shown in Fig. 13. Here the addition of silica was effective up to a certain point, and further addition increased the flow temperature. The minimum flow temperature coincided with about a 3 to 3.2 silica-alumina ratio.

Other examples of lower flow temperatures occurring with higher sillica are pointed out in the section on steel slags.

From the limited data available it can be stated that the fluxing effect of silica with the coal ashes tested is limited, but it may be useful in slightly lowering the flow temperature of slags having a low silica-alumina ratio. It has been proved that this is so for slags having a high iron content, but not for those with low iron, and from the known relationship it is somewhat questionable whether it would help low-iron slags. Work should be done to settle this, but it would require the use of higher temperatures than those employed in this investigation.

Steel Slags. Table 6 gives the analyses of the steel slags tried. Slags A and B are waste products; it is understood that the flushing slag D, because of its high manganese content, is reused; slag C was made up to determine the effect of omitting the manganese and phosphorus. It will be noted that they all have a low alumina content and that all the other constituents except manganese have been mentioned as possible fluxes.

TABLE 6 ANALYSES OF STEEL SLAGS

Slag	A	B	C	D
Type of slag	Tapping	Tapping	Synthetic tapping	Flushing
SiO_2	14.88	17.68	18	29.40
Al_2O_3	4.08	...	..	2.68
Fe_2O_3	5.34	5.52	28	1.01
FeO	17.28	17.0	..	12.61
MnO	10.40	5.07	..	26.74
CaO	35.45	38.60	40	17.19
MgO	12.95	11.02	14	9.32
P_2O_5	1.78	1.87	..	0.76

Fig. 11 shows the results plotted as per cent of original ash. Note that to avoid confusion the temperature scale is twice that of all the other curves, and consequently, for comparison, the slopes are twice what they should be. The table on the figure arranges the ashes in the order of the increasing action of the fluxes on them; that is, the first one is the highest curve.

The deductions from a study of the curves are:

1 Considering curves 1 and 3, fluxes A and B are about the same; ash T-195 has more iron and lime than T-158. One would therefore expect that the result of fluxing the two ashes would be about the same, but curve 3 has a much greater slope than 1. The explanation must be in the higher silica in ash T-195 so that, when the additional silica which is in the flux is added to it, the silica is in excess and the fluxing components are rendered less effective.

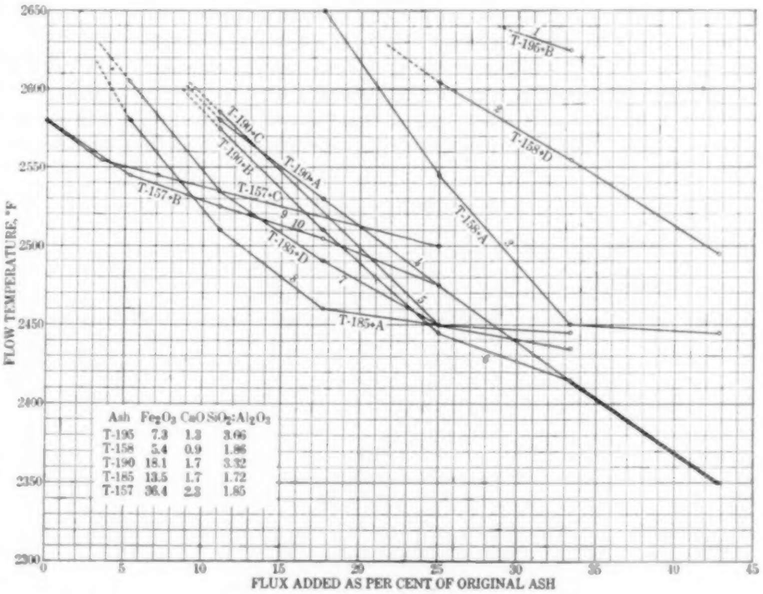

Fig. 11 Plot Showing Effect of Various Steel Slags on Flow Temperatures of Five Coal-Ash Slags

2 The same deduction can be made from curves 4 and 8. Both use flux A, and the iron in T-185 of curve 8 is lower than that in T-190 of curve 4. In spite of that fact, T-185 fluxes better than T-190 because of its lower silica.

3 Curves 2 and 3 are both with ash T-158; curve 2 uses flux D, and curve 3 flux A. Therefore flux A was more effective than D. Comparing fluxes A and D one sees that this effect may be partly due to the higher silica in D, but it is probably that the greater manganese oxide in D is not as effective as the greater iron oxide and lime in A.

4 Curve 10 is with ash T-157, which has a low flow temperature; the effectiveness of flux B as expressed by the slope of 10 was not as great as flux B used with ash T-190 in curve 6. This is explained by Fig. 7, which shows that the lime in the flux will be less effective with the high-iron ash T-157 than with ash T-190 having only 18.1 per cent Fe_2O_3.

5 Curves 5 and 6, and also 9 and 10, compare the effectiveness of fluxes C and B, the first curve in each pair being for flux C. In both pairs flux B was somewhat more effective than C. The idea in these tests was to determine whether the MnO had much influence; the curves show that the flux with the MnO was somewhat more effective, but the method of comparison does not justify assured conclusions. A further study was made on MnO by adding it in 1 per cent quantities to the slag as it existed at the last point of curve 5. The resulting

curve for flow temperature undulated somewhat, but up to 8 per cent MnO the average slope of the line was the same as the last section of curve 5, showing that the MnO under the test conditions had the same effectiveness as slag C and that small amounts did not introduce marked improvement.

These tests show that the tapping slags are effective fluxes, and the data given are sufficient to indicate the effect of the composition of the ash to be fluxed on their usefulness.

Forms of Iron

All the tests in the electric furnace were made in an atmosphere of air. Under reducing conditions platinum ware is quickly attacked and has a short life. The slags and ashes used in the investigation were in various stages of oxidation when received, and performing tests under oxidizing conditions was expected to remove one source of error by maintaining all tests under uniform conditions. Fieldner and others[14] have shown that cone-softening temperatures are largely influenced by the surrounding atmosphere, being higher for both highly reducing and highly oxidizing conditions than when the two effects are balanced. The effect on flow-temperature determinations as made in this investigation could not accurately be foretold, and therefore the following studies were made.

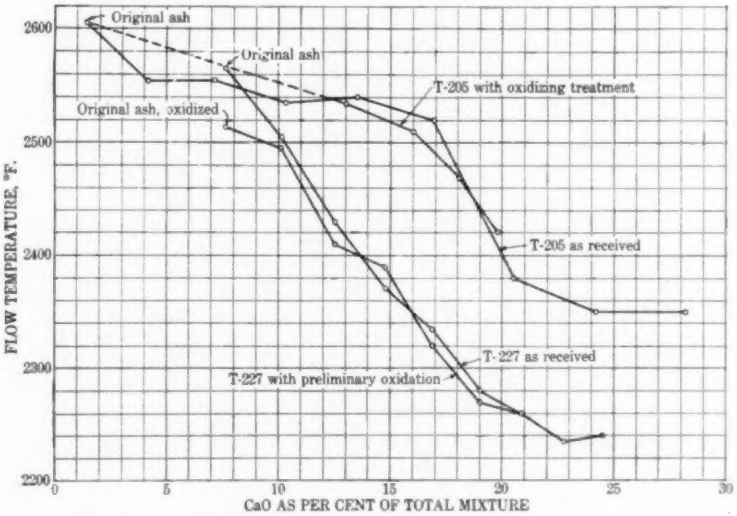

Fig. 12 Plot Showing Effect of Increase in CaO Content and Change in Forms of Iron for Two Similar Coal-Ash Slags

(Oxidation at 2650 deg. fahr.)

Analyses for forms of iron on T-205 and T-227 slags showed the reduction to be about the same. Oxidation by heating each slag at 2590 deg., with oxygen being blown over the molten slag surface, reduced the flow temperature of T-227 slag by 50 deg. in 13 hours and of T-205 by 15 deg. in 11 hours, therefore indicating the better fluidity with oxidized slag. That such results may be a function of internal rearrangement of the slag constituents is possible, but is hardly thought to be the explanation. No petrographic studies of the slags have been made, since it was felt doubtful that useful information on fluxing could be obtained without a long investigation.

Some of the ashes, of which T-227 was one, showed a greater drop in the flow temperature for the first addition of $CaCO_3$ than for the second and third additions, and it was thought that this might be due to oxidation taking place at a higher rate than when no flux was added. That $CaCO_3$ hastens oxidation is shown by tests on two ashes. Using ash T-205, one sample was maintained at 2590 deg. with oxygen blown over the surface; a second sample was mixed with $CaCO_3$ and heated for two hours without oxygen; and the third was mixed with limestone and heated for 12 hours with oxygen. Ash T-227 was given one test when mixed with $CaCO_3$ and heated for 13 hours with oxygen. The forms of the iron at the end of these tests are shown in Table 7.

TABLE 7 OXIDATION OF SLAGS

	FeO	Fe_2O_3	Fe
Ash T-205:			
1 Original ash	22.6	9.0	5.5
2 Oxidized 11 hours at 2590 deg.	11.1	28.5	Trace
3 Added CaO to 21.0 per cent, 1½ hr. at 2590 deg., without oxygen	1.6	30.7	Trace
4 Added CaO to 20.7 per cent, oxidized 12 hours at 2590 deg.	2.9	29.5	Trace
Ash T-227:			
5 Original ash	19.3	11.7	3.1
6 Added CaO to 21.8 per cent, oxidized 13 hours at 2590 deg.	2.1	28.6	Trace

Item 1 shows that, even with pure oxygen over the surface, the oxidation of the FeO is very slow and that there was 11 per cent at the end of 11 hours, whereas with $CaCO_3$ there was only 1.6 per cent left at the end of 1½ hours. The other items confirm this, although they were made for another purpose.

It can therefore be taken that, when determining the flow point of a slag having the iron in a reduced form, little oxidation occurred during the time required to make the determination.

Fig. 12 probably shows this more clearly. Two tests were made with slag T-227. The flow-temperature determination of the slag as received made in the standard method is shown on the curve to be 2565 deg.; the first addition of $CaCO_3$ reduced it to 2505, and further addition to values as shown by the curve. In a second test with the same slag, it was given a preliminary oxidation before adding lime, which reduced the flow temperature to 2515. The first addition of $CaCO_3$ was then made and resulted in a flow temperature of 2495; further additions were made as in the previous test. The figure shows that, except for the effect of the first addition, the two curves are identical within the order of difference to be expected in such tests. The tests with T-205, as shown by its curves, indicate the same result.

The conclusions from these tests are:

(1) That a slag having iron in a reduced form has a higher flow temperature than one in which the iron is largely oxidized.

(2) That the first addition of $CaCO_3$ to a slag having the iron in a reduced form causes an oxidation of the iron which results in a greater drop in flow temperature than occurs when the iron is initially in an oxidized state.

(3) That after the first addition of $CaCO_3$ the fluxing is the same independent of the form of the iron in the original ash.

Temperature-Time Tests

The description of the technique employed on the electric-furnace tests pointed out that after putting an addition of flux into the crucible the mixture was brought up to a temperature not more than 30 deg. higher than the flow temperature found for the previous addition of flux, and then a determination was made of the new flow temperature. This was done to save time and to make the mixture fluid enough that the flux could be thoroughly mixed with the slag; if this were not done there would be no assurance that the flux was distributed through all the slag in the crucible. Following this procedure, a slag which originally had a flow temperature of 2700 deg. might, by successive additions of the flux, finally have a flow temperature of 2300.

---

[14] Fieldner, A. C., et al., "The Fusibility of Coal Ash and the Determination of the Softening Temperature," U. S. Bureau of Mines Bull. 129, 1918.

In service and in the large gas-furnace tests the imposed conditions would be quite different; then one might desire to flux the same ash when its temperature could not exceed 2300 deg. Would this be possible, would the amount of flux required be the same as that found necessary in the small-scale tests, and how long would it take?

One of the objectives of the large-furnace tests was to obtain answers to these questions. As far as they involve action of large masses they can be answered only by large-scale tests, but since such tests are time-consuming and expensive, some studies were made in the electric furnace. It could at least be proved whether the before-mentioned refractory ash and slag, mixed in the proportion to give a flow temperature of 2300 deg., would melt and attain the flow fluidity if kept at not above 2300 deg.; also the time required to attain fluidity would give some indication as to what the relative times would be in the large-scale tests.

To obtain this information, a series of tests were made in the electric furnace, and these tests are briefly summarized. Quantities of flux previously determined from a run in the normal manner were intimately mixed with ash and brought slowly to the temperature where the melt should be fluid; care was taken to avoid a higher temperature. Constant watching and occasional thorough stirring indicated when fluidity was finally attained. In almost every run, "gassing" of the charge seemed to increase viscosity, but on the final evolution of gas the charge became quiet and fluidity was easily judged.

Although 21 tests in all were made, a brief summary should suffice to enable conclusions to be drawn. With ash T-197 an addition of limestone, previously known to have been fluid at 2450 when overheated, became fluid at 2455 in 15 minutes when that temperature was not exceeded. Similarly, enough lime to produce an expected flow temperature of 2245 became fluid at 2245 in 2$^1/_2$ hours; the time was required mainly to work out bubbles of gas which were continuously forming, indicating a slower reaction.

Using T-198, which by itself is not fluid at 2630 deg., sufficient lime was added to produce fluidity at 2535; it became fluid at a maximum temperature of 2545 in 20 minutes. With this same refractory ash and solid flux, fluidity was obtained in 35 minutes at 2390 with a mixture previously known to be fluid at 2390 deg.

Similar results were obtained with T-185, Detroit Edison ash; for a mixture of lime and ash previously found to be fluid at 2215 when the ash had been heated in contact with lime to 2630, standard fluidity was obtained in 65 minutes at 2230 when that was the maximum temperature to which the new mixture was brought.

These tests show the possibility of fluxing reactions at temperatures where both constituents are solid. For instance, with T-185, the penetration point does not occur till 2430 while the initial deformation by the cone test occurs at 2240. In general, it should not be necessary, therefore, to raise the temperature of the ash-flux mixture to a point more than a few degrees higher than the finally attained flow temperature unless unusual speed of fluxing is desired.

Although these tests show that fluxing can be accomplished at very low temperatures, yet to date the minimum limit of temperature has not been determined. Further information could be obtained by a series of flux additions and temperatures coinciding with the curve of Fig. 8.

PENETRATION TEMPERATURE

Little analysis has been made of the penetration temperatures. Their values convey more meaning if expressed as the difference between the flow temperatures and the penetration temperatures, in that these values give some indication of the change in fluidity with temperature. As the difference is large, tapping will be easier as the slag will not stiffen as quickly; small values will indicate tendencies to clog the spout.

Some of the differences for lime and also fluorspar were plotted, and they confirm the effectiveness of the fluorspar in giving a fluid slag which is easy to tap. The comparisons were taken from the tests of ash T-185. With lime the interval between the two temperatures was approximately the same for percentages of lime added up to 40 per cent, the value being about 125 deg. With fluorspar there was a difference of from 350 to 400 deg., showing that the fluorspar gives a long range of fluidity. When a flux consisting of lime and 20 per cent fluorspar was used, the difference was about 180 deg.

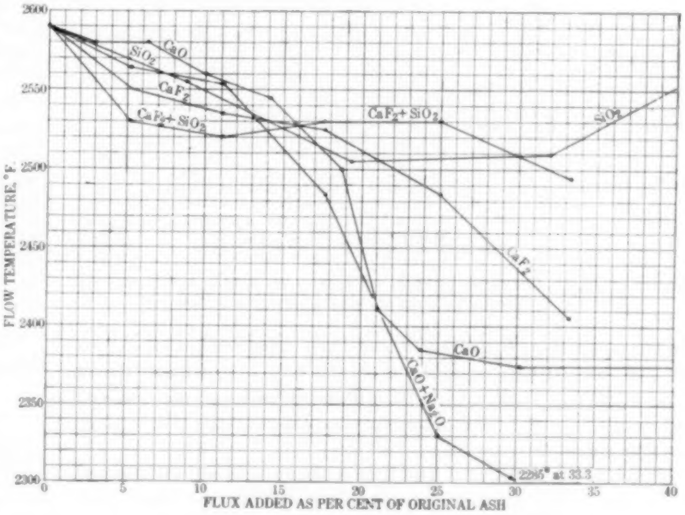

FIG. 13 PLOT SHOWING EFFECT OF VARIOUS FLUXES ON DEEPWATER SLAG (T-205)

(For CaF_2 + SiO_2, weight ratio of fluxes is 0.87 CaF_2 to 1.00 SiO_2. For CaO + Na_2O, weight ratio is 3.4 CaO to 1.0 Na_2O.)

A peculiarity has been apparent when fluxing with lime—namely, that with some ashes the first or second addition of flux produces a relatively low penetration temperature; the meaning of this has not been determined.

DEEPWATER SLAG, T-205

The samples of slag received from the Deepwater Station, T-205, are of special interest because of their high iron content and their highly reduced state; also they are interesting because the deposited slag contains 42 per cent iron as Fe_2O_3, whereas the percentage in the ash of the coal is only 26 per cent.

The ash had a very short fluid range, and the difference between the flow temperatures and the penetration temperatures was only 85 deg. The sudden increase in fluidity was very noticeable.

In the fluxing tests the slag had the peculiarity that in the earlier stages it was resistant to the action of the fluxes; therefore the chemical analysis was carried further than is usually necessary, and the titanium dioxide and phosphorus were determined; these, shown in Table 1, were low, and chemically the analysis showed nothing specially noteworthy other than the low Fe_2O_3 and high FeO and metallic iron, which is discussed under the section on forms of iron.

Because T-205 was at the high-iron end of the ashes, it was tried with a number of fluxes to obtain points for Fig. 7. Fig. 13 shows a number of the tests made; note that this plot also has twice the temperature scale; the flux is given as per cent of original ash.

The CaO curve shows that the action of the flux was not great for the early additions, but after 6 per cent the effectiveness increased uniformly up to 21 per cent. Even the action of fluorspar as shown by the CaF_2 curve was sluggish up to 10 per cent, as also was the action of lime and saltcake, the CaO + Na_2O curve, but both became more active as the percentage of added flux increased. The action of silica in the SiO_2 curve is interesting because, of all the fluxes tried, its effectiveness was constant up to a certain point and then it reversed itself, and a 10 per cent further addition took the flow temperature above the 2630 deg. limit. The silica-alumina ratio of the original ash was 1.79, and at the minimum flow temperature of the curve it was about 3.

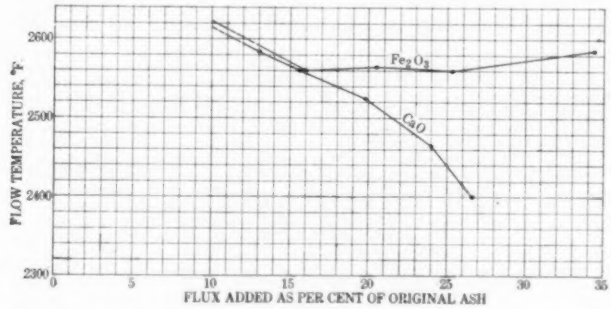

FIG. 14 PLOT SHOWING EFFECT OF CaO AND Fe_2O_3 ADDITIONS ON THE FLOW TEMPERATURE OF GLEN LYN SLAG (T-246)

The CaF_2 + SiO_2 curve is of interest because it was an attempt to utilize a low viscosity ratio of lime and silica. Herty and others[15] have shown that these oxides in the proportions to give calcium meta-silicate, $CaSiO_3$, have a low viscosity with rapid increase in fluidity with increase in temperature. In the tests made the ratio of CaF_2 and SiO_2 used for the flux was that to give SiF_4 and $CaSiO_3$, the former being a gas. The first 5 per cent addition was more effective than any of the other fluxes, but after that, for some unexplained reason, there was no action for the following 20 per cent addition.

It was thought that the peculiarities of the Deepwater slag might be due to the mineralogical forms taken by the constituents because of the high iron content, and that if the percentage of iron present was reduced by adding silica and alumina, then it would act as other slags with a similar iron percentage. To test this, silica and alumina in the same 1.79 ratio of the original slag were added; curves for these tests will not be given. After reducing the Fe_2O_3 in the mix to 20 per cent, lime was added; the resulting flow temperatures were higher than they should be from Fig. 7. Explanations have not been found, and it is probable that there are other factors affecting the high-iron end that have not been recognized.

GLEN LYN SLAG, T-246

Two small samples of slag were received from the Glen Lyn Station with the report that they were on the border line of tapping. They are of interest because they are the most refractory slags received from a slagging-bottom furnace. The second sample was received some months after the first, but the analyses of the two do not differ much. The analyses on the basis of the major constituents are as given in the following table, but because of the extra high MgO in these ashes, the lime has been increased 1 per cent:

	First	Second
SiO_2	54.5	55.3
Al_2O_3	30.8	30.2
Fe_2O_3	9.7	8.9
CaO	5.0	5.6
	100.0	100.0

Using the foregoing analyses it will be found that the points lie outside the 2625-deg. curve of Fig. 7; the flow-temperature determination on the first ash confirmed this. A flow temperature of about 2700 deg. might be expected.

The first ash was tested with lime and ferric oxide. Fig. 14 shows the results, which check well with those computed from Fig. 7. From what is known of the success in tapping this slag, if a flux were used it would be necessary only to lower the flow temperature a little to make the tapping somewhat easier; because of the limitation of test temperatures, Fig. 14 therefore does not give the exact values, but probably 7 per cent of either flux would be required to reduce the flow temperature to 2650 deg. The curves of Fig. 14 visualize what can be derived from Fig. 7; they show that for slags of this type, iron oxide and lime are equally good down to a flow temperature of 2580 deg., but after that the iron is not as effective.

INCINERATOR SLAG, T-209

This slag was from the combustion chamber of an incinerator, the bottom of which gradually filled up with a glassy slag; the operators desired to know whether anything could be added to keep it in a loose form. The opportunity was taken to study its reactions with various fluxes, and it might be that the slag could be run out instead of shutting down to remove it. Fig. 15 shows the tests made. The slag itself had a flow temperature of 2230. Dolomite lowered the temperature 40 deg., but all the other fluxes raised it, except fluorspar, which was quite effective. The fluorspar was not used beyond 25 per cent.

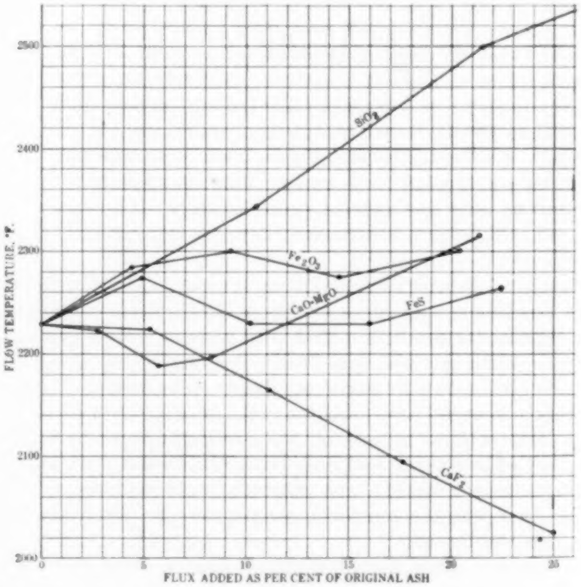

FIG. 15 PLOT SHOWING EFFECT OF VARIOUS FLUXES ON FLOW TEMPERATURE OF INCINERATOR SLAG (T-209)

but 2025 degrees was reached; this is the lowest flow temperature attained by any mix during this investigation.

---

[15] Herty C. H., Jr., et al., "Temperature-Viscosity Relations of the Lime-Silica System," Coop. Bull. 47, U. S. Bureau of Mines and Carnegie Institute of Technology, 1931, p. 15.

Louisiana Slag, T-211, T-212, and T-228

The analyses of the three slags are given in Table 1. The ash deposited in the furnace differs materially from those from coals, and because of changes in the fuels used, the deposited slag will vary from time to time.[16] The samples received were of the same class; they differed materially as lumps, but when averaged for each lot were more nearly alike. The widest differences were evidently dependent on the quantity of extraneous matter mixed with the coke when burned.

Because of the high silica and alkalis, these slags tend to have properties like glass and a long melting range. Thus T-212 started to soften at 1520 degrees, but its flow temperature was above 2630 and probably about 2700.

Tests were made on all these slags. A comparison of fluorspar on two of them is shown in Fig. 3. Fig. 16 shows the relative action of several fluxes on T-212. Assuming that it was necessary to reduce the flow temperature to 2600 deg. for tapping, then the equivalent of about 6 per cent CaO or of calcined dolomite would be required—that is, 10 lb. of limestone or 11 lb. of dolomite per 100 lb. of slag.

These slags flux down to low flow temperatures with constant effectiveness for all fluxes. For lower values dolomite is more effective than limestone, as was also found for the coal ashes.

Tests in Large Gas Furnace

Fig. 17 shows the large gas-fired furnace which was built for this investigation. The desirability of constructing a furnace in which coal could be burned and the ash from it deposited in the furnace was considered, but the additional complications and expense offset the possible advantages. The combustion chamber aimed to draw the gases over the surface of the bed and to give uniform distribution. The four stacks have damper bricks to permit of individual control, and in addition the draft on the common flue to which the stacks are connected was controllable. The upper sheet-iron dampers gave further control and admitted air which mixed with the gases so that the sheet-iron flues could be kept cooler.

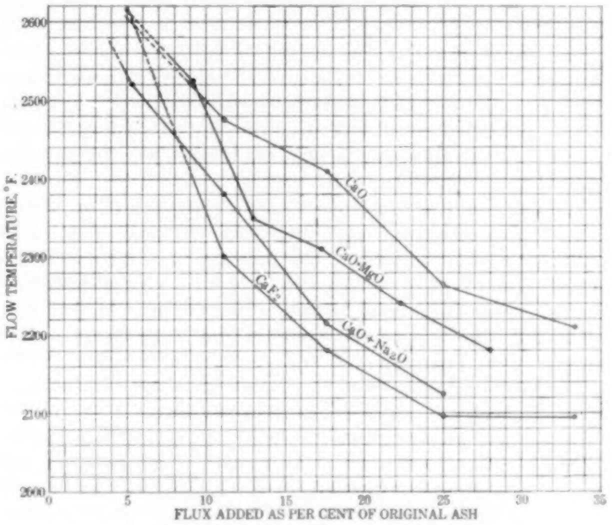

Fig. 16 Plot Showing Effect of Various Fluxes on Flow Temperature of Louisiana Slag (T-212)

(For added CaO and Na_2O, weight ratio is 3.4 CaO to 1.0 Na_2O.)

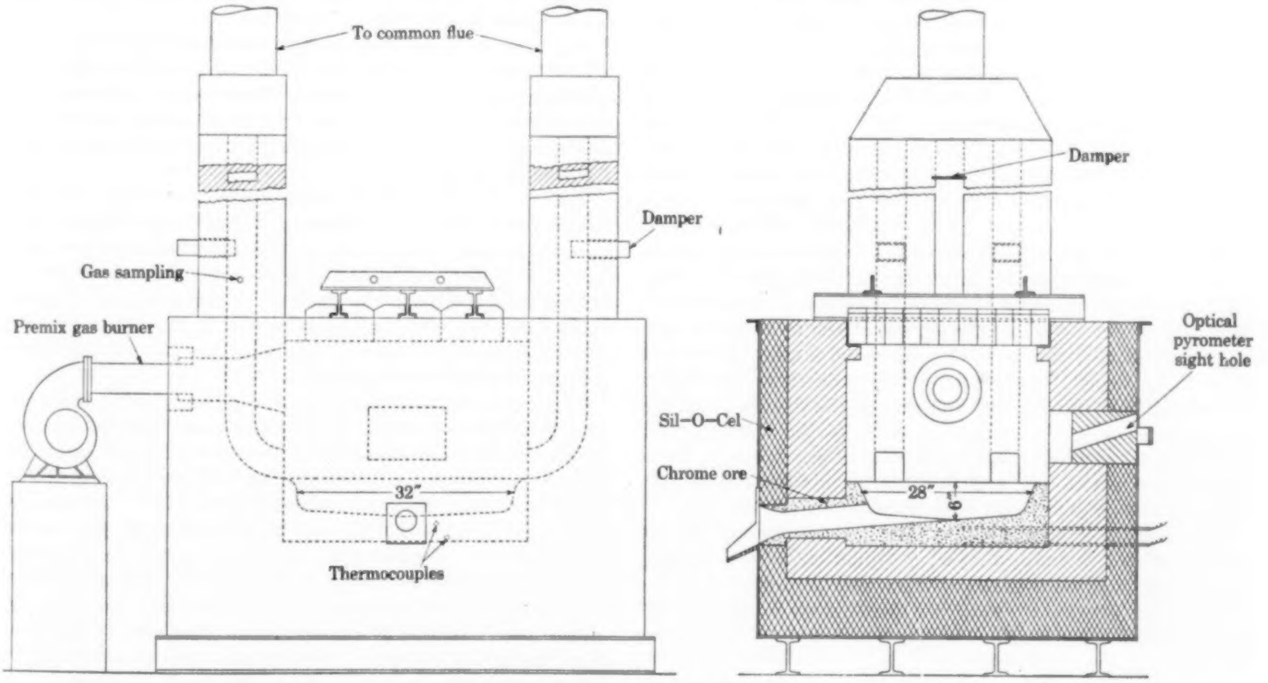

Fig. 17 Large Gas Furnace

The best material to use for the hearth caused some worry. It was important that it should not be absorbed by the slag, and also that the slag could be run out completely and the hearth used for the next test without renewal; also, it should not be too thick. It was decided to try chrome ore first, although at that time this material had not been used for boiler furnaces, as has been done since. It was also proposed to try carborundum, but this has not been used to date. Analyses have shown that the amount of the ore absorbed into the body of the slag is small for any one test, and the most damage has occurred in trying to remove all the slag at the end of a test when excess fluorspar is used.

---

[16] Klotz, H. S., "Use of Oil-Refinery Waste Fuels in Modern Steam Boilers," A.S.M.E., Fuels Division, Chicago Meeting, Feb., 1931.

The temperature of the surface of the slag was observed through a sight hole in the door. The optical pyrometer was carefully calibrated, and observers were trained by checking each other. A further check was made by sighting on a rare-metal couple inserted through the opposite wall, the junction being encased in an alundum ball.

The gas flow was controlled through a meter and an orifice; a continuous measure of the composition of the stack gas was given by a CO_2 indicator. The pressure in the furnace was measured and kept to as near zero as possible without too much leakage at the top of the furnace. There was no difficulty in controlling the burning to maintain the temperature of the surface of the bed within 20 deg. of the desired value.

The two couples buried in the hearth permitted of a fair estimate of the temperature gradient in the slag.

It was not proposed that the ease of tapping this furnace should be used as a measure of the fluxing. The small quantity of slag to be removed, the relatively thick wall, and the necessity of keeping the hole small were not favorable to ease of tapping, but yet the arrangement acted very satisfactorily. The slag was caught on sheet-iron trays.

The general procedure was as follows: The furnace was heated for some hours at a temperature higher than that to be used in the test. The ash or slag was broken to pass a $^1/_2$-in. mesh; to save time the required weight of ash was added in two or three instalments, with the objective of fusing it into one mass. When all the ash was more or less fused, the temperature of the surface was reduced to the desired value. The addition of flux and the subsequent procedure depended on the objectives of the test.

The fluidity of the slag at any time was an important measurement. Several methods which would give numerical, though probably arbitrary values, were considered, but one which simulated the "feel test" of the small electric furnace was adopted. A tool was made consisting of a piece of $^1/_2$-in. pipe 8 ft. long, with a $^1/_2$-in. by 1-in. ell at one end. A piece of 1-in. carbon rod 9 in. long was screwed into the ell, and it was therefore at right angles to the pipe; the end of the carbon rod was kept sharpened to a 45-deg. angle. The carbon rod was used in a manner similar to the platinum stirring rod, and though the fluidity could not be measured with the precision possible in the small furnace, yet the method proved satisfactory; care was taken to avoid stirring the molten slag and thus not to mix it mechanically. Welding carbon was found very satisfactory for the rod.

The samples of slag collected from the bed during the test were restricted to the top layer; it would have been useful if they could have been collected from various depths, but this would have disturbed the slag, and there always would be doubt as to where it came from. The slag which clung to the carbon rod was usually sufficient.

Readings were made every 30 minutes, but the temperature of the surface of the bed was observed as much oftener as was necessary to maintain constancy.

Ten tests have been made to date. More were desirable, but as a choice between that and other work, they were put off to the future. The first two tests were made early in the investigation to obtain an idea of what possibilities there were in the method; at that time there were few data from the small furnace, and it was recognized that the large one could not be used effectively without knowing more about the relations derived from the small tests; consequently, no further tests were made till that work was well advanced. The feeling rod was not developed until after the second test, and the thermocouples were not put in until after the sixth test.

There is one factor which is common to all tests that should be borne in mind—namely, the temperature gradient through the fuel bed and its effect upon the actions which occur. In the electric furnace all the slag in the small crucible was at approximately the same temperature, but a large gradient was possible through the bed of the gas furnace, and it was not known what allowance should be made when deciding on the quantity of flux to be added.

Test No. 1. Ash T-185 was used; it was aimed to keep the surface at 2600 deg. To 100 lb. of ash 18.5 lb. of fluorspar was added. Trouble occurred because the molten slag ate through the taphole. Tapping was tried after $2^3/_4$ hours, but the bottom of the bed was not fluxed, and that tapped was so fluid that it worked behind the sheet-iron lining and into the insulation. Then 10 lb. more of fluorspar was used to clean the bed.

This test illustrated the rapidity of the fluxing effect of fluorspar and its high fluidity when in excess.

Test No. 2. Test No. 2 was made on the most refractory ash, T-158, having 5.4 per cent Fe_2O_3 and 0.9 CaO. The ash and the flux were mixed before putting in the furnace; 100 lb. of ash and 25 lb. of fluorspar—which was equivalent to 21 lb. of CaF_2—were used. The mixture was added in three lots, and the surface temperature was kept at 2600 deg. It was successfully tapped $9^1/_2$ hours after the first additions, and 134 lb. was removed; the extra 9 lb. tapped was probably some of the slag left from the previous test in addition to some chrome ore from the hearth.

Fig. 3 shows that 21 per cent of added flux gives ash T-158 a flow temperature of 2550 deg. Since neither the temperature gradient in the bed nor the fluidity was measured, exact comparisons cannot be made, but the successful tapping showed that the prediction from Fig. 3 was on the safe side for the successful tapping of this ash.

Test No. 3. The slag from the Louisiana Station was used. Ashes T-211 and T-212 represented slag from different locations in the bed; as there was not enough of either for the large-scale tests, they were mixed, and an average curve had to be assumed for predicting the quantity of flux required from the small-scale data. The object of this test was to study the action of fluxing this ash with limestone when the surface temperature was kept at 2550 deg.

The hearth thermocouples were not in place, and the temperature gradient was not known. Later work showed that the average temperature assumed for the bed was too low and therefore the predicted flux too small, but the test was informative.

Ash and limestone in the amounts of 250 lb. and 78 lb., respectively, were used; this was equivalent to 31 per cent of added $CaCO_3$. The limestone was added to the top of the slag in one charge; this made a too thick insulating layer and lowered the temperature of the slag, so a portion was removed and added later. It took $6^3/_4$ hours for the limestone to disappear from the surface of the bed; 9 hours more was allowed to elapse before tapping, and as the slag was not sufficiently fluid, the temperature was increased to 2575, when it was tapped with some difficulty.

A number of the samples collected were analyzed, and the results were very puzzling. Details need not be given, but they acted as guides for future work. The chief difficulty was to explain what had become of the lime, as a sample taken at the surface of the bed contained only 12 per cent of the lime added, and one taken during tapping only 21 per cent. The explanation of this was not discovered until later.

Two analyses were made to determine if much of the hearth was absorbed by the slag. They gave Cr_2O_3 as 0.5 and 0.3 per cent, showing that it was negligible for this ash and flux.

Test No. 4. Ash T-205, Deepwater, was used with limestone, with the aim of fluxing with a surface temperature of 2500 deg. The slag used was 250 lb.; a total of 105 lb. of limestone, or 23 per cent CaO, was added in stages; the first charge was too heavy and materially lengthened the test; from Fig. 13 there should be sufficient flux for 2390 deg. Heating for 20 hours failed to produce a fluidity low enough for tapping; fluorspar was therefore added, and the slag was tapped three hours later.

The slow absorption of the lime was very noticeable, and the progress of the softening through the bed was very slow; after $22^{1}/_{2}$ hours from the first addition of flux the bed was solid 1 in. below the surface. The short interval between the penetration temperature and the flow temperature has been referred to and would be unfavorable for rapid fluxing. Only three of the samples collected were analyzed; two were taken from very fluid pools in the bed and showed an excess of CaO. The third was an attempt to obtain a sample from near the bottom of the bed; it also contained excess lime, but the method of collecting was questionable.

Test No. 5. The object of this test was to determine whether fluorspar would flux ash T-205 more readily than did limestone in test No. 4; the surface temperature was the same, 2500 deg.; the spar was 83 lb., equivalent to 26 per cent CaF_2, which Fig. 13 shows should give a flow temperature of 2455 deg.; the flux was placed on the surface. The melting progressed regularly, but not abnormally fast; after 16 hours the bed was fluid for a depth of $3^{1}/_{2}$ in. and was tapped at 20 hours, although it was not considered to have the standard fluidity.

This test showed a more rapid action for fluorspar than for limestone, but not as great as was expected from the small-scale tests. Again, from later knowledge, it was known that the flux added was not enough to take care of the temperature gradient in the bed. As mentioned before, chemical analyses with fluorspar present are difficult to make and are likely not to be dependable; the three samples analyzed showed a very uneven distribution of the flux.

Test No. 6. This test was a duplication of test No. 4, except that the ash and flux were mixed before being put into the furnace; the object of this was to simulate the action in a slagging-bottom furnace in which it is assumed that the flux is added continuously and is thus thoroughly mixed with the ash as it is deposited. There were 200 lb. of ash T-205 and 85 lb. of limestone used, and the surface temperature was maintained at 2580 deg. The mixture was put in the furnace in three lots, and it took a total of $9^{1}/_{2}$ hours to obtain fluidity of the whole bed.

The mixing of the slag and flux thus gave better action, though some of the improvement would be due to the higher temperature.

Three samples were analyzed. The estimated CaO in the mix was 23.7; a sample from the liquid at the surface at $4^{1}/_{2}$ hours gave 25 per cent CaO; one immediately before tapping, 27 per cent; a composite sample of all the slag tapped gave 23.1 per cent. The limestone was therefore accounted for and was slightly higher at the surface.

Test No. 7. It was necessary to replace the chrome-ore bed after test No. 6, and the thermocouples were added when doing this. This test used 200 lb. of ash T-228 (Louisiana) and 68 lb. of limestone, with a surface temperature of 2400 deg. The object was to attempt to flux at a low temperature and to try to account for the CaO missing in test No. 3. Fig. 8 shows the fluxing effect of $CaCO_3$ on T-228. The test ran 60 hours from the first addition of flux, which was added in three lots spread over the test; the surface temperature was also carried at several values. These changes were not premeditated, but resulted from the knowledge of the temperature gradient in the bed.

Finally the slag was successfully tapped with a surface temperature at 2400 deg., at which time the mean temperature of the slag bed was estimated as 2260 deg. The 68 lb. of limestone added to the 200 lb. of ash, and allowing for 1 per cent impurities in the limestone, gives 33.7 per cent $CaCO_3$ added; from Fig. 8 the predicted flow temperature would be 2250 deg., which is as close a check as could be expected.

Five of the samples taken during the test were analyzed. Those taken from the top of the bed showed very low CaO content; this will be discussed later. An average sample of the whole of the tapped slag gave the equivalent of 33.9 per cent added of $CaCO_3$, which closely checks the 33.7 actually added.

This test showed that the temperature gradient through the bed was greater than had been allowed for in previous tests, and if the correct amount of flux were added, the laboratory results were confirmed.

Test No. 8. Test No. 8 was run immediately after test No. 7 without allowing the furnace to cool and was a test of ash T-198 with limestone and a surface temperature of 2580 deg. The ash is refractory, having 9.8 per cent Fe_2O_3 and 1.7 CaO, and the bed was therefore quite solid when the flux was added. To study what would happen, only enough limestone was added at first to produce fluidity at 2580 deg. The reasons for such a study are discussed later. The absorption of the flux was slow; after 17 hours the top was lumpy, and there were only a few pools about $^{1}/_{2}$ in. deep. More limestone was added, but after 30 hours the surface was lumpy, although the underneath slag was plastic. To test whether an intimate fresh mixture would become fusible under these conditions, 40 lb., in the same proportion of flux to ash, was added to the surface; it fused relatively quickly. The test was run for a total of 50 hours; during the last 15 there was little change, the top being thickly fluid with floating lumps in it and the stiffness increasing with depth. As it was necessary to close the test, fluorspar was added, and it was tapped after $2^{3}/_{4}$ hours.

Fluidity of the whole bed was not expected in this test because the lime content of the mix was only 22.3 per cent, with a resulting Fe_2O_3 of 7.8. Locating this point on Fig. 7 shows that the corresponding flow temperature is 2520, whereas the mean temperature of the bed was about 2380 deg.

Five of the samples collected were analyzed. Some floating lumps which had looked like unabsorbed lime gave only 5.36 CaO, showing that they were mainly ash.

Test No. 9. The purpose of test No. 9 was to determine if an ash having a flow temperature above 2700 deg. could be fluxed in a furnace which could not raise the temperature of the surface of the bed higher than 2500 deg., with the additional limitation that the flux was to be added to the surface of the bed.

For the ash, 100 lb. of T-198, the same as for test No. 8, was used. The total dolomite added was 59 lb., or 30 per cent CaO.MgO; Fig. 9 shows that the resulting flow temperature should be 2360 deg. The final mean temperature of the bed was 2340.

The absorption of the dolomite was slow, but seemed more rapid than the action in the previous test with the limestone, in which the surface temperature was higher but the percentage flux too low. Lumps floating on the surface dissolved very slowly; because these were not all dissolved after 17 hours, and because they would have clogged the taphole, fluorspar was added. Even then solution of the lumps was slow, and it required five hours before it was safe to tap.

The test showed that a refractory ash could be fluxed according to the predictions from the laboratory tests at a mean temperature of 2340 deg., which would be below its penetration temperature.

The test required 59 per cent of dolomite, and the increase in weight of the slag was 31 per cent. Also it showed that the flux could be added to the surface, but better action would result if the flux was added in proportion to the ash deposited.

Some lumps taken from the surface gave by analysis the same CaO.MgO content as the fluid material at the surface, in contradiction to the lumps taken in test No. 8.

Test No. 10. Test No. 10 was to obtain additional data on mass action when using fluorspar, and in particular to determine how the spar tended to distribute through the bed. There was not enough of ash T-198 for this test, so others were mixed to give one of about the same iron and lime content. [Note: Three additional tests are given in the Authors' Closure.—Ed.]

For 125 lb. of ash, 36.5 lb. of fluorspar, or 25 per cent of CaF_2, was used, and the surface temperature was kept at 2500 deg.; this should have been sufficient to flux at 2320. The results did not come up to expectations, either in rapidity of the action or the fluidity. After 33 hours there still were lumps and the slag at the bottom was stringy, so the temperature was raised to ensure ease of tapping.

The cause of the lack of fluidity was an underestimate of the flux required, because the small-scale test with this flux and ash had not been carried low enough and also because the CaF_2 in the fluorspar was taken as greater than it was, and allowance was not made for the silica and alumina which formed the rest of the spar.

Discussion of Large Gas-Furnace Tests

As far as they have been carried, the tests in the large furnace show that the data obtained in the electric furnace could be used to predict the quantity of flux that would be required to produce fluidity, although the work has not been carried far enough to give predictions on the time which would be required. No large-scale tests were made using saltcake and some of the other possible fluxes. It has been thought possible that the use of a small percentage of saltcake with the limestone might accelerate the action, and it was the intention to make some trials.

It will be noted from the reports of the individual large-scale tests that it was acknowledged that full information was not obtained in all tests because of incorrect quantities of flux or other causes. However, each test increased the knowledge of the investigators on what happened and how slags melted. It may be that similar studies have been made, but no such account has been found, and the authors were unable to find answers to a number of questions which suggested themselves, but the answers to which have an important bearing on the investigation. Some of these were as follows:

Assume that a fluxing material is spread on the surface of a bed of slag which is sufficiently solid that the flux will not sink into it, and assume that the surface of the bed is kept at a fixed temperature by combustion above it, and that consequently there is a temperature gradient through the bed, then:

(1) As reactions occur between the slag and the flux, what order of saturation of the flux will occur in the top layers of the slag; will it tend to become supersaturated?

(2) At what rate will the flux progress through the bed? What will be its final distribution?

(3) Will the upper and hotter layers tend to retain a higher percentage of flux and thus deprive the lower layers of the opportunity to become more fluid, so that the fluidity will decrease with distance below the surface?

(4) Will a flux which is molten at the temperature of the surface have an advantage because of its molten condition?

It is possible, of course, to suggest certain chemical, thermodynamical, and hydrodynamical actions or laws that will fix or control the sequence of events that will occur, but because the actions will of necessity be very complex, it would seem that answers can be obtained only by experimentation.

There was curiosity on these questions because it was feared that, unless the bed became fluid enough for convection to occur in the bed, there would be a tendency for the flux to segregate in the upper part of the bed; also the answers to them have an important bearing on operation.

Distribution of Flux in the Bed

Under test No. 3 it was stated that the samples taken from the surface showed a deficiency in CaO and that in later tests this feature was carefully watched and a number of samples were taken and analyzed.

All the data collected will not be given in this report, but the evidence shows that although limestone or dolomite is placed on the top of a nearly solid bed of slag, yet ultimately the concentration at the surface is much below the average, and because a composite sample shows a quantity of flux equal to that known to be in the bed, therefore the concentration of flux at the bottom must be above the average.

The same was found with dolomite and with fluorspar. Against this evidence, in test No. 6, where the limestone and slag were mixed before placing in the furnace, the concentration at the top was about normal.

The deficiencies in flux at the top were quite large, 50 per cent in tests Nos. 3 and 7, and 40 per cent in test No. 8, all when using limestone.

To check this, a special test was made in a small gas furnace, but under similar conditions of heating to the large furnace. The average computed CaO was 17 per cent; the CaO at the surface, middle, and bottom was 4.6, 13.4, and 22.4, respectively.

No assured explanation can be given. The natural one is that the porous calcined stone absorbs heavy slag, perhaps by preference taking the iron, and then gradually eats its way to the bottom of the bed faster than it is dissolved into the slag; but one would not have predicted such a course of events and movement toward the lower temperature.

Whatever the cause, as far as this may occur it is all to the good from the standpoint of fluxing. Because the temperature decreases downward, more flux will be required to produce the same fluidity as that at the upper portion; consequently, the fluidity through the bed will be more uniform and a greater depth can be run off at one tapping than would be possible if the flux were uniformly distributed through the bed.

Results as Applied to Slagging-Bottom Furnace

As stated in the introduction, no advice has been received since the investigation started that any station burning coal in a slagging-bottom furnace has found it impossible to remove the slag by tapping. It is not known how many stations are on the border line, or whether many have trouble in starting the flow—which trouble could be lessened by a partial fluxing.

Also, it has been pointed out that when planning the investigation, for lack of more definite information, it was assumed that the slag should be such that it would flow with the necessary freedom when at a temperature of 2550 deg., this value being the temperature of the bed at the middle of the thickness which it was desired to run off in one operation; consequently, to prolong the life of the test furnace the maximum temperature used was fixed at 2630 deg., and when testing a refractory slag, the smallest order of fluxing measured was the quantity of flux to lower the flow temperature to 2630.

It has turned out that 2630 is low, and that in many installations the slag is tapped at a higher temperature; if in such plants a certain coal gave a slag with a flow temperature of 2800 which could not be tapped, then it would be necessary only to add sufficient flux to reduce the flow temperature to 2700, for example. An assured value for the quantity of flux required for the foregoing illustration is not given by the work done to date, but a knowledge of the quantity to flux the slag to 2625 is probably sufficient; the minimum quantity to overcome difficulties with average operation would under any circumstances be fixed by experience.

If a flux were used as a regular procedure, then in the type and size of boilers installed to date the economics would be the controlling factor. On this basis, the investigation has shown that, for slagging-bottom furnaces, limestone, dolomite, and iron ore, or their equivalent in waste products, are the only fluxes that need be considered.

In the choice between limestone and dolomite, the investigation does not give assured data for flow temperatures above 2600, but it is probable that their effectiveness is approximately the same down to 2600 deg. and that they could be used interchangeably; therefore, only limestone and iron will be discussed.

All predictions for quantity of flux necessarily assume that the chemical analysis of the slag is known. Knowing the analysis and using Fig. 7, the flow temperature of the slag as deposited can be found; having this point, its position relative to the line representing the flow temperature it is desired to reach can be studied, and a point on it selected, the composition of which will probably entail the lowest cost of flux. The costs used in this respect are \$2.75 for CaO as limestone and \$7.25 for Fe$_2$O$_3$ as iron ore; thus for the same cost one can use 2.6 times as much CaO as Fe$_2$O$_3$. Knowing the desired new composition of the slag, the weights of limestone and iron ore required per 100 lb. of slag can be computed from formulas [1] and [2] of the appendix.

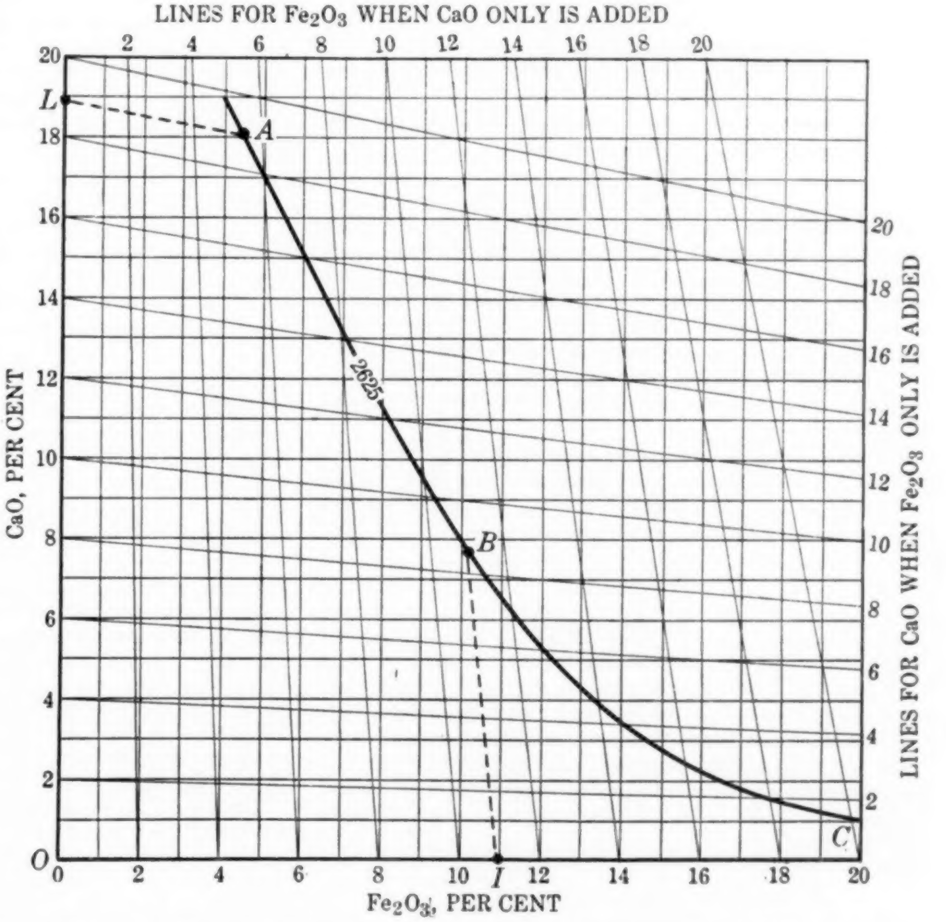

FIG. 18 PLOT SHOWING THE DERIVATION OF THE ECONOMIC QUANTITIES OF CaO AND Fe$_2$O$_3$
(For ashes having flow temperatures greater than 2625, when fluxed to 2625.)

The economic curves were not plotted on Fig. 7 because of the confusion they would cause. If the conditions are limited to fluxing slags having a flow temperature greater than 2625 deg., and make the problem that of desiring to reduce it to 2625, the economics can be simplified.

Fig. 18 shows a portion of Fig. 7, and only the 2625 flow-temperature curve is plotted; the functions of the sloping lines were explained in connection with Fig. 7. Using the foregoing costs, it happens that the economic tangent derived by the method in the appendix coincides with the straight portion of the 2625 curve. The following facts result:

(1) If the point corresponding to the composition of the deposited ash falls within the area *OLABIO*, then any point on *AB* can be taken for the composition of the fluxed slag, and all points on this line will give the same and also the lowest cost for the total flux.

(2) If the point falls in the area *BIC*, then the lowest cost of flux will result from using lime alone and no iron.

(3) The continuation of the 2625 line *BA* upward has not been determined, but if we assume that no deposited ash will contain less than 5 per cent Fe$_2$O$_3$, then the general statement can be made that, if a deposited ash has a flow temperature above 2625, there is no cheaper way of fluxing it than by using limestone.

(4) Although limestone will give a low cost in flux, yet the total weight added to the bed will usually be greater than if the same fluxing were done by also using iron.

Limestone can be used also for occasional fluxing, such as around the taphole. The absorption of limestone is slow, and quicker action results from using fluorspar. Information on this feature is not complete, and further tests will be made.

GENERAL SUMMARY

The relations shown by Fig. 7 for iron and lime are the most important outcome of this investigation. It gives the relations for only one state of fluidity, but a rough idea of the relations for the more plastic condition represented by the penetration temperature will be obtained when their values are analyzed.

The relations for the other fluxes were not worked out as completely, but the data given are probably sufficient for general use.

The investigation as here presented is not considered complete, and a limited extension of it is planned, including that of obtaining flow-temperature curves for Fig. 7 for higher temperatures.

It is expected that additional data on fluxing that can be added to those here given will be obtained in the next phase of this general investigation related to the use of fuels in slagging-bottom furnaces. It has been agreed with the committee to study the selective action in the combustion chamber of such furnaces as fixing the quality and quantity of the ash deposited. This will necessitate the testing of a large number of ashes and slags collected from the slagging furnaces.

The success obtained in this next phase will be dependent largely on the help that is received from operating stations, and the demands that it will be necessary to make on them will be far greater than for the fluxing phase.

ACKNOWLEDGMENTS

This investigation has been carried out under the authorization of O. P. Hood, chief engineer, mechanical division. R. A. Sherman, fuel engineer, and E. Taylor, assistant fuel engineer, conducted some of the earlier work; M. E. Bessemer, junior fuel engineer, has worked on the investigation for the greater part of its life. The many chemical analyses required were made in the chemical laboratory under the direction of W. A. Selvig. Helpful suggestions were received from C. H. Herty, Jr., physical chemist.

Acknowledgment is made of the support given to the investigation by the members of the committee and its chairman, P. B. Rice; also to the engineers of a number of stations who have supplied information and samples.

Appendix

PERCENTAGES

WORK such as that reported requires frequent changes from one basis of percentages to another. Usually these are straightforward, but the following two formulas are helpful for a system in which there are two fluxes and both vary.

Call one flux X and the other Y and assume that they are used in plots such as Figs. 5 and 7. Assume also that the slag to which the fluxes are to be added contains originally some of both fluxes.

Let

A_x = per cent of flux X in the original ash
A_y = per cent of flux Y in the original ash
x = per cent of flux X in the slag after it is fluxed
y = per cent of flux Y in the slag after it is fluxed
W_x = weight of flux X added per 100 lb. of original ash
W_y = weight of flux Y added per 100 lb. of original ash

(Note: Both W_x and W_y are the flux as it appears in the slag—that is, CaO and not limestone.)

Then

$$W_x = \frac{(100 - A_y)x - A_x\,(100 - y)}{100 - (x + y)} \qquad [1]$$

$$W_y = \frac{(100 - A_x)y - A_y\,(100 - x)}{100 - (x + y)} \qquad [2]$$

ECONOMIC AMOUNT OF FLUX

A study was made to derive the simplest method of determining the economic amounts of flux. The derivation of the formula and method need not be given, but it results in the following: Use the foregoing symbols, and, in addition, let

C_x = cost of X per unit weight
C_y = cost of Y per unit weight

Then for a minimum cost

$$\frac{dy}{dx} = -\frac{100\,\dfrac{C_x}{C_x - C_y} - y}{100\,\dfrac{C_y}{C_x - C_y} + x} \qquad [3]$$

If the costs of X and Y are the same,

$$dy/dx = -1, \text{ or } 135 \text{ deg.} \qquad [4]$$

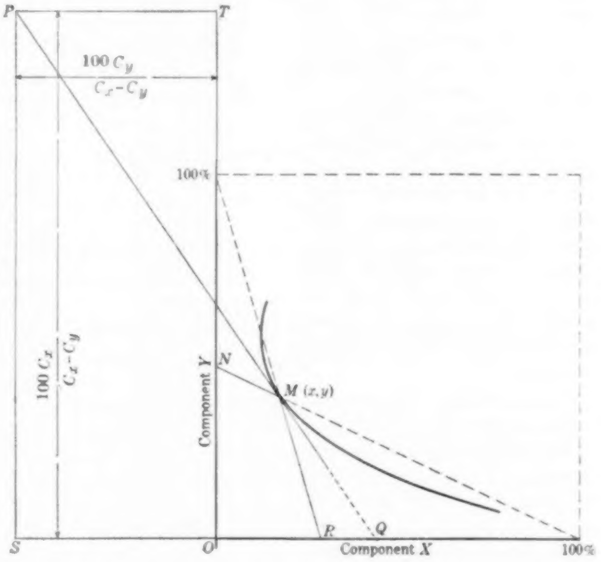

FIG. 19 DIAGRAM SHOWING PRINCIPLE OF DETERMINATION OF ECONOMIC MIXTURE

Since the curves are irregular, Equation [3] cannot be solved, but there is a simple way of doing it graphically for assembly of curves like Figs. 5 and 7. Fig. 19 shows this for the condition that cost of X, C_x, is greater than C_y.

The point P is found as shown, and the tangent from it to any one of the curves gives the point M. The quantity of fluxes at M (x, y) are those which will make the total cost of flux less than that of any other point on the curve.

The meaning of the point M is that if the point for the composition of the original ash lies in the area $ONMR$, then the correct quantity of fluxes must be added to bring the composition to that of M; formulas [1] and [2] would be used.

If the point for the composition of the original does not lie within the area $ONMR$, the point M cannot be reached by adding fluxes; if it lies above the line NM, then the lowest cost will result if only flux X is added; if the point lies to the right of MR, then only flux Y would be added.

If the flow-temperature curve is not a simple one, solutions can still be obtained, but the discussion would be rather long.

Discussion

ARTHUR J. HERSCHMANN.[17] It would be interesting to know how the fluxing material would be prepared for, and how introduced into the furnace chamber. Would it be conditioned as to size and temperature?

---

[17] Agent for Vitkovice Steel Works, New York, N. Y. Mem. A.S.M.E.

Blast-furnace slag was used many years ago for cement manufacture in Bohemia. The writer does not know whether slag from pulverized coal would be less suited for that use nor is he sufficiently posted on cement manufacturing to know the reasons governing such possibilities at the present time.

W. W. Boyd.[18] Chrome ore (chromite $FeCr_2O_4$) is a mixture of oxides of iron and chromium; it is the most inert of all refractory materials, having no tendency to unite with anything.

The use of chrome ore as a hearth lining is open to the objection that a certain amount of iron is absorbed from the charge by the lining, and transfer may occur between the charge and lining according to the equilibrium characteristics of the ash under test. Since all of the ash analyses show iron present, the lining eventually will contain iron, which might give erroneous results.

To clean the hearth, it may be useful to use a jet of compressed air played upon the hearth by an iron pipe in the hands of the operator. With the furnace up to temperature and the slag out, the jet can be used to "wash" out the remainder. On this small gas furnace, oxygen might be useful.

The suggestion to use carborundum (silicon carbide) as a lining brings up a characteristic which is troublesome—the slags freeze at high temperatures; likewise, it acts opposite to the bath—if the bath is acid, the carborundum acts basically.

G. K. Saurwein.[19] These experiments have been carried out to find answers to the problems and serious difficulties that are encountered in the operation of the slag-tap type of furnace. As the granular form of ash is much simpler to handle, the question arises as to whether it is worth while to continue the use of the wet-bottom furnace. Of course, if an outlet for the refuse from either type of furnace could be found, the question would easily settle itself. When powdered coal first began to be extensively used, say 8 or 10 years ago, operators were hoping that satisfactory outlets for ash would be developed, with perhaps some profit, but at any rate that the refuse could be disposed of without imposing too much of a burden on the operators or causing a nuisance to the public. The ash-disposal question will become more acute as time goes on. Are we coming any nearer to the solution of that problem?

This question of what to do with the ash interests greatly all powdered-coal users and is without doubt of sufficient importance to be assigned for study to a sub-committee of the Research Committee.

Authors' Closure

Replying to Mr. Herschmann, in the original plans made by the committee it was proposed to carry out an additional phase of the investigation, which would have been conducted at a station on a full-size operating boiler, but because no station to date has found it necessary to use fluxes extensively, this additional work has not been done. At that time several methods were suggested for introducing the flux into the furnace. It was agreed that it would probably not be advisable to add the flux to the coal before pulverizing because, apart from the hardness of most possible fluxes, the flux should not be introduced as a fine powder, but the pieces should be at least large enough to ensure that they would not be carried out of the furnace with the gases. Two methods looked feasible; one, to pulverize to a large-mesh size and add to the pulverized coal on its way to the burner, but this would probably be inadvisable because of the extra wear on pipes and burners; the other, to crush to a mesh of $^1/_2$ in. or less, and to distribute the flux over the bed at intervals through one or more nozzles by means of an air blast. For occasional use good distribution could be obtained by injecting through sight holes situated well above the bed.

The study of possible uses for or means of disposing of the slag as tapped has not been a part of this investigation, but it is understood that several companies and individuals are giving this subject careful consideration.

Replying to Mr. Boyd, it was necessary to replace the chrome-ore lining after the test no. 6 because the relatively thin sides were eroded. Although the slags which had been used contained high iron, particularly the Deepwater, yet the penetration into the material of the lining was not deep. However in tests nos. 11 and 12, in which iron ore was used as a flux, the analyses of the resulting slag showed a deficiency in iron, and absorption by the bed may account for this. The composition of the lining will be determined when it is renewed.

Considerable additional work has been done since this paper was written. This has included three further tests on the large gas furnace to study the action of iron ore and of salt cake. Brief reports on these tests have been added. They confirmed that the data from the small-scale tests given in the paper can be safely applied in predicting the action of all the fluxes used.

Additional Tests on Large Gas Furnace

The following three tests were made after the paper was written. They are required to complete the data given in the paper.

Test No. 11. The purpose of this test was to study the action when using iron ore alone with a slag low in CaO, and to follow this by adding limestone; it was in effect a study of changes over the plot of Fig. 7. A charge of 125 lb. of ash T-185 was used. On the basis of Fig. 7 it had a content of 1.9 per cent of CaO and 14.1 of Fe_2O_3 and a flow temperature of +2630; the point corresponding to it is shown on the figure. The iron ore used had a Fe_2O_3 content of 78 per cent and the limestone 51 per cent of CaO. A reducing atmosphere was maintained throughout the test.

The ash was heated as in previous tests with a surface temperature of 2680, but though fused it was solid. The first addition of ore was 17.2 lb., with the surface temperature maintained at 2660. Action was very slow, and after 13 hours the bed was pasty in spots, but mainly covered with layers of unmelted ore. A second addition of 22.5 lb. of iron ore was equivalent to an average of 31.5 per cent Fe_2O_3 in the charge. At the end of 25 hours more there was a fluid layer of 1 in. with a hard surface below; the mean temperature of the bed at that time was 2340. Samples taken at this time gave:

	FeO	Fe_2O_3	as Fe_2O_3
Fluid surface	12.8	15.5	29.7
Floating lumps	6.2	40.6	47.5

The conclusion is that the reduction of the iron ore to FeO was slow, as was its absorption into the bed, but yet that the majority of the ore was below the fluid layer. The iron distribution through the fluid layer was not determined, nor is it known how far the added iron had penetrated into the more solid part of the bed. This slow action would be expected because Fig. 7 shows that the fluidity is not increased materially by the addition of iron.

In a boiler furnace some unconsumed carbon will be deposited on the bed and might help the reduction of the Fe_2O_3 to FeO. To simulate this action a mixture of silica sand, iron ore, and anthracite fines was added to one-half the bed; it contained 8.6 lb. of Fe_2O_3 and 0.9 lb. of SiO_2. To the other half of the bed was added 10 lb. of limestone.

On the iron ore-silica half there was vigorous bubbling, and at the end of 1 hour the surface was again fluid for 1 in., but with the same abrupt change from liquid to solid. On the limestone half, the surface was also fluid at the end of the hour, but the transition from liquid to solid was not as abrupt. At $7^1/_2$ hours the iron ore-silica side was fluid to $1^1/_2$ in. depth, with abrupt transition; the limestone side was fluid for $2^1/_2$ in., with gradual transition.

To equalize the lime distribution, 10 lb. of limestone was added to the iron ore-silica side, and 22 lb. distributed evenly over the whole surface. Vigorous boiling occurred with rapid increase in fluidity. At the end of 4 hours the whole bed showed an approximately uniform fluidity through its depth, but this fluidity was below the standard because not enough lime had been added for the mean temperature of 2460 deg. To rectify this, 15 lb. of limestone was added, mainly to the center and iron-silica side. The slag was successfully tapped 3 hours later.

An analysis of a composite sample of the tapped slag gave 17.9 per cent CaO, 14.7 FeO, and 9.5 Fe_2O_3, or an equivalent of 25.8 per cent Fe_2O_3. Fig. 7 gives a flow temperature of 2435 deg. for this composition, against an estimated mean temperature for the bed of 2460; this agreement shows that, for the range of temperatures covered by this test at least, the values given by Fig. 7 can be depended on for the quantity of flux required.

This text confirmed that iron ore alone is not a suitable flux for ashes low in lime; that the rate of absorption of the iron ore is slow; that with a high iron content the rate of action of CaO is rapid.

Test No. 12. Test no. 12 was a repetition of test no. 11 except that the iron ore and limestone were premixed instead of all the ore being added first and the limestone later. The ash and procedure used were the same as in test no. 11. The first addition of flux was 22 lb. of iron ore and $35^1/_2$ lb. of limestone. The surface temperature was kept at 2660.

At the end of 1 hour a thin layer of slag covered most of the surface, and at the end of 3 hours the entire bed was covered with $^3/_4$ in. of fluid slag, but the bed beneath was quite solid. At the end of 6 hours from the application of the flux the entire bed was penetrable and of approximately the same fluidity; the layer of very fluid slag on the surface had disappeared.

[18] Hamilton, Ohio. Assoc-Mem. A.S.M.E.

[19] Engineer, Lehman Hall, Harvard University, Cambridge, Mass. Mem. A.S.M.E.

A second addition of flux of 15 lb. of iron ore and 25 lb. of limestone was added, the total flux being that estimated to give fluidity at 2430 deg. One hour later there was again a layer of fluid slag over part of the surface, but the greater part was lumpy. From this time, the bed gradually became more fluid and was tapped 13 hours from the second addition of flux.

This test showed that when the iron ore and limestone are applied at the same time, the fluxing action is relatively rapid.

The analysis of a composite sample of the slag tapped gave 17.1 per cent CaO, 9.6 Fe_2O_3, and 9.2 FeO. The Fe_2O_3 equivalent was thus 19.8 against 24 per cent estimated from the materials used. This discrepancy may be partly due to the material added not having the estimated iron content, but the weight of the slag tapped in both this and in test no. 11 was below the weights estimated from the materials put in the furnace; it is probable that some slag, high in iron, was absorbed by the lining of the bed.

The evidence collected from tests nos. 11 and 12 on the distribution of the iron oxides in the bed is conflicting. Samples taken by the feeling rod before the final fluidity was attained indicated that the iron oxide content was greater in the lower layers. On the other hand, samples taken from the top layer of the bed previous to tapping gave the following:

	Fe_2O_3	FeO	as Fe_2O_3	CaO
Test 11, surface-*R*	17.5	21.4	41.3	3.1
Test 11, surface-*L*	8.4	24.0	35.1	10.5
Test 11, composite	9.5	16.3	25.8	17.9
Test 12, surface	25.4	10.4	37.0	13.9
Test 12, composite	9.6	9.2	19.8	17.1

The surface sample *R* in test no. 11 was from the side to which the iron ore-silica mixture had been added, and *L* from the other side. The reason for the high iron content in the surface samples has not been determined. These and all other samples of these two tests confirmed the tendency of the lime content to increase with depth. The lime in the composite samples agrees with the estimate of that added, 17.2 per cent.

Test No. 13. The object of this test was to determine whether an addition of a small proportion of salt cake to limestone would help the fluxing. The ash used was 125 lb. of T-185, the same as for tests nos. 11 and 12. The surface temperature was kept at 2660 deg., and the mean temperature of the bed was about 2460 deg.

The first flux addition was 27 lb. limestone and $5^1/_2$ lb. salt cake. After $2^1/_4$ hours the bed was soft nearly to the bottom and of nearly uniform fluidity, although the surface was uneven.

To watch the relative action, the second addition consisted of 17 lb. of limestone to the left half and 17 lb. of limestone and 5.1 lb. of salt cake to the right. After 1 hour the left half showed less absorption than the right. After $4^1/_2$ hours from the second addition the left half showed more lumpy material at the bottom than did the right and was not quite as fluid. After $6^1/_2$ hours the whole bed was of the same fluidity and free from lumps, and it was tapped.

Because salt cake is a relatively thin fluid at 2625 deg., it was not possible to ensure that the distribution aimed at was maintained. However, the test showed that the salt cake increased the rate of fluxing, but not enough to warrant its use because of its high cost.

The analyses of samples from this test are not too reliable, because 11, 12, and 13 were run consecutively and the tap hole had become plugged so that the bed could not be thoroughly drained; also the distribution in the bed might not have been uniform. The analyses were as follows:

	CaO	$Na_2O + K_2O$
Sample from top before tapping	19.6	4.2
Composite	18.9	4.2

This indicates uniform distribution of the CaO.

The conclusion from the three tests nos. 11, 12, and 13 with ash T-185 is that limestone by itself would not only be more economical, but the addition of iron ore would increase the weight of slag to be tapped and would lengthen rather than shorten the time required for fluxing. The use of salt cake, although not economical, increased the rate of action and decreased the time required to produce the required fluidity.

The SO_4–CO_3 Ratio for the Prevention of Sulphate Boiler Scale

By EVERETT P. PARTRIDGE,[1] NEW BRUNSWICK, N. J., W. C. SCHROEDER,[2] ANN ARBOR, MICH., AND R. C. ADAMS, JR.,[3] ANNAPOLIS, MD.

The investigation described in this paper is a logical development of R. E. Hall's well-known work. The authors felt that the true value of the SO_4–CO_3 ratio must be appreciably greater than the value calculated by Hall, and, as a result, a program of research at the University of Michigan was sponsored by The Detroit Edison Company to determine more accurately, if possible, the solubility relations of boiler waters. The work done on this project is described by the authors.

E. P. PARTRIDGE

W. C. SCHROEDER

R. C. ADAMS, JR.

WHEN R. E. HALL applied physical chemistry to the control of boiler-water conditions he rendered an inestimable service to boiler operators. His work described in his well-known bulletin[4] and in numerous publications has stimulated many other investigations. The one described in the present paper is a logical development from Hall's pioneering efforts. While the authors believe that the present paper modifies the numerical value of Hall's SO_4–CO_3 ratio to an important degree, they feel that their investigations in no way detract from the brilliance of Hall's earlier efforts.

It seemed probable to the authors that the true value of the SO_4–CO_3 ratio must be appreciably greater than the value calculated by Hall. As a result a program of research at the University of Michigan was sponsored by the Detroit Edison Company in order to determine more accurately, if possible, the solubility relations in boiler waters. The research on this project was carried on continuously from February, 1929, to July, 1931.

METHODS OF DERIVING THE SO_4–CO_3 RATIO

Only a brief comparison of Hall's derivation of his SO_4–CO_3 ratio and of the present authors' method of evaluating this ratio will be given in this paper, since the subject has been discussed in a more complete form in a paper presented before the American Chemical Society which is to be published soon. The purpose of the present paper is to place the results before boiler operators for discussion.

Hall's Derivation. Hall evaluated the SO_4–CO_3 ratio for the simultaneous existence of solid anhydrite ($CaSO_4$) and solid calcite ($CaCO_3$) in equilibrium with a boiler water at a given temperature by using the concept of the solubility product. His method of derivation is open to three criticisms. The first of these is that a boiler steaming at a high rating may not actually approach an equilibrium condition, but instead the boiler water may be more or less supersaturated with respect to either anhydrite or calcite or both substances. The second criticism is that Hall made a long extrapolation of Kendall's uncertain data for the solubility of calcite in the range up to 100 deg. cent. in order to obtain the solubility product for calcite at boiler temperatures. The third point is that Hall's use of the ionization data of Noyes involves considerable uncertainty, since it leads to rather large variations in the value of the solubility product, which theoretically should be a constant. Hall himself noted these variations,[5] but since the fluctuations for both anhydrite and calcite were in the same direction, he assumed that they would largely cancel out in the ratio.

A New Method of Evaluating Hall's Ratio. Most boiler waters fall in the range of dilute solutions as usually defined by the physical chemist. It seemed, therefore, that it might be profitable to apply some of the newer developments in the field of dilute solutions to the study of boiler-water equilibria. Some years ago Lewis and Randall[6] had discussed their development of the activity concept with relation to dilute solutions, and Debye and Hückel subsequently supplied a highly mathematical theoretical substantiation of the empirical conclusions reached by Lewis and Randall. It is interesting to note that the Debye-Hückel theory has recently been applied to the field of boiler-water chemistry by McKinney.[7]

The present authors started from Lewis and Randall's definition of the "ionic strength" as a measure of the total concentration of a dilute solution and of the "mean molality" as a measure of the solubility of a saturating substance in such a solution. The ionic strength, represented by the symbol μ, is defined by the equation, $\mu = \frac{['] + 4[''] + 9['''] + \ldots}{2}$ where the brackets represent the respective sums of the concentrations of all the uni-valent, bi-valent, and tri-valent ions present in the solution under consideration. Concentrations are customarily expressed in mols per 1000 grams of solution and are stoichiometric values involving no theoretical considerations of ionization. The mean molality for a substance such as $CaSO_4$ or $CaCO_3$ is the square root of the product $[Ca][SO_4]$ or $[Ca][CO_3]$, stoichiometric values again being used. In considering the equilibrium between $CaSO_4$ and $CaCO_3$ it is possible to save one step in the calculation of data by using, instead of the mean molality, merely the products $[Ca][SO_4]$ and $[Ca][CO_3]$.

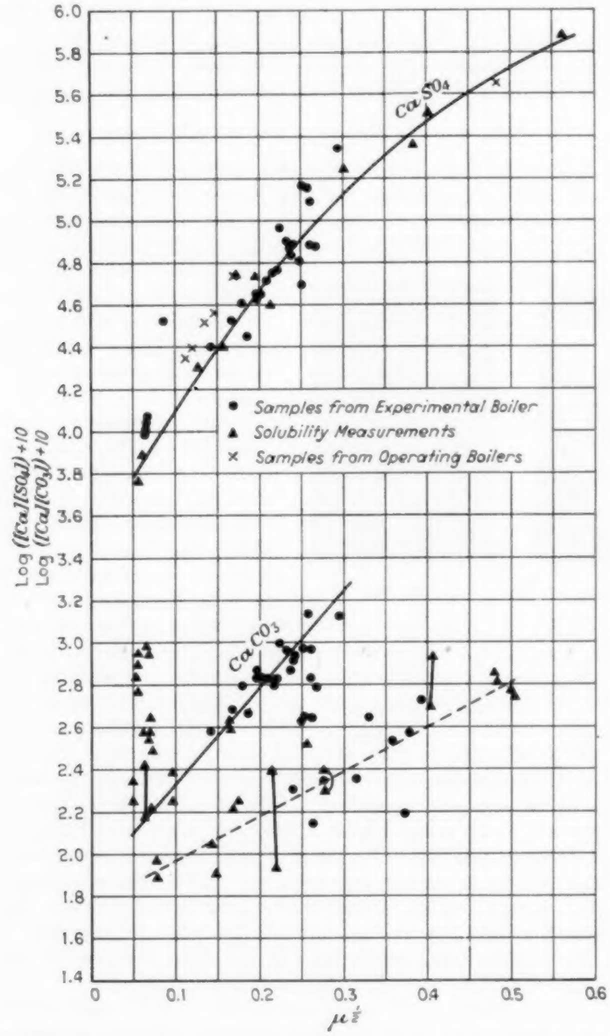

FIG. 1 CURVES REPRESENTING SOLUBILITIES OF $CaSO_4$ AND $CaCO_3$ AT 185 DEG. CENT. (150 LB. PER SQ. IN.) AS A FUNCTION OF IONIC STRENGTH OF SOLUTION

Concentrations expressed in mols per 1000 grams H_2O were used in calculating values of log ($[Ca][SO_4]$) and log ($[Ca][CO_3]$).]

For all dilute solutions saturated with respect to anhydrite the values of some function of the product $[Ca][SO_4]$ plotted against the values of some function of the ionic strength should define a curve or a narrow band. In other words, the solubility of anhydrite as expressed in terms of $[Ca][SO_4]$ should be approximately constant for all solutions of the same ionic strength regardless of the specific composition of these solutions. For actual use it is convenient to plot log ($[Ca][SO_4]$) and log ($[Ca][CO_3]$) against $\mu^{1/2}$. If a sufficient number of complete analyses were available for solutions saturated at a given temperature with either anhydrite or calcite or both solid phases, it would be possible by plotting the results in the manner described to define a range within which points for anhydrite fall and another range in which the points for calcite fall. If these ranges were narrow, they might be represented by single curves. The equilibrium value of the SO_4-CO_3 ratio at any given ionic strength might then be determined from the difference in ordinate of these curves, since

$$\frac{[Ca][SO_4]}{[Ca][CO_3]} = \frac{[SO_4]}{[CO_3]}$$

for a solution saturated with respect to both anhydrite and calcite. Converting this equation to logarithmic form yields,

$$\log\Big([Ca][SO_4]\Big) - \log\Big([Ca][CO_3]\Big) = \log\frac{[SO_4]}{[CO_3]}$$

The difference in ordinate of the curves is then the logarithm of the desired equilibrium SO_4-CO_3 ratio.

THE EVALUATION OF THE SO_4-CO_3 RATIO

The method outlined was used in determining the SO_4-CO_3 ratio at 185 deg. cent. corresponding to a boiler pressure of 150 lb. per sq. in. gage. The resulting graphs of data are shown in Fig. 1. This includes solubility values for calcium sulphate in pure water and in solutions of Na_2SO_4 and NaCl,[8,9] boiler-water analyses from actual boilers[9] which were known to be depositing either anhydrite or calcite or both substances, and a large amount of data from the experimental boiler operated in the laboratory by the authors. The individual data are presented and discussed in another paper[10] and only the general significance of the diagram will be treated here.

Discussion of Data. In spite of wide variations in the composition of the various solutions the points for anhydrite define a curve fairly well. The points for calcite, however, spatter considerably. The authors see three possible explanations for this result. In the first place, two crystal forms of calcium carbonate have been reported in boiler scale. These are aragonite and calcite, the latter being the more stable form. Presumably these two forms have differing solubilities. While aragonite is probably the less stable form under boiler-water conditions, it might persist for considerable periods of time. In addition, it is possible that fluctuations in boiler-water composition might cause reversal from calcite to aragonite, although this is improbable. The second explanation, which seems plausible to the authors, is that the various solutions even at a temperature of 185 deg. cent. may remain supersaturated with respect to calcium carbonate for long periods of time, and that the degree of super-saturation may vary considerably. The third explanation would be inaccuracy in the sampling methods and analytical procedure used in con-

nection with the experimental boiler. Sampling was carried out with an internal filter and a cooling coil to reduce the filtered solution to room temperature before it was released from boiler pressure. All samples were guarded with the utmost care from contamination by the atmosphere. The authors believe that the values for Ca, obtained by the method involving precipitation as oxalate and titration with $KMnO_4$, and the values for CO_3, obtained by an evolution method rather than the customary titration methods, are accurate to within 1 p.p.m. Due to the small concentrations involved, the percentage error in these determinations is in many cases appreciable. The maximum analytical error in locating a point for $CaCO_3$ on the logarithmic ordinate of Fig. 1 should, however, not be more than ±0.15, while the actual vertical spread reaches a value of 1.

While the possibility of two crystal forms and uncertainty in analysis, coupled with the probability of supersaturation, render it impossible to draw a single curve representing the solubility of calcite in complex solutions, it is possible to draw a straight line through the upper range of the values. Since this line represents the maximum concentrations with respect to $CaCO_3$ obtained in the investigation, the use of values on this line in the calculation of the SO_4–CO_3 ratio will yield a value of the latter which is safe, although it may not be the precise equilibrium value which might be obtained by extremely refined methods.

The broken line drawn through the lower range of points for $CaCO_3$ may possibly define approximately the solubility of the less soluble of the crystal forms of $CaCO_3$, but the authors do not wish to stress this suggestion. The solubility curves of both aragonite and calcite may, however, be reasonably assumed to lie within the region bounded by the solid and the broken line.

At the lowest values of the ionic strength there are a number of high points for $CaCO_3$ which represent solubility measurements in the closed experimental boiler used as an autoclave at 150 lb. pressure. This was initially charged with solid $CaCO_3$ and distilled water. During the course of the experiment the value of log ([Ca][CO_3]) dropped irregularly to a value on the solid line and then increased again. On addition of Na_2CO_3 with corresponding increase in the ionic strength of the solution, much lower values were obtained along the broken line. A second solubility experiment yielded the sets of paired values shown which indicate less initial supersaturation than was evident in the first experiment.

A New Value for the SO_4–CO_3 Ratio

At 150 lb. per sq. in. gage pressure the value of the SO_4–CO_3 ratio calculated by Hall is 11. Much higher values are obtained from Fig. 1 by using the curve for $CaSO_4$ and the solid line through the upper range of points for $CaCO_3$. These values are indicated in Table 1 for various values of $\mu^{1/2}$. Due to the arbitrary use of a straight line through the $CaCO_3$ data, the calculated values of the ratio vary with the ionic strength. While the exact value of the ratio is in doubt, the authors feel quite safe in stating that it is at least 100, and may be appreciably greater.

The conclusion that the SO_4–CO_3 ratio has a value greater than 100 is substantiated by the results from controlled scale-formation tests made in the experimental boiler. The significant data from three runs are shown in Table 2. During runs *D* and *E*, which lasted 12 and 13 days, respectively, the solution fed to the boiler contained approximately 55 p.p.m. $CaSO_4$ and 55 p.p.m. Na_2CO_3, or slightly more soda ash than was theoretically equivalent to the concentration of Ca. After this water entered the boiler, $CaCO_3$ was precipitated as sludge, but the reduction in Ca concentration thus effected was not sufficient to prevent the formation during both runs of very thin layers of anhydrite scale on the hot tube, across which heat was being transferred at the rate of 39,000 B.t.u. per sq. ft. per hr. No attempt was made during these runs to control the SO_4–CO_3 ratio, which varied during run *D* from slightly above 100 up to 162 and then down to slightly less than 100, and during run *E* from slightly above 100 to 265 and back down to 179. Since at some time during each of these runs the boiler water must have been depositing not only $CaCO_3$ sludge, but also $CaSO_4$ scale, the "equilibrium" SO_4–CO_3 ratio must lie somewhere in the range of values calculated from the boiler-water analyses made during the runs.

	384	2025	26.0	78	

During run *F* an attempt was made to hold the SO_4–CO_3 ratio in the boiler at a value of 100 by varying the amount of soda ash added to the feedwater, which was a solution of calcium sulphate containing 48 p.p.m. $CaSO_4$. In spite of the fact that the ratio value was rather high during the first six days, the hot tube at the end of the 16-day run showed practically no calcium sulphate on its surface, the very thin deposit being almost entirely $CaCO_3$ and iron rust.

The fact that $CaCO_3$ was the solid deposited in run *F*, while the thin scales of runs *D* and *E* were almost entirely $CaSO_4$, seems definite proof that the safe value of the SO_4–CO_3 ratio is above 100. The authors feel that the next step should be experimental operation of a large boiler under close control to test the practical effects of maintaining high ratio values. Any work of this nature will be wasted effort, however, unless the SO_4 and CO_3 concentrations are determined more accurately than has been the custom in boiler-water control. The authors have elsewhere[11] described the development of an evolution method for total carbon dioxide with which very accurate values for CO_3 may be obtained, in contrast to the high results indicated by the phenolphthalein-methyl orange or modified Winkler titrations. They have also noted the fact that turbidimetric determination of SO_4 may give high values for SO_4 in a boiler water even though the instrument indicates correctly with sulphate solutions containing no other substances.

[11] W. C. Schroeder, E. P. Partridge, and L. F. Collins, "Determination of Carbonate and Hydroxide in Boiler Waters," submitted to *Industrial and Engineering Chemistry*.

Significance of the New Ratio Value

The great objection to the use of soda ash as a chemical for the internal conditioning of boilers has been the high alkalinity produced in the boiler water by the hydrolysis of carbonate. The difficulty encountered in maintaining the SO_4–CO_3 ratio set by Hall for the prevention of sulphate scale without overstepping the Na_2SO_4–alkalinity ratio recommended for the inhibition of caustic embrittlement has led in many cases to the substitution of various phosphate salts in place of soda ash as a conditioning chemical. It now seems probable, however, that the CO_3 concentration required by Hall's original calculation of the SO_4–CO_3 ratio was considerably larger than necessary, and there is a chance that soda ash may still hold an important place in boiler-water treatment.

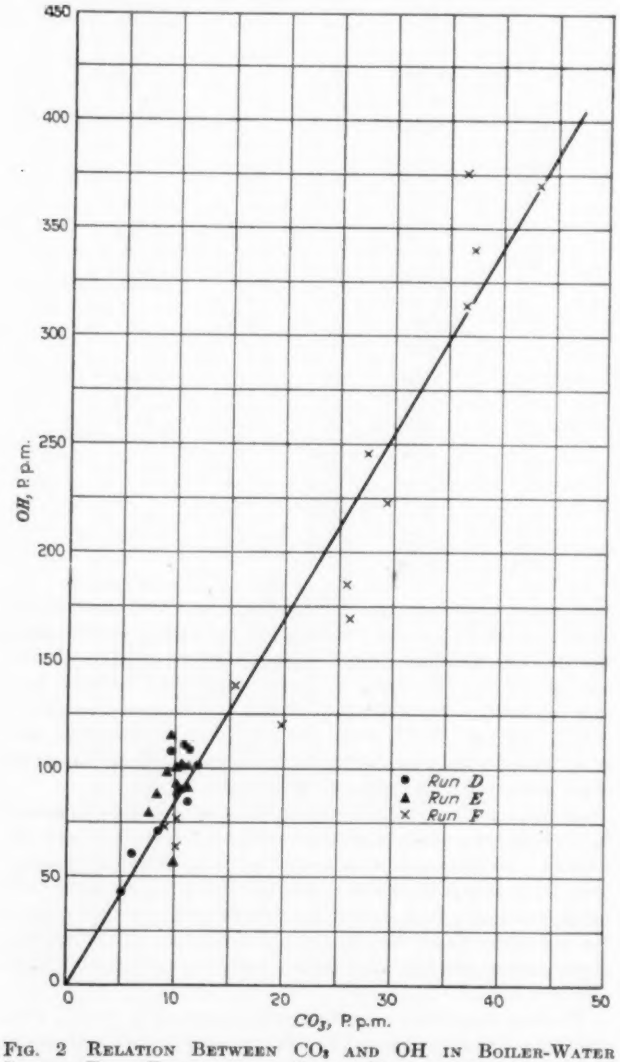

Fig. 2 Relation Between CO_3 and OH in Boiler-Water Samples From Experimental Boiler During Scale-Formation Tests

The soda ash added as conditioning chemical to a feedwater may be thought of as divided into two portions. The first portion is that amount which is chemically equivalent to the Ca in the feedwater and which will be removed from solution in the boiler by precipitation as solid $CaCO_3$. The second portion is the excess of Na_2CO_3 which is necessary to maintain a given CO_3 concentration and hence a given SO_4–CO_3 ratio in the boiler water. It is this Na_2CO_3 which is largely responsible for the development of alkalinity, since the precipitated $CaCO_3$ is quite effectively removed from the scene of action. Obviously, if it is possible to decrease the amount of excess Na_2CO_3 used in a boiler, the alkalinity produced by hydrolysis will be correspondingly decreased, other factors remaining the same. Since the rate of hydrolysis of dissolved carbonate is rather rapid, it is much better practice to add Na_2CO_3 continuously at as even a rate as possible than it is to make large additions intermittently. In the latter case the concentration of CO_3 is temporarily raised to a high value, but drops rapidly to a very low value, resulting in an increase in OH concentration with but brief protection as far as the SO_4–CO_3 ratio is concerned. On the other hand, when the feed of Na_2CO_3 is accurately and continuously proportioned to the flow of feedwater to the boiler, the maximum benefit from the standpoint of scale prevention may be obtained with the minimum increase in OH concentration.

The results obtained in the experimental boiler were quite encouraging. If the OH concentration in the boiler water is plotted against the CO_3 concentration, for all of the boiler-water samples taken during runs *D*, *E*, and *F*, Fig. 2 is obtained. A straight line represents the data within its limits of accuracy. From this line $OH/CO_3 = 8.5$. That is, with the experimental boiler operating continuously at 150 lb. gage pressure and with an intermittent blowdown due to sampling of less than 0.5 per cent of the feed, the boiler water contained on an average less than 9 p.p.m. OH for each p.p.m. CO_3. If a boiler were operated under good control with an average ratio $SO_4/CO_3 = 100$ to prevent sulphate scale formation, and if, by careful proportioning of the soda ash used for conditioning, the ratio $OH/CO_3 = 8.5$ obtained in the experimental work were realized, then the embrittlement ratios[12] would have the values $Na_2SO_4/NaOH = 7.4$ and $Na_2CO_3/NaOH = 0.087$. The Na_2SO_4–$NaOH$ ratio is far above the value of 2.5, which is believed to be the upper limit of the embrittlement range.

Looking at it from the other view-point, an SO_4–CO_3 ratio of 100 would allow the development of 24 p.p.m. OH in the boiler water for each p.p.m. CO_3 before the edge of the embrittlement range would be reached.

While these calculations are based upon small-scale work in an experimental boiler, and thus are subject to the criticism that plant operation never does succeed in duplicating laboratory results, the authors feel that there is no fundamental reason why any boiler operated at up to 150 lb. pressure under competent chemical control cannot be held in the region of boiler-water composition limited on the one hand by the maximum SO_4–CO_3 ratio allowable for scale prevention and on the other by the minimum Na_2SO_4–$NaOH$ ratio which is believed to inhibit embrittlement. To the authors it even seems possible that boilers might be operated at higher pressures with soda ash as a conditioning chemical if any considerations made this desirable. In this connection, the original data upon which the curves of Larson[13] are based would be extremely valuable, since from them it should be possible to calculate rates of hydrolysis.

Discussion

Frederick G. Straub.[14] It is interesting to note that the authors of this paper recognize the errors involved when the solubility product was used to calculate this ratio. However, the writer wonders if, in using the newer method of evaluating the SO_4-CO_3 ratio which involves the concept of ionic strength, mean molalities, and other assumptions, we might not be led astray again.

Since we are working at temperatures where we have very meager information as to the real solid phase which exists in equilibrium with the liquid phase, it appears as though the less calculating we do and the more actual determinations we run, the better off we will be. Due to the fact that the authors have not furnished the data from which were calculated the datum points in Fig. 1, it is not known whether other salts were present when these solubility data were collected. This is very important, since if these tests were made in the presence of sodium hydroxide, it would be found that the effect of the hydroxide on the solubility of the calcium would not be compensated for by the increase in ionic strength. This in turn would reflect in the ratios calculated in Table 1. The results obtained in Table 2 should give a fairly correct idea as to the ratios necessary, since they involve actual tests and the assumptions made are reduced in number. However, it is believed that the presence of sulphate scale in tests *D* and *E* and its absence in *F* do not prove that a ratio below 100 will prevent sulphate scale. Unfortunately in run *F* the CO_3 was much higher than in the previous tests, and it is believed that the sulphate scale was prevented by the increase in CO_3. In other words, if the CO_3 is kept above 20 p.p.m. and NaOH is present, sulphate scale would be prevented irrespective of the sulphate content.

The results of research work which we have been conducting along this line, but mainly at higher pressures (that is, up to 3000 lb. steam pressure), indicate that there is no SO_4-CO_3 ratio. The amount of CO_3 necessary is independent of the sulphate present. Thus in these tests, with about 25 p.p.m. of CO_3 present, sulphate scale would have prevented scale even if the sulphate had been twice as high as it was.

The data plotted in Fig. 2 are interesting, since they show a definite relationship between the CO_3 and the OH in the operating boiler. This is similar to the results experienced in our tests on the decomposition of sodium carbonate in steam boilers. The author's results, which indicate that boilers can operate with soda ash, should certainly be good news to many boiler operators.

Authors' Closure

The authors heartily concur with Mr. Straub on some points and just as heartily disagree with him on others. For example, let us always have more actual experimental data that are reliable; these data will, however, mean very little unless they can be satisfactorily correlated. Due to the complex composition of boiler waters, such correlation of results has previously been extremely difficult. In the paper a method was presented which allows interpretation of results from any boiler water, no matter how complex, provided its composition is completely determined and the solid material deposited from it is accurately identified.

The method presented by the authors is just as applicable to a boiler water high in hydroxide as to one high in sulphate. Mr. Straub's conclusion to the contrary is evidently based upon his study of the solubility of $CaSO_4$ in NaOH solutions.[15] As the present authors have noted in their discussion of his work, the apparently anomalous decrease in Ca concentration which he found with increase in OH was probably due to the formation of $Ca(OH)_2$ in the solid phase and Na_2SO_4 in solution when the initial concentration of NaOH at 360 deg. fahr. was greater than about 2 millimols per 100 grams H_2O. The authors venture the opinion that if Mr. Straub will calculate values for log ($[Ca][SO_4]$) and $\mu^{1/2}$ from the actual analyses of his final solutions, which should have been in equilibrium with $CaSO_4$, instead of from his initial compositions, his points for 360 deg. fahr. will fall reasonably near the upper curve in Fig. 1 of the paper.

The data presented in Fig. 2, which indicated hydroxyl concentrations during runs D and E, and in the upper curve of Fig. 1, which shows the relation between the ionic strength and the stoichiometric solubility product of anhydrite during these same runs, confirm the statement that hydroxide has no appreciable specific effect upon solubility equilibria.

What increasing hydroxyl concentration actually does is to hasten the approach to equilibrium by tending to prevent supersaturation with respect to calcium carbonate. Most of the lower points shown for $CaCO_3$ in Fig. 1 represent samples containing appreciable concentrations of OH, while most of the higher points represent samples low in OH. As noted in the paper, a more complete discussion of the data is to appear in *Industrial and Engineering Chemistry*.

The authors would like to call attention to the fact that the comparison of solubility data by the use of the ionic strength and the stoichiometric solubility product is empirical rather than theoretical. In fact, the concept of these particular functions and their use has been based entirely on experimental results. Plotting of solubility relations through the use of these functions does not demand that the results follow any hard and fast mathematical formula, but simply gives a means of comparing the solubility of a salt in one solution with the solubility of the same salt in any other solution. To paraphrase an old saying, the proof of the plotting is in the reading. The fact that data for many individual substances in any number of different complex solutions in the dilute solution range have been correlated for a number of years by a method similar to that used by the authors is good evidence for the value of this method. Furthermore, deviations of any considerable magnitude serve as warnings to the investigator to check his analytical methods, to investigate his control of experimental conditions, or to anticipate supersaturation or undersaturation, as the case may be.

Possible confusion of ideas may be prevented if it is emphasized at this point that a knowledge only of the Ca concentration of a boiler water does not allow one to predict whether anhydrite or calcite will be deposited as solid by evaporation. The Ca concentration merely tells how much of one or the other substance may be thrown out of solution by concentrating the boiler water a certain amount. In this way, the Ca concentration represents a solubility value, but in order to predict which substance will be deposited, the relation between the SO_4 and CO_3 concentrations, that is, the SO_4-CO_3 ratio, must be known.

When Mr. Straub says that "if the CO_3 is kept above 20 p.p.m. and NaOH is present, sulphate scale would be prevented irrespective of the sulphate content," he is making a dangerously broad claim, which he qualifies somewhat in his next paragraph. Actually it is quite possible that a concentration of 20 p.p.m. CO_3 would prevent sulphate scale in the presence of much more than 2000 p.p.m. SO_4, but there is some SO_4 concentration at which sulphate scale would form. The value of 100 for the SO_4-CO_3 ratio was given by the authors merely as a safe lower limit. Some of the data indicate ratio values greatly in excess of this.

Most of the lack of agreement between Mr. Straub and the authors is a matter of point of view and definitions. Mr. Straub says, in effect, that if the SO_4-CO_3 ratio has a very large value it does not exist. The authors prefer to admit on one hand the fundamental hypothesis of chemical equilibrium and on the other the proverbial difficulty of attaining this equilibrium, while attempting to measure dynamically rather than statically a limiting value for the SO_4–CO_3 ratio which will be amply safe as a criterion for boiler control.

Design and Investigation of a Spring in Which All Coils Nest Simultaneously

By J. B. Reynolds[1] and O. B. Schier,[2] Bethlehem, Pa.

J. B. Reynolds

The purpose of this study was to design a spring of constant slope, the lower coils of which would not nest until loads larger than those causing corresponding coils to nest in constant pitch springs were placed on the spring. The results obtained when the spring of constant slope was compared with one of constant pitch made it seem desirable to try to design a spring in which all coils would nest simultaneously. Work with this spring and with those previously investigated leads to the conviction that end effects considerably influence the amount of deflection. This spring, having a complete dead coil at each end, must be somewhat affected by this influence, though no experiments have been made to determine how much. The result of this influence would be that the experimental deflections would be greater than the theoretical, which agrees with the results found.

O. B. Schier

Introduction

In a study[3] of the design and characteristics of conical springs, experiments showed that when a conical spring of constant pitch, supported on a plane, deflects under load, the lower coils are the first to nest. The added deflection in the remaining coils under additional load results in corresponding additional stresses that are not fully shared by the lower coils. The purpose of that study was to design a spring of constant slope, the lower coils of which would not nest until loads larger than those causing corresponding coils to nest in constant pitch springs were placed on the spring.

Interesting results were obtained when the spring of constant slope was compared with one of constant pitch; hence, it seemed desirable to try to design a spring in which all coils would nest simultaneously. In a spring with this characteristic, it appeared evident that there would be a greater uniformity in the division of work throughout the coils and an increase of stress in the lower coils of the spring. Also the design formula for such a spring would be easy to apply in practical design, since it would readily predict the load-deflection characteristic and corrections for change of base radius, due to nesting of coils as in other types of conical springs, would be unnecessary.

Description of Spring and Spring Materials

The spring as designed consists of four active coils with one complete dead coil at each end (see Fig. 1). The bottom diameter is $6^1/_2$ in., while the top diameter is $3^1/_2$ in. These diameters were chosen to allow a clearance of $^1/_8$ in. between coils when the spring is fully compressed. The height is 10 in. All dimensions are those of the neutral axis.

The spring was designed with what may appear an exaggerated size so that large deflections might be obtained for comparatively small loads, thus permitting a more accurate determination of deflections in the spring.

The material used is a chrome-vanadium stock of the following analysis:

C	Mn	P	S	Si	Cr	Va
0.45	0.71	0.020	0.029	0.20	1.01	0.17

This stock consisted of eight $^1/_4$-in. round rods each 14 ft long. This length was sufficient to make one spring and allow for two test specimens. These specimens were used to determine the yield point and ultimate stresses and the moduli of elasticity and of shear for the steel.

Mathematical Design

The mathematical design of a spring of the kind described is based upon two requirements. The first is that the projection of the neutral axis of the spring upon a plane perpendicular to its geometric axis shall be the spiral of Archimedes, the equation of which is of the form $r = r_o + k\theta$. The second is that the angle formed by the tangent to the neutral axis and the base plane shall vary in such a way as to have all the coils nest simultaneously.

In the derivation of the formula for this conical spring the following notation is used:

[3] "The Design and Investigation of Conical Springs With Coils of a Constant Slope," by J. B. Reynolds and O. B. Schier, presented at the same meeting as this paper.

Presented at the Open Meeting of the A.S.M.E. Special Research Committee on Mechanical Springs, held in connection with the Annual Meeting, New York, N. Y., November 30 to December 4, 1931, of The American Society of Mechanical Engineers.

r_o = base radius of active portion of spring
r_n = top radius of active portion of spring
n = number of active coils in spring
θ = vectorial angle of base spiral for point on axis of spring
$k = (r_n - r_o)/\theta_n$
θ_n = vectorial angle corresponding to r_n
P = applied load
A = area of cross-section of the spring material
E = Young's modulus of elasticity of the spring material
G = shearing modulus of the spring material
L = total length of active spring material
D = axial deflection
p = variable slope angle
z = height of any point (r, θ, z) above the base of the neutral axis of the spring in the unloaded state

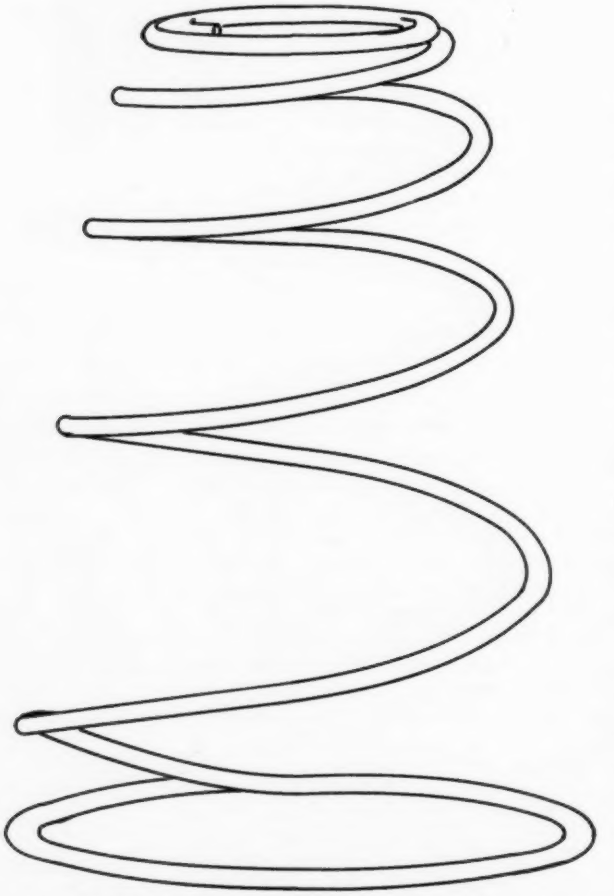

FIG. 1 SPRING WITH FOUR ACTIVE COILS AND ONE DEAD COIL AT EACH END

z_n = total height of the neutral axis above the base under no load
f = reciprocal of the load causing complete compression
I_v = moment of inertia of A with respect to the tangent to the neutral axis
I_u = moment of inertia of A with respect to a line in the cross-section and also in a vertical plane through the center of the cross-section
I_w = moment of inertia of A with respect to a horizontal line in the cross-section through its center.

The mathematical analysis (see Appendix) leads to the following formulas:

$$f = 42\,(I_v/A^4G)(r_n^4 - r_o^4)/4kz_n \qquad [1]$$

$$z = (r^4 - r_o^4)z_n/(r_n^4 - r_o^4) \qquad [2]$$

$$D = fPz \qquad [3]$$

DESIGN OF MANDREL

In the design of the mandrel upon which the springs were wound, use was made of Equation [2]. This equation shows that the neutral axis of the spring lies upon a frustum of a fourth degree surface of revolution. Therefore, the mandrel required a curved profile instead of a straight one such as is ordinarily used for winding springs of a constant pitch. Previous experience with the construction of springs with coils of constant slope emphasized the value of using a full semi-circular groove around the mandrel in which to place the spring steel. To facilitate the removal of the completed spring from this groove a collapsible mandrel was designed.[4]

METHOD OF WINDING SPRINGS

To wind the steel into springs it was thought best to have it heated to a plastic state. This method was followed in order to prevent the spring from changing shape due to initial stresses as it would if the steel were wound cold. Provision had to be made for heating the 14-ft lengths of stock to a uniform heat. Previous experience in heating with an oxyacetylene torch had proved unsatisfactory. It was therefore decided to use a current-resistance method for obtaining this uniform heat.

To wind a spring, a length of stock is placed in a tight-fitting brass terminal at the small end of the mandrel. From the mandrel the stock passes approximately horizontally through a tension tool with adjustable rolls which gives the necessary tension for winding. A rope attached to a counterweight over a pulley helps to support the heated rod. This serves to hold it nearly straight and so aids in feeding the material through the tension tool. The second electric terminal is a brass clamp fastened near the end of the rod.

With a current of 300 amp and a flow of 33 v, the required winding temperature of 1400 F was reached after heating for 1 min. This current was obtained by stepping a current of 15 amp at 220 v up to 660 v, and then stepping this voltage down to 33 v, giving 300 amp of current. An auto-transformer was used in the line to maintain a constant current as the resistance of the steel varied with the temperature. The temperature was measured with an optical pyrometer. With the temperature held constant at 1400 F, the steel was wound in the groove on the mandrel. The remaining steel was then cut off, the mandrel collapsed, and the spring was removed from the mandrel. The remaining stock was cut into standard lengths for tension and torsion specimens and marked for identification.

HEAT TREATMENT ARBOR

For the heat treatment of the springs it was desired to use the current-resistance method of heating, since no furnace of suitable size was available for this purpose. It was essential that all coils be supported at the quarter points to prevent deflection under their own weight at the high temperatures necessary for normalizing and quenching. Since it also was essential that all the current flow through the steel in the spring, some form of material other than metal had to be used to form the fins of the arbor. A commercial form of sheet asbestos was used. It withstands high temperatures and is a very poor conductor of electricity.

The arbor consists of four fins, the profiles of which are cut to correspond to the profiles at the quarter points on the mandrel.

---

[4] For detailed description see "The Design and Investigation of a Spring in Which All Coils Nest Simultaneously," a thesis by O. B. Schier, Lehigh University, 1931.

These fins are bolted together between 1-in. angle irons, which give strength to the arbor. It was necessary to clamp the dead coil at the top and bottom of the spring to prevent deformation by expansion when the spring was heated.

HEAT TREATMENT

From experience in heat treating springs of chrome-vanadium steel, it was known that normalizing and quenching temperatures of 1600 and 1550 F, respectively, give good results. However, because of the smaller cross-section of the material used in these springs, the tempering temperature was reduced to 750 F to try to improve the elastic properties of the spring.

The spring, on the arbor, was heated to 1600 F by the current-resistance method and then allowed to cool in air. It was then heated to 1550 F and quenched in an oil bath. In each case the temperature was measured with an optical pyrometer. Had there been a suitable way of accurately measuring the tempering temperature, the current-resistance method would have been used for the final treatment. As the temperature of 750 F gave no visible color, the optical pyrometer could not be used. Therefore, a salt bath consisting of sodium nitrate and potassium nitrate fused in equal parts was heated to the temperature of 750 F. This temperature was measured by using a thermoelectric couple immersed in the bath and connected to a millivoltmeter with a direct-reading temperature scale. The spring was placed in this bath and held for 30 min.

The finished spring when placed under a load of 90 lb for 24 hr acquired a permanent set of 0.05 in. in a total deflection of 10 in.

TESTING REQUIREMENTS

In testing the spring it was desirable that the following requirements be met: (1) that there be an axial application of load, (2) that the top of the spring be permitted to rotate or not as desired, and (3) that the spring be prevented from tipping. By the design and construction of special attachments it was possible to use an Olsen testing machine for the tests. The tests were as follows: Loading and unloading of the spring in 10-lb increments of load with—

1 the top of the spring unconstrained from rotation
2 the top of the spring constrained from rotation
3 the top of the spring unconstrained under repeated loading.

Sufficient runs were made in each test to determine whether the spring characteristics were constant under repeated testing. In every series of tests and for each increment of load up to the maximum load of 90 lb, the following data were recorded: (1) Axial deflection of spring, (2) angular deflection, and (3) net height of each coil; that is, the distance from the bottom of the spring to the top of each coil.

The axial deflections were measured with an inside micrometer from a fixed reference plane to the top of the spring. The angular deflections were obtained by the use of the attachment[4] designed for the Olsen testing machine. The measurements of the net height of each coil were made with a surface gage. A radial line was scribed across the top of each coil so that the measurement would be made to the same point for each reading. These lines were placed 360 deg apart and directly above the heel of the spring.

A Ewing tensometer was used to measure the elongation of the specimens in tension in determining the modulus of elasticity of the steel. The specimens were not necked because of their small diameter of $^1/_4$ in. This prevented the determination of the yield point of the steel, since failure occurred outside of the gage length before the yield point was reached. An average value of 28,000,000 lb per sq in. was obtained for the modulus of elasticity. This value agrees with that obtained in previous tests on chrome-vanadium steel subjected to a similar heat treatment.

The modulus of shear could not be determined for the $^1/_4$-in. steel because of difficulty encountered in the use of the torsion machine. However, as the modulus of elasticity agrees with the value obtained in a previous study, a value for the modulus of shear of 11,300,000 lb per sq in., as taken in the previous study, was used in computing deflections.

RESULTS OF TESTS

Fig. 2 is a graphical representation of the coil actions of the spring and clearly indicates the uniformity of action for the various end constraints, since the curves cannot be separated. From the figure it is evident that the requirement that all coils nest simultaneously has been nearly realized and that a load of about 90 lb will completely compress the spring. It is also evident that the different coils of the spring have the same characteristic, since the deflection curves are of the same general type. It will be noted that the load-deflection curves are approximately straight lines up to one-half the total load. At half the total load each curve begins to take a curvature which increases as the load increases. This indicates that for ranges of deflection equal to or less than half of the total, the deflection is directly proportional to the load. However, for larger deflections this condition has not been realized.

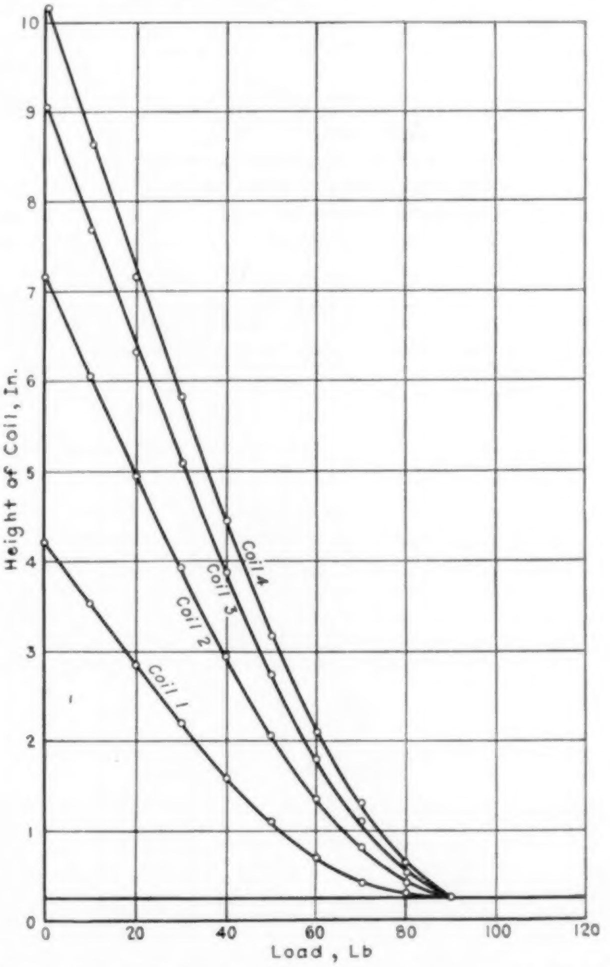

FIG. 2 CURVES REPRESENTING ACTION OF COILS IN A CONICAL SPRING IN WHICH ALL COILS NEST SIMULTANEOUSLY

In computing the theoretical values of deflection for comparison with the experimental values, the following equation, as developed by J. B. Reynolds, was used:

$$D = fPz$$

where D = deflection of any point on the spring initially at a height z above the base
f = the reciprocal of the load causing complete compression
P = load.

The value of f is obtained from Equation [1], which is as follows:

$$f = (42\, I_v/A^4G)(r_n^4 - r_o^4)/\, 4\, kz_n$$

where

I_v = moment of inertia of A with respect to the tangent to the neutral axis
A = area of cross-section of spring material
G = shearing modulus of the material
r_n = top radius of the spring
r_o = base radius of the spring
k = $(r_n - r_o)/\theta_n$
z_n = total height of the spring.

Fig. 3 compares deflections for the full height of spring as determined experimentally with those computed by the foregoing formula. The variation is considerable, and possible explanations of this will be presented later in the report.

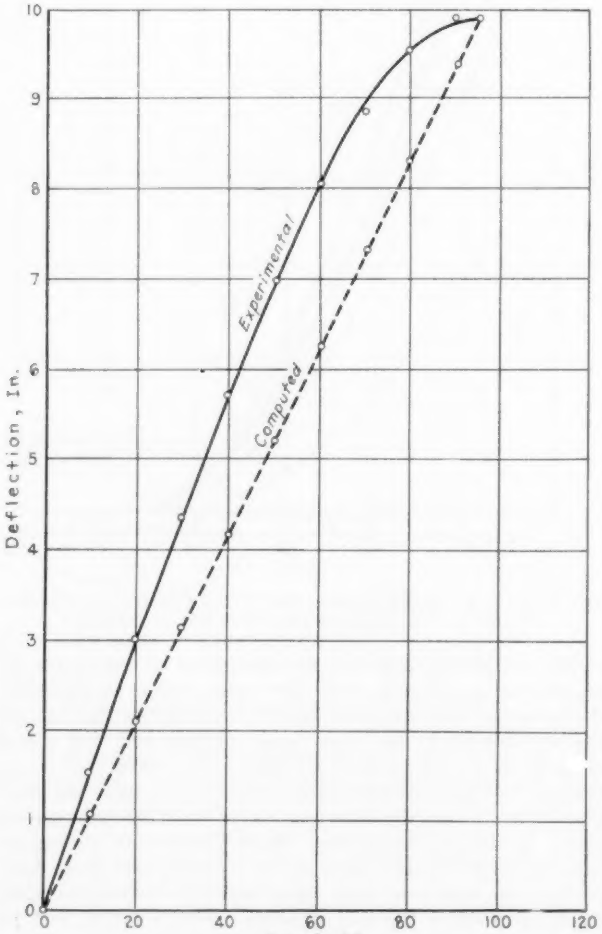

FIG. 3 COMPARISON OF LOAD-DEFLECTION CURVES FOR COMPUTED AND EXPERIMENTAL VALUES

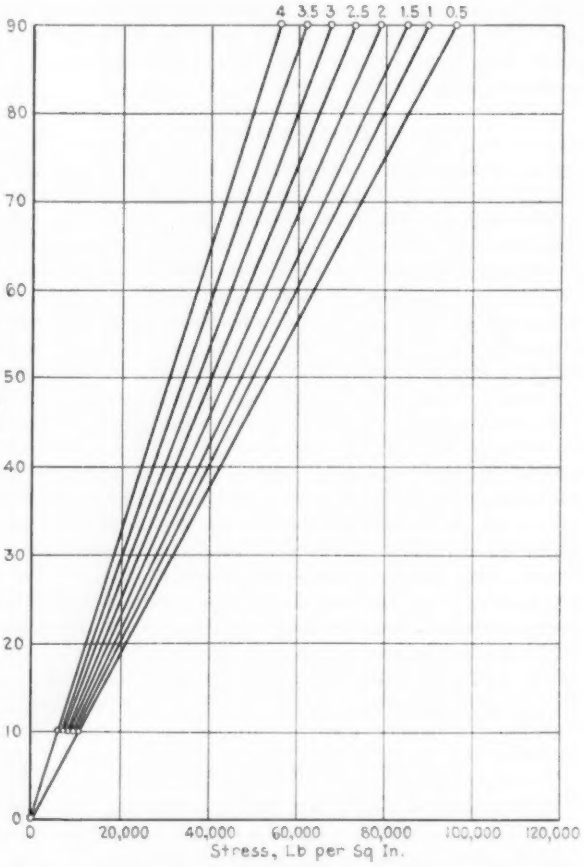

FIG. 4 LOAD-STRESS CURVES FOR EACH HALF COIL IN THE CONICAL SPRING
(Figures indicate numbers of coils.)

In the theoretical determination of stresses, use was made of the following formula given by A. M. Wahl:[5]

$$S = \frac{16\ Pr_1}{\pi d^3}\ k$$

where

S = maximum shear stress, lb per sq in.
P = axial load on spring
r_1 = mean base radius of each half coil
d = diameter of stock
k = stress multiplication factor
$= \dfrac{4c - 1}{4c - 4} + \dfrac{0.615}{c}$
c = $2r_1/d$

In calculating the stresses the load was considered axial, and the change in the base radius, when the first half of the first coil nest was not considered.

Fig. 4 represents the distribution of stresses on the inside of the coils for each half turn. These are theoretically the maximum stresses in the section at these points. The figure shows that the stresses increase directly with the loads and by equal intervals for successive half coils; that is, the stresses in this spring are proportional to the radii of the coils. The greatest stress is therefore found at the heel of the bottom coil and amounts to 101,000 lb per sq in., which is within the range of allowable shearing stress.

---

[5] "Stresses in Heavy Closely Coiled Helical Springs," by A. M. Wahl, Trans. A.S.M.E., vol. 51, 1929, paper APM-51-17.

Conclusions

Work with this type of spring and those previously investigated leads to the conviction that end effects considerably influence the amount of deflection. This spring, having a complete dead coil at each end, must be somewhat affected by this influence, though no experiments have been made to determine how much. The result of this influence would be that the experimental deflections would be greater than the theoretical, which agrees with the results found. It also is to be noted that the slope of the theoretical load-deflection line varies inversely with the modulus of shear. Thus a reduction in the modulus of shear would rotate the straight line in Fig. 3 counterclockwise about the origin and make it more nearly coincide with the experimental curve. As pointed out in a previous report, the modulus of shear is somewhat uncertain.

It seems advisable to make experimental studies of various methods of constraining the ends of the spring to determine, if possible, the best practical method. Different methods of end constraint result in different eccentricities of loading. Hence, a study of end constraints will involve a study of eccentricity of loading. Maximum stresses in the spring are affected by the eccentricity of loading.

Manufacturers are still skeptical of results obtained by Wahl in connection with maximum stresses in helical springs. It therefore seems advisable to make experimental stress determinations on conical springs to bring further evidence to bear on this matter.

In developing the mathematics on which the design is based, it was necessary for simplification to neglect many terms which, though small, would have some effect. No effort has been made to determine the possible amount of this effect. If accuracy of investigation justifies it, further refinements in mathematics can be made.

Appendix

The purpose of this discussion is to derive formulas for the design of a conical spring in which all coils nest simultaneously. The results will be obtained in terms of constants for the material of which the spring is made, the load applied, and the dimensions of the spring.

In the derivation of the formulas for this spring the following notation is used:

r_o = base radius of active portion of spring
r_n = top radius of active portion of spring
n = number of active coils in spring
θ = vectorial angle of base spiral for point on axis of spring
$k = (r_n - r_o)/\theta_n$
θ_n = vectorial angle corresponding to r_n
P = applied load
A = area of cross-section of the spring material
E = Young's modulus of elasticity of the spring material
G = shearing modulus of the spring material
L = total length of active spring material
D = axial deflection
p = variable slope angle
z = height of any point (r, θ, z) above the base of the neutral axis of the spring in the unloaded state
z_n = total height of the neutral axis above the base under no load
f = reciprocal of the load causing complete compression
I_r = moment of inertia of A with respect to the tangent to the neutral axis
I_u = moment of inertia of A with respect to a line in the cross-section and also in a vertical plane through the center of the cross-section
I_w = moment of inertia of A with respect to a horizontal line in the cross-section through its center.

The requirements are, first, that the projection of the neutral axis of the spring upon a plane perpendicular to its geometric axis shall be the spiral of Archimedes, the equation of which is of the form $r = r_o + k\theta$, and second, that the angle formed by the tangent to the neutral axis and the base plane shall vary in such a way as to have all the coils nest simultaneously.

From the relations developed in the Appendix of a former report,[3] a spring of constant slope, is found the general formula for conical springs:

$$\left.\begin{aligned} dD = rd\theta_r = [42\, I_r P \cos p/A^4G + P \sin p \tan p/EI_u] \\ r^2(r^2+k^2)^{\frac{1}{2}}d\theta + [Pk^2 \sec p/EI_w - 42\, I_r Pk^2 \cos p/A^4G - \\ Pk^2 \sin p \tan p/EI_u](r^2+k^2)^{\frac{1}{2}}d\theta. \end{aligned}\right\} .[1]$$

Letting $a = 42\, I_r/A^4G$ (for a circular section $a = 1/I_rG$), $b = 1/EI_u$, $c = 1/EI_w$, Equation [1] may be written:

$$\left.\begin{aligned} dD = P(a \cos p + b \sin p \tan p)r^2(r^2+k^2)^{\frac{1}{2}}d\theta \\ + Pk^2(c \sec p - a \cos p - b \sin p \tan p)\,(r^2+k^2)^{\frac{1}{2}}d\theta \end{aligned}\right\} \ldots [2]$$

The variable angle p may be eliminated from [2] by using the differential right triangle of height dz, base $(r^2 + k^2)^{\frac{1}{2}}d\theta$ and hypotenuse dL, giving

$$\left.\begin{aligned} dD/d\theta = P[a(r^2+k^2)^{\frac{1}{2}}d\theta/dL + (bdz/(r^2+k^2)^{\frac{1}{2}}d\theta)dz/dL] \\ r^2(r^2+k^2)^{\frac{1}{2}} + Pk^2[cdL/(r^2+k^2)^{\frac{1}{2}}d\theta - a(r^2+k^2)^{\frac{1}{2}}\,d\theta/dL \\ - (bdz/(r^2+k^2)^{\frac{1}{2}}d\theta)dz/dL](r^2+k^2)^{\frac{1}{2}} \\ = Pr^2[a(r^2+k^2)d\theta/dL + (bdz/d\theta)dz/dL] + Pk^2[cdL/d\theta \\ - a(r^2+k^2)d\theta/dL - (bdz/d\theta)(dz/dL)] \end{aligned}\right\} .[3]$$

It is required that the spring shall compress so that every point on its neutral axis at an original height z above the base of the neutral axis shall be at a compressed height Cz, where C is a constant having different values for different amounts of compression; that is, varying directly with the load P, but not for different points on the neutral axis of the spring. If D_z is the deflection of a point at a height z, then

$$Cz + D_z = z \ldots\ldots\ldots\ldots\ldots\ldots [4]$$

or

$$D = D_z = (1 - C)z = fPz$$

in which f is the reciprocal of the load which will completely compress the spring. From Equation [4]

$$dD/dz = fP \ldots\ldots\ldots\ldots\ldots\ldots [5]$$

Now, $dD/dz = (d\theta/dz)\, dD/d\theta = (dD/kd\theta)\, dr/dz$, so that by Equations [3] and [5]

$$\left.\begin{aligned} fP = (dr/kdz)\, P[a(r^2+k^2)\, d\theta/dL + (bdz/d\theta)\, dz/dL]r^2 \\ + Pk^2[cdL/d\theta - a(r^2+k^2)d\theta/dL - (bdz/d\theta)dz/dL] \end{aligned}\right\} \ldots[6]$$

and putting for $d\theta$, dr/k,

$$\left.\begin{aligned} f = (dr/kdz)[a(r^2+k^2)dr/kdL + (bkdz/dr)\, dz/dL]r^2 \\ + k^2[ckdL/dr - a(r^2+k^2)\, dr/kdL - (bkdz/dr)\, dz/dL] \end{aligned}\right\} \ldots[7]$$

Since

$$dL = [r^2 + k^2 + (dz/d\theta)^2]^{\frac{1}{2}}d\theta = [r^2 + k^2 + k^2(dz/dr)^2]dr/k$$

or

$$dL/dr = [r^2 + k^2 + k^2(dz/dr)^2]^{\frac{1}{2}}/k$$

we get:

$$\left.\begin{aligned} f[r^2 + k^2 + k^2(dz/dr)^2]^{\frac{1}{2}}/k = (dr/kdz)a(r^2+k^2)r^2/k \\ + bk(dz/dr)^2r^2 + k^2[c(r^2 + k^2 + k^2(dz/dr)^2)/k - a \\ (r^2+k^2)/k - bk(dz/dr)^2] \end{aligned}\right\} \ldots\ldots[8]$$

or

$$\left.\begin{array}{l} kf[r^2 + k^2 + k^2(dz/dr)^2]^{\frac{1}{2}}dz/dr = (r^2 + k^2)[ar^2 + \\ \quad (c - a)k^2] + k^2[br^2 + (c - b)k^2](dz/dr)^2 \end{array}\right\} \ldots\ldots [9]$$

When powers of k above the third are dropped, there remains:

$$kf[r^2 + k^2 + k^2(dz/dr)^2]^{\frac{1}{2}}(dz/dr) = ar^4 + ck^2r^2 + bk^2r^2(dz/dr)^2 \ldots\ldots\ldots [10]$$

Squaring both sides of Equation [10] gives:

$$\left.\begin{array}{l} k^2f^2[r^2 + k^2 + k^2(dz/dr)^2](dz/dr)^2 \ (ar^4 + ck^2r^2)^2 \\ \quad + 2bk^2r^2(ar^4 + ck^2r^2)(dz/dr)^2 + b^2k^4r^4(dz/dr)^4 \end{array}\right\} \ldots\ldots\ldots [11]$$

Again dropping k^4 and higher powers, we have:

$$k^2f^2r^2(dz/dr)^2 = a^2r^8 + 2ack^2r^6 + 2abk^2r^6(dz/dr)^2 \ldots\ldots [12]$$

or

$$k^2(f^2 - 2abr^4)(dz/dr)^2 = r^4(a^2r^2 + 2ack^2)$$

whence

$$k(f^2 - 2abr^4)^{\frac{1}{2}}dz/dr = r^2(ar + ck^2/r - c^2k^4/2ar^3) \ldots\ldots [13]$$

and, therefore,

$$\left.\begin{array}{l} kdz = ar^3dr/(f^2 - 2abr^4)^{\frac{1}{2}} + ck^2r\,dr/(f^2 - 2abr^4)^{\frac{1}{2}} \\ \qquad - c^2k^4dr/2ar(f^2 - 2abr^4)^{\frac{1}{2}} \end{array}\right\} \ldots\ldots [14]$$

Neglecting the term in k^4 and integrating [14], we find:

$$\begin{array}{l} kz = (^1/_4b)[(f^2 - 2ab)^{\frac{1}{2}}r_o^2 - (f^2 - 2ab)^{\frac{1}{2}}r^2] + [ck^2/2 \\ \quad (2ab)^{\frac{1}{2}}]\{\sin^{-1}[(2ab)^{\frac{1}{2}}r^2/f] - \sin^{-1}[(2ab)^{\frac{1}{2}}r_o^2/f]\} \ldots\ldots\ldots [15] \end{array}$$

Now the factor ab/f is small, so we expand in powers of this fraction, and dropping powers above the first, get:

$$\left.\begin{array}{l} kz = (^1/_4b)[f - abr_o^4/f - f + abr^4/f\} + [ck^2/2(2ab)^{\frac{1}{2}}] \\ \qquad [(2ab)^{\frac{1}{2}}r^2/f - (2ab)^{\frac{1}{2}}r_o^2/f\} \end{array}\right\} \ldots\ldots [16]$$

or

$$kz = a(r^4 - r_o^4)/4f + ck^2(r^2 - r_o^2)/2f \ldots\ldots\ldots [17]$$

The second term on the right is very small, so for an equation of the approximate surface upon which the neutral axis lies, the equation becomes:

$$r^4 = r_o^4 + 4kfz/a \ldots\ldots\ldots\ldots\ldots\ldots [18]$$

or, in rectangular coordinates, for the surface of revolution:

$$(x^2 + y^2)^2 = r_o^4 + 4kfz/a \ldots\ldots\ldots\ldots\ldots [19]$$

To determine f, Equation [18] gives:

$$f = a(r^4 - r_o^4)/4kz \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots [20]$$

so that if r_n is the top radius and z_n the total height,

$$f = a(r_n^4 - r_o^4)/4kz_n \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots [21]$$

This gives:

$$z = (r^4 - r_o^4)z_n/(r_n^4 - r_o^4) \ldots\ldots\ldots\ldots\ldots\ldots [22]$$

or

$$r^4 = r_o^4 - (r_n^4 - r_o^4)z/z_n \ldots\ldots\ldots\ldots\ldots\ldots [23]$$

Design and Investigation of Conical Springs With Coils of a Constant Slope

By J. B. Reynolds[1] and O. B. Schier,[2] Bethlehem, Pa.

J. B. Reynolds

The development of design and the investigation of the characteristics of conical springs with coils of constant slope rather than constant pitch are presented, and also the paper compares the actual performance of these springs with those of constant pitch as well as with the theoretical performance. The conclusions drawn from the investigation are: It is possible with existing formulas to predict the behavior of conical springs. For chrome-vanadium steel of the analysis given, the best heat treatment is to normalize at 1600 F, cool in air, quench at 1550 F in oil, and temper at 900 F in air. Conical springs of constant slope behave more like helical springs than do conical springs of constant pitch as regards load-deflection characteristics.

O. B. Schier

Introduction

In recent years there has been a growing demand for more information regarding all types of mechanical springs. Considerable study has been given to helical springs and much experimental work has been done. Improved formulas for their design have been developed, though these formulas have not been generally accepted by the industries. Recently, the helical spring has been replacing the conical spring in many of its practical applications. This is true even in cases where the form of the conical spring is decidedly advantageous. One reason for this radical change is to be found in the many instances of failure in conical springs. It is thought that these failures are caused by improper design, resulting in high stresses in some coils of the spring. These high stresses may be materially increased by improper heat treatment, repeated loading, and a synchronism of the period of vibration of the spring with that of the motion of the machine. Limited space requirements, likewise, have an important bearing upon the design of springs and hence in this problem of high stresses.

The conical springs most frequently used in the past have been characterized by coils of constant pitch. It is the object of this paper to present the development of design and the investigation of the characteristics of conical springs with coils of constant slope rather than constant pitch; also to compare the actual performance of these springs with those of constant pitch as well as with the theoretical performance.

Description of Springs and Spring Material

The general plan of the investigation was to prepare two series of springs that differ only in respect to pitch and slope of coils. Each type of spring was made in two cross-sections, a rectangular and a circular. All springs, regardless of type or cross-section, are of four active coils and one complete dead coil at each end. The height, which is the same for all springs, is 10 in., and the top diameter, likewise the same for all springs, is $3^{1}/_{2}$ in. The bottom diameter of the springs of rectangular stock is $6^{1}/_{2}$ in., but for the springs of circular stock this diameter was increased to $9^{1}/_{2}$ in. to allow for the same clearance between coils when nested as that between the coils of the lighter rectangular stock. All dimensions of spring size are those of the neutral axis.

The diameters and height of the springs, considering the number of free coils and the dimensions of the material used, indicate an exaggerated size. The springs were designed with these dimensions so that large deflections might be obtained for comparatively small loads, thus permitting a more accurate determination of deflections in the spring coils.

The material used is a chrome-vanadium steel rolled from two heats, the analyses of which are as follows:

	C	Mn	P	S	Si	N	Cr	Va
Rect.	0.46	0.78	0.027	0.027	0.24	0.00	1.04	0.16
Round	0.47	0.70	0.015	0.030	0.20	0.05	1.03	0.16

The dimensions of the rectangular stock are $^{9}/_{16}$ in. by 0.235 in., and the diameter of the circular stock is $^{1}/_{2}$ in. The stock consisted of six bars of each cross-section, each 14 ft long. This length was sufficient to make one spring and allow for two test specimens. These specimens were used to determine the yield point and ultimate stresses and the moduli of elasticity and of shear for the steel.

Mathematical Design

The mathematical analysis for the spring of constant slope, which is the subject of this investigation, is based upon two requirements. The first is that the projection of the neutral axis of

Reynolds was born on May 17, 1881, near New Castle, Pa. He attended country school and New Castle High School; attended Lehigh University on competitive scholarship, 1903–1907; took B.A. degree, 1907; was instructor in mathematics and astronomy, 1907–1913; took M.A. degree at Lehigh, 1910; assistant professor of mathematics and astronomy, 1913–1922; granted degree Ph.D. at Moravian College, 1919; associate professor, 1922–1927; guest professor, Princeton University, 1926–1927; professor of mathematics and theoretical mechanics at Lehigh University, 1927. Mr. Reynolds is the author of many articles and textbooks.

[2] Research Assistant, Lehigh University. Oscar B. Schier was born in Baltimore, Md., on July 18, 1907. He attended the public grade schools for eight years, and then entered the Baltimore Polytechnic Institute; upon graduation in 1926, was admitted to Lehigh University with advanced standing; was graduated in 1929 with M.E. degree, and was appointed the James Ward Packard Fellow.

Presented at the Open Meeting of the A.S.M.E. Special Research Committee on Mechanical Springs, held in connection with the Annual Meeting, New York, N. Y., November 30 to December 4, 1931, of The American Society of Mechanical Engineers.

the spring upon a plane perpendicular to its geometric axis shall be the spiral of Archimedes, represented by the equation $r = r_o + k\theta$. The second is that a tangent to the neutral axis at every point shall make the same angle a with this plane.

In the derivation of the formulas for this spring the following notation is used:

r_o = base radius of active portion of spring
r_n = top radius of active portion of spring
n = number of active coils in spring
θ = vectorial angle of base spiral for point on axis of spring
k = $(r_n - r_o)/\theta_n$
θ_n = vectorial angle corresponding to r_n
P = applied load
A = area of cross-section of the spring material
E = Young's modulus of elasticity of the steel
G = shearing modulus of the steel
L = total length of active spring material
D = axial deflection
a = constant-slope angle
z = height of any point (r, θ, z) of the neutral axis of the spring above the base plane
z_n = total height of the neutral axis above the base plane under no load
θ_z = angular deflection about the geometric axis
I_v = moment of inertia of A with respect to the tangent to the neutral axis
I_u = moment of inertia of A with respect to a line in the cross-section and also in a vertical plane through the center of the cross-section
I_w = moment of inertia of A with respect to a horizontal line in the cross-section through its center
S_1 = an integral
$= {}^1/_4[\theta_n(r_n + r_o)(r_n^2 + r_o^2) + k^2\theta_n(r_n + r_o) - (k^3/2)\log_e(r_n/r_o)]$
S_2 = an integral
$= {}^1/_2(r_n + r_o)\theta + (k/2) \log_e (r_n/r_o)$
Q = $42\, PI_v(S_1 - k^2S_2)/A^4G$
B = $P(S_1 - k^2S_2)/EI_u$
C = Pk^2/EI_w

The mathematical analysis (see Appendix) leads to the following formulas:

$$D = z_n + (Q + C - z_n)/[1 - (Q + C - z_n)(2B + C - Q)/2L^2] \ldots\ldots [1]$$

$$Q_z = P\theta_n \sin a[1/EI_u - 42\, I_v/A^4G]\, (r_n^2 + r_or_n + r_o^2)/3 \ldots [2]$$

$$z = (r_n^2 - r_o^2) \tan \theta/2k \ldots\ldots\ldots\ldots\ldots [3]$$

DESIGN OF MANDREL

In the design of the mandrels upon which the springs of constant slope were wound, use was made of Equation [3]. This equation shows that the neutral axis of the spring lies upon a frustum of a paraboloid of revolution. Therefore the mandrel required a curved profile instead of a straight one, such as was used for winding the springs of constant pitch.

Four mandrels,[3] machined from low-carbon steel, were required for winding the four types of springs to be used in the tests. Accuracy in the construction of the mandrels was considered important, and for this reason the precaution was taken to have all dimensions accurate to one-hundredth of an inch.

METHOD OF WINDING

To wind a spring the stock was fed through a tension tool, mounted on the lathe carriage, and then gripped in a slot at the small diameter of the mandrel. As the stock was heated with an oxyacetylene torch, the mandrel was slowly turned in the lathe, while the carriage and tension tool were moved by hand at a speed just sufficient to feed the stock against the shoulder cut in the surface of the mandrel. When the spring was cool, the remaining stock was cut off and the spring was removed from the mandrel. The remaining stock was then cut into standard tension and torsion specimen lengths, necked, and marked for identification.

HEAT TREATMENT

Although information was available for the heat treatment of chrome-vanadium steel, it was decided to try to determine the treatment best adaptable to conical springs. Four small test pieces were cut from the rectangular stock for the determination of the critical temperature and the Rockwell C hardness. Three of the specimens were normalized at 1600 F and then quenched in oil at a temperature of 1550 F. These temperatures were high enough above the determined critical temperature of 1405 F to assure the relieving of all stresses created during the winding of the spring. The specimens were then tempered at 850, 950, and 1050 F, respectively, for the determination of the Rockwell C hardness. The results were:

Specimen No.	Tempering temperature, F	Rockwell C hardness
1	850	45
2	950	43
3	1050	41–42

A comparison of these results with the standard[4] established by the American Society for Steel Treating revealed that tempering temperatures of 950 F and 1050 F were too high to give sufficient hardness to this steel. However, as a precaution two springs of rectangular stock and uniform pitch were treated at the temperatures of 950 F and 1050 F, respectively. The spring tempered at 1050 F was too soft to give a true permanent set. To avoid extreme end effects at the top of the spring, the spring tempered at 950 F was loaded to only 450 lb for 24 hr and was found to have acquired a permanent set of 1.62 in. A third spring of the same type and material was then tempered at 900 F and placed under a load of 450 lb for 24 hr. The set was found to be 1.23 in. All sets are for a total deflection of approximately 9 in. under the maximum load. Though this set was still large, the tempering temperature was not reduced further pending the testing of a spring of rectangular stock and constant slope given the same treatment. This procedure was followed because this type of spring has a greater pitch in the first coil, which led to the belief that less set would occur. It was found that this type of spring acquired only 0.55 in. permanent set under the same loading conditions.

Though no identical comparison of characteristics could be made between the springs of rectangular stock and those of circular stock because of the increase in the base diameter of the latter springs, it was desirable to have these springs receive the same heat treatment to permit comparison of yield-point stresses for the two stocks. Therefore two springs of circular stock, one of constant pitch and one of constant slope, were normalized at 1600 F, quenched in oil at 1550 F, and tempered at 900 F. When loaded to 900 lb for 24 hr, the spring of constant pitch acquired a permanent set of 0.10 in., while the spring of constant slope acquired a set of 0.29 in. under an equal load during the same time. Here, again, the total deflection at maximum load was approximately 9 in.

---

[3] For a detailed description of construction, see Progress Report No. 8 of the A.S.M.E. Special Research Committee on Mechanical Springs, "The Design of Conical Springs With Coils of a Uniform Slope," by J. B. Reynolds and O. B. Schier, presented at Annual Meeting, New York, N. Y., December 1 to 5, 1930, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

[4] A.S.S.T. Handbook, pp. 149–152.

These results were judged to be satisfactory, so that the treatment given to all springs and test specimens was as follows:

Treatment	Temperature, F	Cooling medium
Normalize	1600	Air
Quench	1550	Oil
Temper	900	Air

It was essential that there should not be any change in the shape of the spring when it reached a plastic state during the heat treatment. Therefore, an arbor was designed to hold every coil of the spring in place. The arbor was constructed of steel plates welded together to form four fins, the profiles of which corresponded to the inside dimensions of the spring. Each coil was supported at four points at the lower edge, while the top and bottom dead coils were held by shoulders on the fins. Three springs of each type were treated individually on one arbor. The tempering was done in an electric furnace, providing positive control of the tempering temperature, so that each spring received the same final treatment.

TESTING REQUIREMENTS

In testing the springs it was desirable that the following requirements be met: (1) that there be an axial application of load, (2) that the top of the spring be permitted to rotate or not as desired, and (3) that the spring be prevented from tipping. By the design and construction of special attachments it was possible to use Riehle and Olsen testing machines for the tests. These tests were as follows: Loading and unloading of the spring in 50-lb increments of load with—

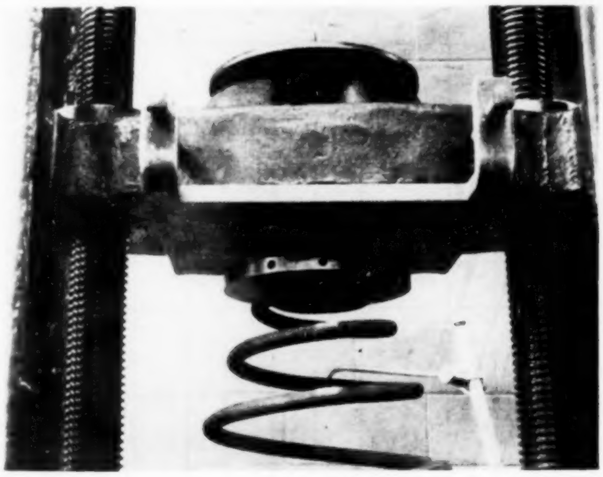

FIG. 1 THRUST BEARING WITH TORQUE PINS IN PLACE

(1) the top of the spring unconstrained from rotation
(2) the top of the spring constrained from rotation
(3) the top of the spring unconstrained under repeated loading ten times as rapidly as possible.

Sufficient runs were made in each test to determine whether the spring characteristics were constant under repeated testing. In every series of tests and for each increment of load up to the maximum of 500 lb for the springs of rectangular stock and 900 lb for the springs of circular stock, the following data were recorded: (1) axial deflection of spring, (2) angular deflection, and (3) net height of each coil; that is, the distance from the bottom of the spring to the top of each coil.

The axial deflections were measured with an inside micrometer from a fixed reference plane to the top of the spring, as shown in Fig. 2. The angular deflections were obtained by using an attachment designed to fit both the Olsen and Riehle testing machines, used in testing the springs of rectangular stock and circular stock, respectively. This attachment, shown in Fig. 1, consists of an S-K-F thrust bearing, one race of which is fastened to a plate which clamps on the movable platen of the machine and the other race of which is fastened to a circular plate which centers the top of the spring under the bearing. Through this

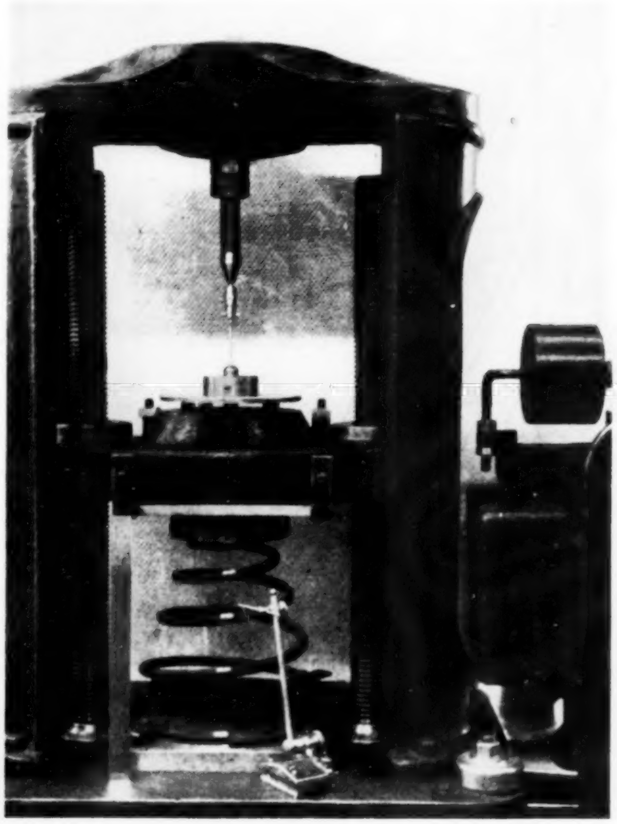

FIG. 2 SPRING UNDER INITIAL LOAD

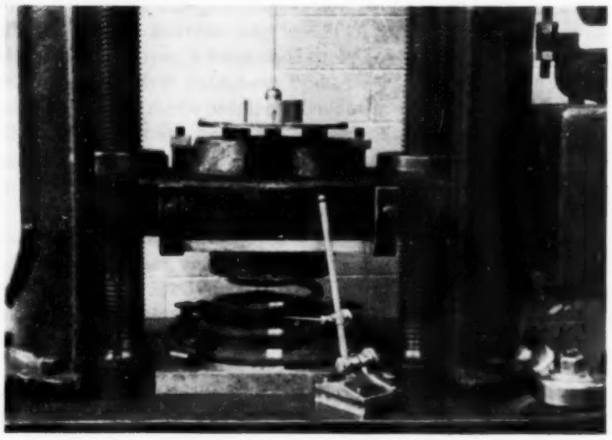

FIG. 3 SPRING PARTLY COMPRESSED, SHOWING NESTING OF COILS

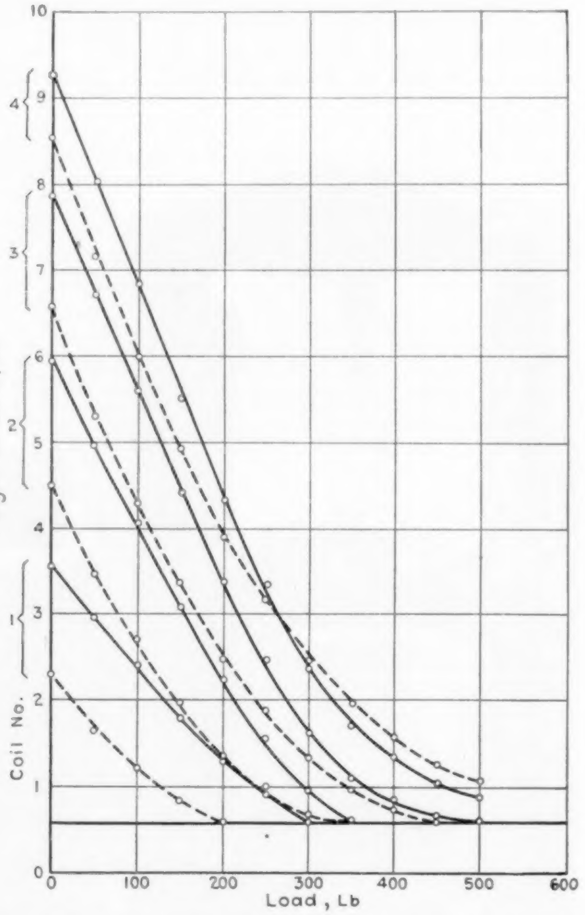

FIG. 4 COMPARISON OF COIL ACTIONS IN TWO CONICAL SPRINGS OF RECTANGULAR STOCK, WITH TOP FREE TO ROTATE

(Solid line, coils of constant slope; broken line, coils of constant pitch.)

plate are two holes in which torque pins can be inserted and screwed into the platen. These pins prevent turning of the bearing. To this circular plate is screwed a post which projects through the bearing, platen, and graduated disk on top of the platen. To the post is attached a pointer which moves over the disk, graduated in degrees, as the spring rotates under the application of load. Little change results in the tare of the machine, since the torque pins are the only change made in the apparatus when changing from constrained to unconstrained rotation.

The measurements of the net height of each coil was made with a surface gage as shown in Fig. 3. With the gage sitting on the machine table, the pointer was adjusted until it touched the top of the coil. The gage was then swung around, and the distance of the pointer above the table was measured with a steel scale. A radial line was scribed across the top of each coil so that the measurement would be made to the same point for each reading. These lines were placed 360 deg apart and directly above the heel of the spring.

A Ewing tensometer was used to measure the elongation of the tension specimens for determining the modulus of elasticity of the steel. The specimens of the rectangular stock were necked to an area $^3/_8$ in. by 0.235 in., while those of the circular stock were necked to a $^3/_8$ in. diameter. The results obtained from the tests on the rectangular specimens tempered at 1050, 950, and 900 F show the importance of proper heat treatment. The results are as follows:

Tempering temperature, F	Yield-point stress, lb per sq in.	Ultimate stress, lb per sq in.
1050	159,000	164,800
950	162,000	165,000
900	189,000	198,000

From the specimen with a temper of 900 F the modulus of elasticity was found to be 28,000,000 lb per sq in. The circular stock, which was of a slightly different analysis, had a yield point stress of 199,000 lb per sq in. and an ultimate strength of 206,000 lb per sq in. for a temper temperature of 900 F. This steel also had a modulus of elasticity of 28,000,000 lb per sq in.

Torsion tests were made on specimens from the circular stock to determine the modulus of shear of the chrome-vanadium steel. An average of several tests gave a modulus of shear of 11,300,000 lb per sq in. The shear modulus was not determined for the rectangular stock, because the small section of the necked specimen would not permit an accurate determination. The value was assumed to be the same as for the circular stock, but later evidence shows that this assumption was probably in error.

RESULTS OF TESTS

Fig. 4 gives a comparison between the coil actions of a spring of rectangular stock with coils of constant slope and one with coils of constant pitch while the top of the springs are free to rotate. It will be noticed that the coils of constant slope more

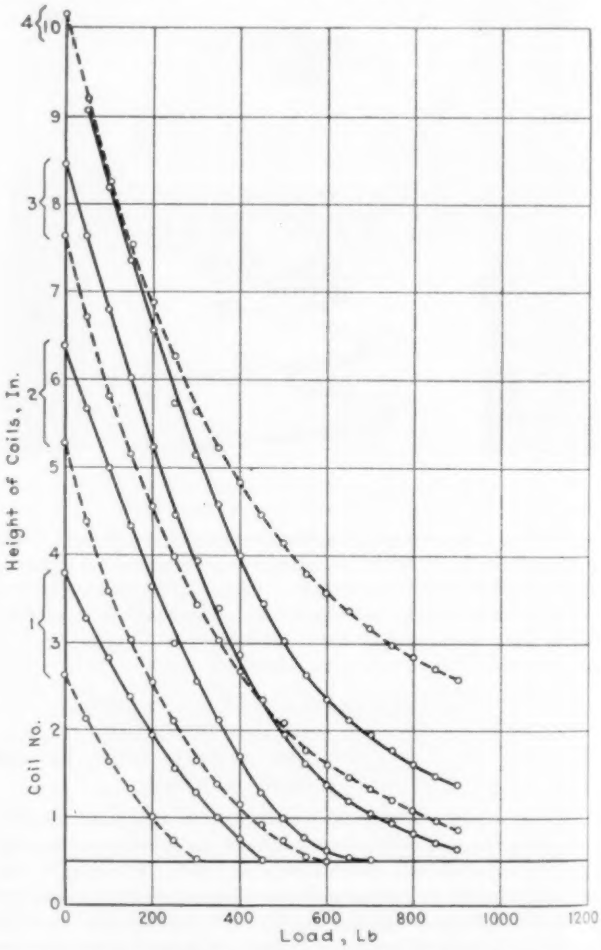

FIG. 5 COMPARISON OF COIL ACTIONS IN TWO CONICAL SPRINGS OF CIRCULAR STOCK, WITH TOP FREE TO ROTATE

(Solid line, coils of constant slope; broken line, coils of constant pitch.)

nearly approach the straight-line characteristic of the helical spring than do the coils of constant pitch. This is due principally to the delayed nesting of the lower coil, which does not occur until a load is applied that is greater than that making the lower coil of the constant-pitch spring nest. This prolongs the free action of the upper coils. The permanent set in the spring of constant slope is less than that in the spring of constant pitch, there being a difference of $^3/_4$ in. in their final heights.

There was made a similar comparison of the same springs, with the exception that the top of the spring was constrained from rotation. The actual difference between the two types of end conditions proved so small for these springs that there seems to be little advantage in the use of unconstrained rotation.

Fig. 5 is a comparison between the coil actions of a spring of circular stock with coils of constant slope and one with coils of constant pitch. As in the springs of rectangular stock the coils of constant slope approach the straight-line characteristic of the helical spring. It is thought that the sharp angle between the dead coil and the lower active coil has considerable effect on the action of the spring coils. This effect, here called end effect, is far more pronounced in the spring of circular stock because of the larger base diameter and correspondingly larger pitch. The departure of the curves from a straight line up to a load of 450 lb, where the first coil nests, is thought to be largely caused by this end effect.

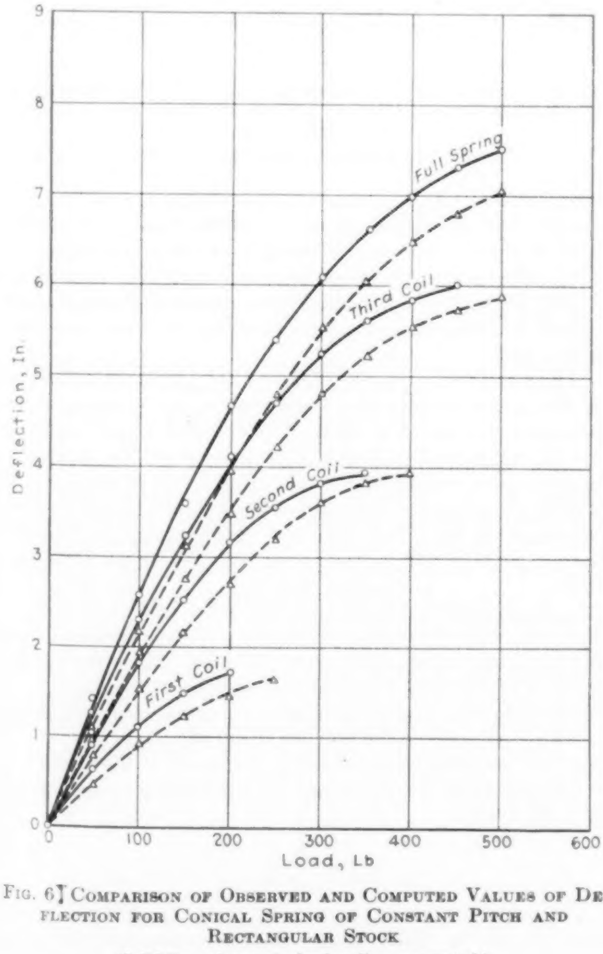

FIG. 6 COMPARISON OF OBSERVED AND COMPUTED VALUES OF DEFLECTION FOR CONICAL SPRING OF CONSTANT PITCH AND RECTANGULAR STOCK

(Solid line, observed; broken line, computed.)

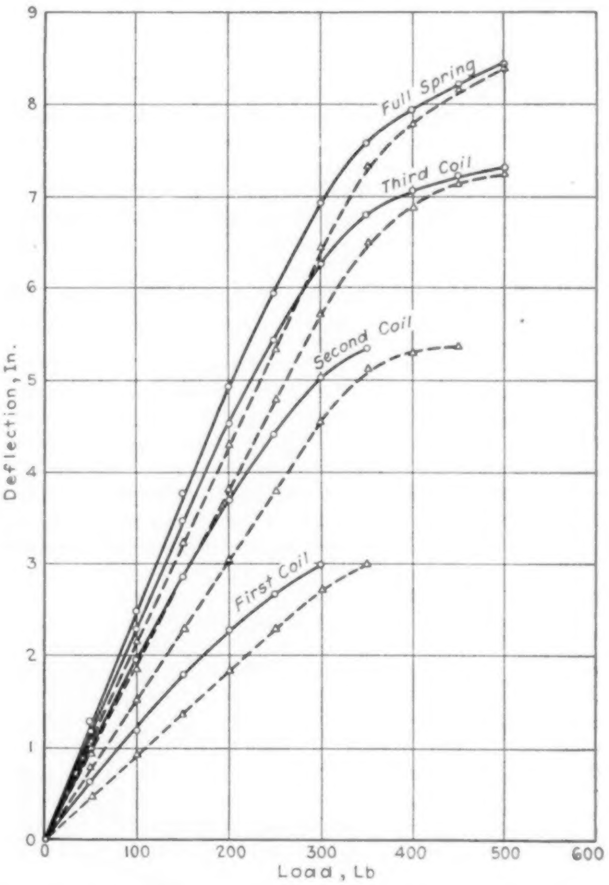

FIG. 7 COMPARISON OF OBSERVED AND COMPUTED VALUES OF DEFLECTION FOR CONICAL SPRING OF CONSTANT SLOPE AND RECTANGULAR STOCK

(Solid line, observed; broken line, computed.)

In computing deflection for the spring of rectangular stock and constant pitch, the formula for rectangular stock as adapted to conical springs by J. K. Wood[5] has been used, with the results shown in Fig. 6. This formula is as follows:

$$D = K_c K_f \frac{19.6\, P r_1{}^3 n}{G t^3 (b - 0.56t)}$$

where

D = unit deflection of each half coil, in.
P = load, lb
r_1 = base radius of each half coil
r_2 = top radius of each half coil
n = number of coils = $^1/_2$
G = modulus of shear, lb per sq in.
t = width of stock, in.
b = depth of stock, in.
K_c = $(1 + e)(1 + e^2)/4$
K_f = $1 + 2(1 + e + e^2)/3c(1 + e)(1 + e^2) - 1/c^2(1 + e^2)$
e = r_2/r_1
c = $2r_1/t$.

A similar formula is used in computing the curves for circular stock in Fig. 8. This formula is as follows:

$$D = K_c K_f \frac{64\, P r_1{}^3 n}{G d^4}$$

---

[5] "Conical Spring Design; Some New Factors and Formulas," by J. K. Wood, 1929, *Am. Mach.*, vol. 71, pp. 620–624.

where the values are the same as above and

d = diameter of circular stock, in.
c = $2r_1/d$.

The unit deflection for each half coil was obtained by calculating a constant for each half coil and multiplying this by the increments of load. The constants vary with the base radius and top radius of each half coil. Thus by varying the values of c and e and in turn K_c and K_f by using a varying base radius, the total deflections of each coil were similar to the experimental deflections.

To compute the deflections for the springs of constant slope the formula developed by J. B. Reynolds was used. It is as follows:

$$D = z_n + (Q - z_n)/[1 - (Q - z_n)(2B - Q)/2L^2]$$

where

D = total deflection of the spring, in.
z_n = total height of spring after permanent set, in.
Q = $4\pi^2 P I_v (S_1 - k^2 S_2)/A^4 G$, where $I_v = \pi d^4/32$ for the circular stock and $I_v = bt(t^2 + b^2)/12$ for the rectangular stock
B = $P(S_1 - k^2 S_2)/EI_u$
L = $(\sec a)[(r_o + r_n)\theta_n + k \log_e (r_n/r_o)]$.

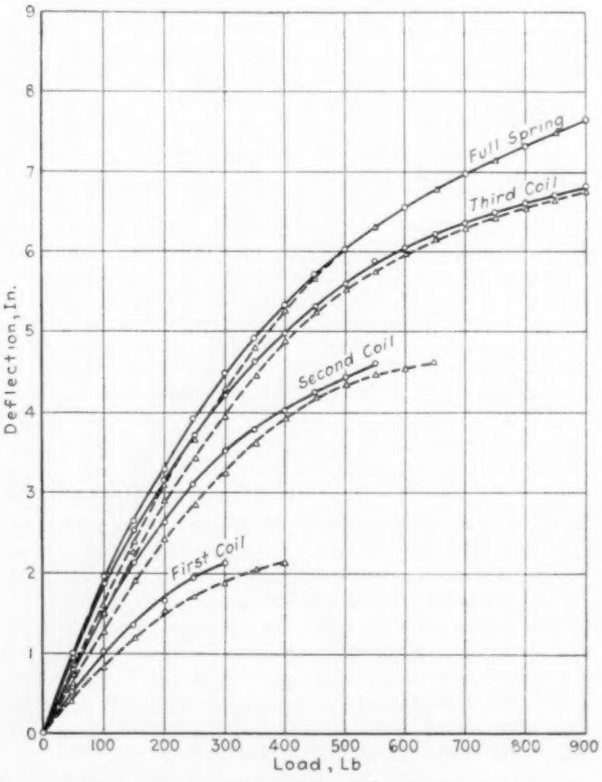

Fig. 8 Comparison of Observed and Computed Values of Deflection for Conical Spring of Constant Pitch and Circular Stock
(Solid line, observed; broken line, computed.)

Figs. 6 and 7 give the comparison between observed and computed deflections for two conical springs of rectangular stock. Fig. 6 compares the deflections in a spring of constant pitch, while Fig. 7 compares the deflections in a spring of constant slope. The lack of agreement in Figs. 6 and 7 is probably partly due to the value of the shear modulus used in the formula. As previously mentioned, this value was not determined for the rectangular stock, and so the value of 11,300,000 lb per sq in. is likely to be in error. This error is cumulative, since the deflections as calculated are unit half-coil deflections which are then added to give the total. A decrease of the modulus of shear would increase the deflection, and it is believed that the value, as chosen, may be high.

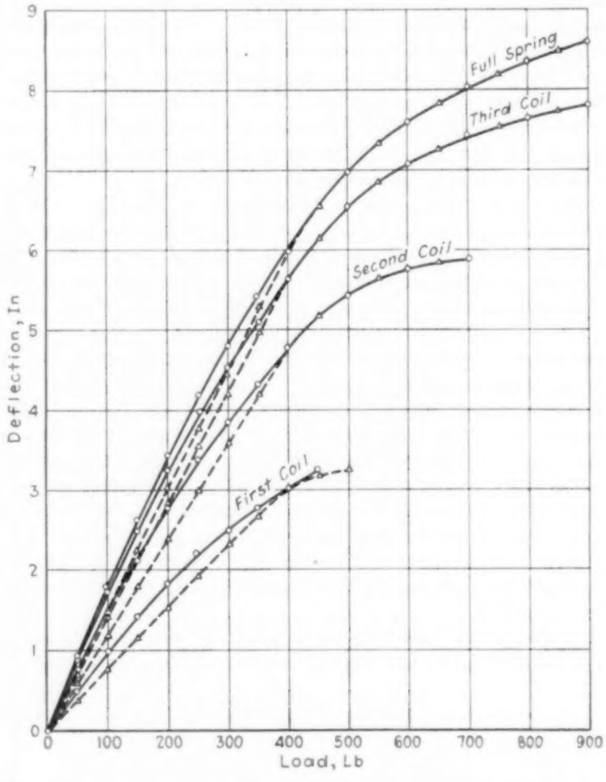

Fig. 9 Comparison of Observed and Computed Values of Deflection for Conical Spring of Constant Slope and Circular Stock
(Solid line, observed; broken line, computed.)

Figs. 8 and 9 compare the observed and computed deflections for two conical springs of circular stock. Fig. 8 compares the deflections in a spring of constant pitch, while Fig. 9 compares the deflections in a spring of constant slope. The agreement detween these deflections is good. The variation that appears between the curves up to the load of 400 lb is probably due almost entirely to the end effect at the base of the spring; for after the first coil nests at 450 lb, the curves coincide for the remaining loads.

In the springs of both rectangular stock and circular stock those with coils of constant slope give a better agreement than do the springs of constant pitch. Whether this is due to the accuracy of the deflection formula developed in the paper or to the differences of end effect cannot be stated until further research is conducted on the problem of end effects.

In the theoretical determination of stresses in the springs of rectangular stock, use was made of the following formula given by A. M. Wahl:[6]

$$S = Pr_1 \frac{(3b + 1.8t)k}{b^2 t^2}$$

---

[6] "Further Research on Helical Springs of Round and Square Wire," by A. M. Wahl, Trans. A.S.M.E., 1930, vol. 52, paper APM-52-18.

where

S = maximum shear stress, lb per sq in.

P = axial load on spring

r_1 = mean base radius of each half coil

b = depth of rectangular section

t = width of rectangular section

k = stress multiplication factor

$= \dfrac{4c-1}{4c-4} + \dfrac{0.615}{c}$

c = $2r/t$

This formula was used for computing stresses in springs of both constant pitch and constant slope. The factor k is the multiplication factor for stresses on the inside of the coil where the maximum stresses occur. Fig. 10 represents the computed stresses in each half coil in springs of rectangular stock. The dotted lines show the increase in stress in the coils of constant slope over the stress in the coils of constant pitch. From Fig. 10 it will be seen that the maximum theoretical stress occurs in the middle section of the fourth coil in both types of springs. It follows that failure is most likely to occur here. This has been found to be the case in numerous examples of failure in springs in operation.

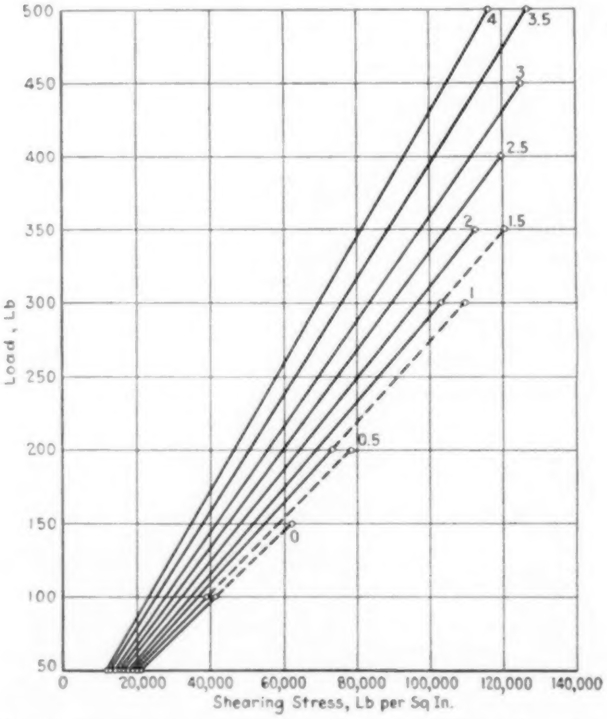

Fig. 10 Comparison of Load-Stress Curves for Each Half Coil in Two Conical Springs of Rectangular Stock

(Solid line, coils of constant pitch; broken line, coils of constant slope. Figures indicate number of coil.)

The stresses in springs of circular stock have been computed from the following formula given by A. M. Wahl:[7]

$$S = \frac{16\,Pr_1}{\pi d^3}\,k$$

where

S = maximum shear stress, lb per sq in.

P = axial load on spring

r_1 = mean base radius of each half coil

d = diameter of stock

k = stress multiplication factor

$= \dfrac{4c-1}{4c-4} + \dfrac{0.615}{c}$

c = $2r/d$

Fig. 11 represents the computed stresses at each half coil in springs of circular stock. The maximum theoretical stress occurs in the middle section of the third coil in both types of springs. However, the stress in the full third coil is almost exactly equal to that in the middle section, and failure may occur at either section.

In connection with the determination of stresses it should be pointed out that there is yet much to be done. The work was begun with a definite plan in mind for the development of a spring which would acquire higher stresses in the lower coils than have been previously obtained in springs with coils of constant pitch. That is, an endeavor was made to obtain a more uniform division of stresses throughout the spring coils. The study of stresses, however, was not carried to the extent first planned because of the unmeasured variation from the testing requirement of an axial application of load. It was thought that one full dead coil at both the top and bottom of the spring would approximately meet this requirement. However, the results of this investigation seem to imply considerable end effects and corresponding eccentricity of loading.

The load as actually applied to the spring acts as a combination of a force and a couple. The effective force on the top coil is applied somewhere between the axis of the spring and the point where the active coil joins the dead coil. This point shifts as the load is increased, since the bearing point or heel at the bottom of the spring moves as the coils nest. That is, as the coils nest the base radius decreases and the heel of the spring

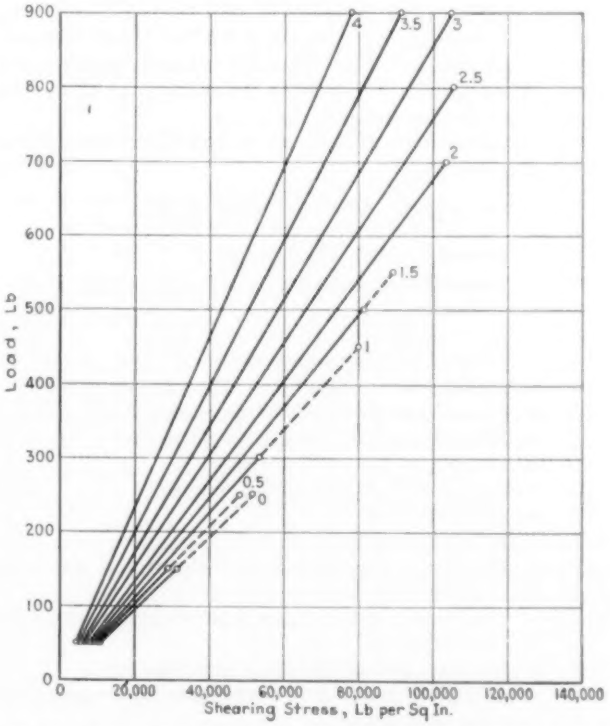

Fig. 11 Comparison of Load-Stress Curves for Each Half Coil in Two Conical Springs of Circular Stock

(Solid line, coils of constant pitch; broken line, coils of constant slope. Figures indicate number of coil.)

---

[7] "Stresses in Heavy Closely Coiled Helical Springs," by A. M. Wahl, Trans. A.S.M.E., 1929, vol. 51, paper APM-51-17.

rotates about the axis of the spring. Thus for a light load, with all active coils free, the heel at the top of the spring is in an axial plane over the heel at the base so that both forces lie a maximum distance to one side of the spring axis. This condition gives maximum stresses in the coils at the half points directly opposite from the heel. With a load on the spring sufficient to move the heel around to the half point in any coil, the forces have now been shifted to the opposite side of the spring axis. However, the distance of the forces from the spring axis is not as great as before because of the reduced base radius; thus the increase in stresses to be added to those existing is less than for the above condition.

It seems, then, that the maximum stresses can occur only at the half points in the coils directly opposite the heel of the spring under full load.

CONCLUSIONS

The following conclusions can be drawn from the results of the investigation:

1 It is possible with existing formulas to predict with considerable accuracy the behavior of conical springs.

2 For chrome-vanadium steel of the analysis given in this paper the best of several heat treatments tried was: Normalize at 1600 F; cool in air; quench at 1550 F in oil; temper at 900 F in air.

3 Conical springs of constant slope behave more like helical springs than do conical springs of constant pitch as regards load-deflection characteristics.

4 The coils of conical springs of constant slope seat less quickly under load than do those of constant pitch, but develop higher theoretical stresses.

5 There is need of research work on end effects in conical springs.

Appendix

The purpose of this discussion is to derive formulas for the design of a conical spiral spring and for the angular deflection under a known load. The results will be obtained in terms of constants for the material of which the spring is made, the load applied, and the dimensions of the spring.

In the derivation of the formulas for this spring the following notation is used:

r_o = base radius of active portion of spring
r_n = top radius of active portion of spring
n = number of active coils in spring
θ = vectorial angle of base spiral for point on axis of spring
k = $(r_n - r_o)/\theta_n$
θ_n = vectorial angle corresponding to r_n
P = applied load
A = area of cross-section of the spring material
E = Young's modulus of elasticity of the steel
G = shearing modulus of the steel
L = total length of active spring material
D = axial deflection
a = constant slope angle
z = height of any point (r, θ, z) of the neutral axis of the spring above the base plane
z_n = total height of the neutral axis above the base plane under no load
θ_z = angular deflection about the geometric axis
I_v = moment of inertia of A with respect to the tangent to the neutral axis
I_u = moment of inertia of A with respect to a line in the cross-section and also in a vertical plane through the center of the cross-section
I_w = moment of inertia of A with respect to a horizontal line in the cross-section through its center.

It is assumed that the projection of the neutral axis of the spiral spring upon the plane of its base is a plane spiral whose equation is $r = r_o + k\theta$ and that the tangent to the neutral axis at all points makes a constant angle a with the plane of the base. The angle a will differ for different loads on the spring, but will be assumed constant for a given load. The initial radius of the plane spiral is r_o. It is the value of r for $\theta = 0$. If r_n is the final radius of the plane spiral and θ_n equals 2π times the number of coils n of the spring which act freely, then $r_n = r_o + k\theta_n$, from which k may be obtained. By that part of the spring which acts freely is meant the portion which does not come in contact with the base or with the mechanism by which the pressure is applied.

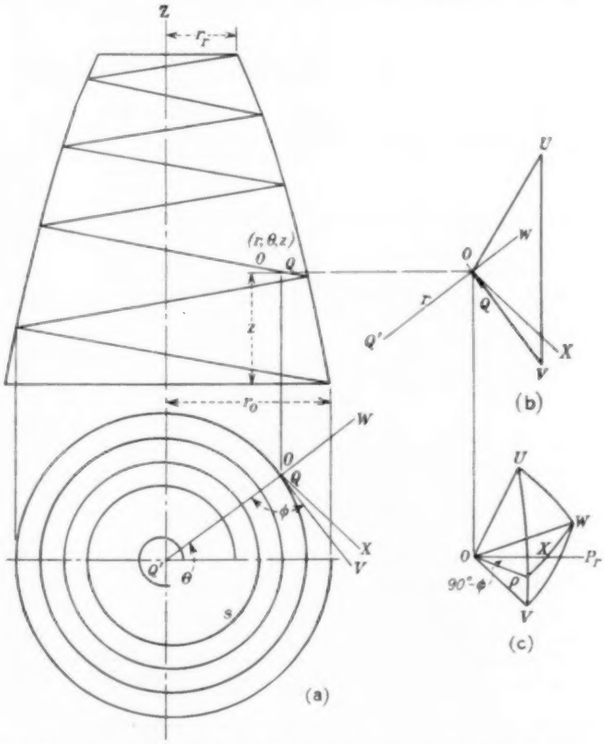

FIG. 12 NEUTRAL AXIS OF THE SPRING IN HORIZONTAL AND VERTICAL PLANES

Let ϕ be the angle between the radius vector r and the tangent to the plane curve $r = r_o + k\theta$, then $\tan\phi = r/(dr/d\theta) = r/k = \sin\phi/\cos\phi$. Since ϕ is nearly 90 deg, $\sin\phi$ is nearly unity, so we may write $\cos\phi = k/r$ and $\sin^2\phi = 1 - k^2/r^2$. If the length of the plane curve is called s and that of the neutral axis L, then $ds = dL\cos a$, for L makes a constant angle a with the plane of s. From this $dL = [r^2 + (dr/d\theta)^2]^{\frac{1}{2}}d\theta \sec a = (\sec a/k)(k^2 + r^2)^{\frac{1}{2}}dr$. Since k is small, dL is expanded in powers of k, giving $dL = (\sec a/k)[r + k^2/2r - k^4/8r^3 + \ldots]dr$. Integration between the limits r_o and r_n leads to (1) $L = (1/2)(\sec a)[(r_o + r_n)\theta_n + k\log_e(r_n/r_o) - k^4\theta_n(r_o + r_n)/8r_n^2r_o^2]$, a formula from which to get L that will be needed later.

Fig. 12(*a*) shows projections of the neutral axis of the spring in horizontal and vertical planes. Consider a small portion QO of the plane curve s. $Q'OV$ is the angle ϕ. OX is drawn perpendicular to $Q'O$ and OW perpendicular to the tangent OV.

Fig. 12(*b*) shows a small portion QO of the neutral axis of the spring as seen obliquely. *OV* is tangent to the neutral axis. *OU* is perpendicular to *OV* in the vertical plane through *OV*, and *OW* is perpendicular to both *OV* and *OU*. *OX* is perpendicular to *OQ'* in the horizontal plane *XOQ'*, as in Fig. 12(*a*).

Fig. 12(*c*) is a schematic diagram showing right spherical triangles, on a sphere with *O* as center, used to assist in getting angular relations for resolution of the vector *Pr* along *OX* into components along *OV*, *OU*, and *OW*. The vector *Pr* arises from the consideration that for the point *O* the pressure *P* may be thought of as a vertical force applied at *Q'* producing a torque *Pr* about *OX* which may be represented by a vector in the direction of *OX*. The assumption that the resultant of the pressure applied to the spring to compress it is equivalent to a force *P* along the axis of symmetry of the spring is, in effect, assuming that the pressure is symmetrically distributed about this axis where it is applied.

A length dL of the spring may be thought of as a beam subject to moments which tend to bend it an angular amount $d\theta_w$ about the axis *OW* and an angular amount $d\theta_u$ about the axis *OU* and to twist it through an angle $d\theta_v$ about *OV*, its neutral axis. The resultant of all these angular displacements must be an angular displacement $d\theta_x$ about *OX*. The amount that *O* will move parallel to the axis of symmetry of the spring due to this angular displacement is then $rd\theta_x$. This is dD. The integral of dD throughout the length of the spring gives *D*, the total deflection or compression of the spring.

Let the torque *Pr* be resolved into components T_w, T_u, T_v about *OW*, *OU*, *OV*, respectively; then from Fig. 12(*c*):

$$T_w = Pr \cos XOW = Pr \cos \phi,\ T_u = Pr \cos XOU = Pr \sin a \sin \phi$$

$$T_v = Pr \cos XOV = Pr \cos a \sin \phi.$$

Also,

$$d\theta_x = d\theta_v \cos XOV + d\theta_u \cos XOU + d\theta_w \cos XOW.$$

By the principles of mechanics of materials,

$$d\theta_w = T_w dL/EI_w,\ d\theta_u = T_u dL/EI_u,\ d\theta_v = 42\, I_v T_v dL/A^4G$$

in which *E* is Young's modulus for the material of which the spring is made and *G* is its modulus of shear. I_w is the moment of inertia of a cross-section of the spring material with respect to the axis *OW* and I_u the corresponding moment of inertia with respect to the axis *OU*. I_v is the moment of inertia of a cross-section about *OV* and *A*, its area.

From the relations so far given:

$$\left.\begin{aligned} dD = rd\theta_x = {} & [42\, I_vP \cos a/A^4G + P \sin a \tan a/EI_u] \\ & r^2(r^2 + k^2)^{\frac{1}{2}}d\theta + [Pk^2 \sec a/EI_w - 42\, I_uPk^2 \cos a/A^4G \\ & - Pk^2 \sin a \tan a/EI_u](r^2 + k^2)^{\frac{1}{2}}d\theta \end{aligned}\right\} \ldots\ [1]$$

Replacement of $d\theta$ by dr/k and integration between the limits r_o and r_n yields:

$$\left.\begin{aligned} D = {} & P(42\, I_v \cos a/A^4G + \sin a \tan a/EI_u)S_1 + Pk^2 \\ & (\sec a/EI_w - 42\, I_v \cos a/A^4G - \sin a \tan a/EI_u)S_2 \end{aligned}\right\} \ldots\ [2]$$

in which S_1 and S_2 are integrals defined as follows:

$$S_1 = 1/k \int_{r_o}^{r_n} r^3(1 + k^2/r^2)^{\frac{1}{2}}dr$$

$$= 1/k \int_{r_o}^{r_n} (r^3 + k^2r/2 - k^4/8r + \ldots)dr$$

$$= (r^4_n - r^4_o)/4k + k(r^2_n + r^2_o)/4 - (k^3/2) \log_e (r_n/r_o) \ldots$$

$$= (1/4)[\theta_n(r_n + r_o)(r_n^2 + r_o^2) + k^2\theta_n(r_n + r_o) - (k^3/2) \log_e (r_n/r_o)]$$

and

$$S_2 = 1/k \int_{r_o}^{r_n} r(1 + k^2/r^2)^{\frac{1}{2}}dr = 1/k \int_{r_o}^{r_n} (r + k^2/2r \ldots)dr$$

$$= 1/k[(r_n^2 - r_o^2)/2 + (k^2/2) \log_e(r_n/r_o) \ldots]$$

$$= 1/2(r_n + r_o)\theta_n + (k/2) \log_e(r_n/r_o)$$

When regrouped, the result for *D* may be written:

$$D = Q \cos a + B \sin a \tan a + C \sec a \ldots\ [3]$$

in which

$$Q = 42\, PI_v(S_1 - k^2S_2)/A^4G,\ B = P(S_1 - k^2S_2)/EI_u$$

$$C = Pk^2/EI_w$$

Now the angle *a* depends upon the compression *D* in such a way that if z_n is the free height of the spring, $\sin a = (z_n - D)L$, and hence to second powers of $(z_n - D)L$, which is always a small quantity,

$$\sin a \tan a = (z_n - D)^2/L^2,\ \sec a = 1 + (z_n - D)^2/2L^2$$

$$\cos a = 1 - (z_n - D)^2/2L^2$$

Hence the deflection may be written:

$$D = Q + C + (2B + C - Q)\,(z_n - D)^2/2L^2$$

and for a close approximation:

$$D = z_n + (Q + C - z_n)/[1 - (Q + C - z_n)\,(2B + C - Q)/2L^2] \ldots\ [4]$$

If the term in $(z_n - D)^2/2L^2$ be neglected, then $D = Q + C$, and since *Q* and *C* vary directly with *P*, to this degree of accuracy, *D* varies directly with *P*. Experiments show that this is nearly true for considerable ranges of *P*.

Instead of using the approximate result from [4], one may use [3], solving it by trial. First let $a = 0$, giving $D = Q + C$; with this value of *D* determine *a* by $\sin a = (z_n - D)/L$; with this value of *a* determine a new value D_1 of *D*. With D_1 get a new value a_1 of *a*, and with this another value D_2 of *D*, etc. The values *D*, D_1, D_2, etc., will rapidly converge toward the exact value of *D*.

The angular deflection θ_z of the spring about the vertical is given by

$$\begin{aligned} d\theta_z & = d\theta_u \cos a - d\theta_v \sin a \\ & = T_u \cos a dL/EI_u - 42T_vI_v \sin a dL/A^4G \\ & = (1/EI_u - 42\, I_v/A^4G)Pr \sin a \cos a \sin \phi dL \end{aligned}$$

Upon expanding and integrating, it is found that

$$\theta_z = P \sin a[1/EI_u - 42\, I_v/A^4G]\theta_n(r_n^2 + r_nr_o + r_o^2)/3 \ldots\ [5]$$

in which powers of *k* above the third have been dropped.

The height *z* of any point (r, θ, z) on the neutral axis above the base, since $d_z = dL \sin a$, is $z = L \sin a$, or by [1]

$$z = \tan a[r_n^2 - r_o^2 + k^2 \log (r_n/r_o) - k^4(r_n^2 - r_o^2)/8r_n^2r_o^2]/2k \ldots\ [6]$$

This is the equation of the surface upon which the neutral axis of the spring lies. If k^3 and higher powers are dropped, the equation reduces to that of a paraboloid of revolution with respect to the axis of the spring. Thus

$$z = (r_n^2 - r_o^2) \tan a/2k \ldots\ [7]$$

or in rectangular coordinates

$$z = (x^2 + y^2 - r_o^2) \tan a/2k$$

RP-54-13

Determination of Carbonate, Hydroxide, and Phosphate in Boiler Waters

Progress Report of Subcommittee No. 8 of the Joint Research Committee on Boiler-Feedwater Studies[1]

By W. C. SCHROEDER,[2] ANN ARBOR, MICH., and C. H. FELLOWS,[3] DETROIT, MICH.

Work of Subcommittee No. 8 of the Committee on Boiler-Feedwater Studies this year has involved critical examination of the methods generally used for examining boiler water, with a view of establishing methods for plant control and referee work that later might be recommended for adoption as standard in the industry. There has been much dissatisfaction with several methods for determining certain constituents in boiler water. This is because the methods used were developed for examining other types of water and consequently are not always applicable for accurate testing of water in steam boilers.

Those methods which, in the opinion of the subcommittee, required immediate consideration because they had to do with the determination of constituents important in control work in most plants, and because no generally accepted scheme of procedure had been found to yield satisfactory results, were: (1) Methods for the determination of alkalinity, especially that due to carbonate salts; (2) those for dissolved oxygen and carbon dioxide; and (3) those for the determination of phosphates and silicates, inasmuch as these salts influence alkalinity and, in some cases, interfere with its determinations.

It was felt that the most logical way to clear up the questions arising in connection with these methods was to put the matter before a competent technician who would devote his entire time to the problem. The subcommittee was authorized to establish a fellowship in some university to carry out the work, and one was established at the University of Michigan. The first problem taken up was methods for determining alkalinities and some of those ions influencing alkalinity and its determination. The report tells of the progress made in carrying out this work.

AT THE MEETING of the Committee on Boiler-Feedwater Studies held in Pittsburgh, Pa., in May, 1931, the proposed work of the reorganized Subcommittee No. 8 was discussed. The work involved critical examinations of the methods generally used for examining boiler water, with the view of establishing methods for plant control and referee work that later might be recommended for adoption as standard in the industry.

W. C. Schroeder

C. H. Fellows

It was brought out in general discussion that a great deal of dissatisfaction with several methods for determining certain constituents in boiler water existed. This was due principally to the fact that the methods had been developed for use in the examination of other types of water and consequently were not always applicable for accurate testing of the water in steam boilers.

Those methods which, in the opinion of the subcommittee, required immediate consideration because, first they had to do with the determination of constituents important in control work in most plants, and second, because no generally accepted scheme of procedure had been found to yield satisfactory results, were (*A*) methods for the determination of alkalinity, especially that due to carbonate salts; (*B*) those for dissolved oxygen[4] and carbon dioxide; and (*C*) those for the determination of phosphates and silicates inasmuch as these salts influenced alkalinity and, in some cases, interfered with its determinations.

It was felt that the most logical way to clear up the questions arising in connection with these methods was to put the matter before a competent technician who would devote his entire time to the problem. The subcommittee was authorized to establish a fellowship in some university to carry out the work. As a result, a fellowship was established at the University of Michigan, and the first problem to be taken up was that involving the methods for the determination of alkalinities and some of those ions influencing alkalinity and its determination. This paper sets forth, as briefly as is consistent, the progress made to date in carrying out this work.

[2] Fellow in Boiler-Feedwater Studies, 1931–1932, Department of Chemical Engineering, University of Michigan. Detroit Edison Fellow in the Study of Boiler-Scale Formation, 1930–1931. Received the degrees of Bachelor of Science in Chemical Engineering, and Master of Science in Engineering from the University of Michigan.

[3] Chemist, Research Department, The Detroit Edison Company. He was educated at Purdue University and the School of Chemical Engineering, and began work with The Detroit Edison Company in 1919. Since that time Mr. Fellows has taken an active part in the development of the application of chemistry to power-plant practices. He is a member of the American Chemical Society and an active member on several committees identified with other national engineering societies. He is chairman of the Power-Stations Chemistry Subcommittee of the National Electric Light Association and is directing the activities of the Committee on Methods of Water Analysis of the Boiler-Feedwater Studies Committee.

Presented at the Annual Meeting, New York, N. Y., Nov. 30 to Dec. 4, 1931, of The American Society of Mechanical Engineers.

[4] Although this subcommittee published an acceptable method for dissolved oxygen several years ago, that method appears not to have yielded entirely satisfactory results in all cases, and it was felt further study would be justified.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

It happened that, previous to the establishment of this fellowship, a very considerable amount of work dealing with the determination of carbonates had already been carried out at the University of Michigan. Some of the results of this work have been submitted to *Industrial and Engineering Chemistry*, and the first part of the present report has been condensed from that paper.

These earlier studies were carried out in connection with the analysis of solutions taken from an experimental boiler. As the results of this work offered at least a tentative method for the accurate determination of carbonate it was decided to give a greater amount of attention to the determination of hydroxide, and, if possible, some consideration to the determination of phosphate.

The results of this earlier work and those of the present investigation may be summarized briefly to show that: First, all of the methods generally in use for the determination of carbonate are open to large errors at low concentrations of carbonate and high concentrations of hydroxide. It is at such concentrations that most boilers operate in which the carbonate determination is important. A method which is very reliable and which is fairly rapid has been worked out for the determination of carbonate. Second, the determination of the hydroxide concentration by either the A.P.H.A. or the Winkler method is not greatly in error. Methods have been worked out for increasing the accuracy of this determination. Third, a method for the determination of phosphate has been investigated which seems to be extremely accurate as well as very rapid. The determination is not interfered with by any of the ions ordinarily found in samples of boiler water.

The determination of carbonate was studied in both laboratory and plant. A discussion of the findings of each of these investigations will be taken up and this will be followed by a discussion of the determination of hydroxide and of the determination of phosphate.

DETERMINATION OF CARBONATE

The literature on the analysis for carbonate makes it very apparent that investigators other than those interested in boiler-water analysis have found difficulties in determining small amounts of carbonate. Endless details, modifications, and rediscoveries of various methods have been given. In general the methods of analysis may be divided into two classes, (*a*) those involving the titration of the original sample, and (*b*) those involving an initial evolution of carbon dioxide.

The first class in general depends on either the color change of indicators to determine the end point of the titration or changes in electrical potential. The A.P.H.A. and the Winkler method, which are generally used for the determination of hydroxide and carbonate in boiler waters, belong in this class. Titration of the original sample with indicators is open to very many errors as the work of many investigators has shown. It would seem that some improvement might be made by an electrometric method for the determination of the end points. Such end-point determination has not been very generally tried in plant practice due to the complexity of the equipment involved. It has been used by several investigators with good success in the laboratory.

Methods of analysis involving the initial evolution of the carbon dioxide seem to be free of many of the very serious errors involved in the titration of the original sample. This is especially true if there is any danger of the original sample being contaminated by unknown impurities such as may exist in a boiler water. A variety of methods has been used for measuring the total carbon dioxide evolved from a sample. These various methods utilize measurement of gas pressure or volume, the freezing-out of solid carbon dioxide, and absorption in various solid or liquid media. Many of these methods have been developed in fields rather distant from boiler-water chemistry. Their possible application to the latter depends upon how simply and how accurately they may be used for the determination of the small amounts of carbon dioxide present in boiler waters.

The present work has concerned itself to some extent with an investigation of the accuracy of the A.P.H.A. or the phenolphthalein-methyl orange method for the determination of carbonate, and the Winkler method. An attempt has been made to develop equipment which will make it possible to use the evolution method for the determination of carbonate without inconvenience in plant practice. The results of this work will be discussed under the headings, "Laboratory Investigation and Results," and "The Improved Evolution Apparatus."

Laboratory Investigation and Results

Two pieces of apparatus were designed for the determination of carbonate in boiler waters. The first of these was used in the laboratory in connection with work on an experimental boiler. The second apparatus, which was both simpler and more accurate, was subsequently developed for the plant studies described in the second part of this report. The fundamental idea was the same for both pieces of apparatus. The total carbon dioxide was liberated by addition of acid and heating, and this carbon dioxide was carried by an air stream into an excess of standard barium hydroxide, precipitating barium carbonate. The residual barium hydroxide was then titrated with standard acid. This method is not at all new and its original application may date back to Dalton. Its successful application to the determination of carbonate in solution depends upon the following factors:

1 Complete evolution of all carbon dioxide in the sample.

2 Complete absorption of the liberated carbon dioxide in barium hydroxide.

3 Complete precipitation of barium carbonate equivalent to the amount of carbonate liberated and absorbed.

4 Titration (of residual barium hydroxide) to definite reproducible end points.

5 Freedom from contamination by carbon dioxide of the atmosphere.

In general, the second condition is the one least likely to be satisfied by ordinary apparatus. Since it is necessary to sweep the carbon dioxide out of the original sample by means of an air stream initially free of carbon dioxide, a considerable volume of gas must be passed through whatever absorbing unit is used. As a bubble of gas containing carbon dioxide on passing through barium hydroxide immediately forms a film of barium carbonate at the gas-liquid interface, it is highly improbable that complete absorption can be attained except by prolonged contact or intimate mixing.

The first absorption apparatus consisted essentially of a train for freeing the air of carbon dioxide, a flask into which the sample was introduced and in which a regular phenolphthalein-methyl orange titration or a Winkler titration could be carried out, and an absorption system which would sweep all of the carbon dioxide from the air passed through it. In the actual determination of the total carbon dioxide of the sample by evolution, the carbon-dioxide free air was passed through the heated acidified sample, sweeping out all of the carbonate of the sample in the form of carbon dioxide and carrying it into the barium-hydroxide absorption system, where it was precipitated as barium carbonate. After all of the carbon dioxide had been liberated and absorbed the excess barium hydroxide was titrated with standard acid.

In this system complete removal of the carbon dioxide from the acidified and heated sample could be insured by passing the air stream through it for a sufficiently long time. A period of 15 min. was found to be ample for solutions containing up to 90 p.p.m. of CO_3. Practically complete absorption was insured by passing the gas stream first through a flask containing some of the barium hydroxide and then through a long absorption tower containing the rest of the hydroxide which was filled with glass beads. The completeness of absorption was further checked by passing the gas through a sight bulb before it left the system. In case any carbon dioxide had passed through the absorption system this bulb became cloudy.

Complete precipitation was insured by using standard barium hydroxide which was initially saturated with barium carbonate. By carrying out the titration of the excess barium hydroxide with uniform illumination, which was secured by placing the flasks in which the titration was carried out in an illuminated box, closely reproducible results were obtained. Blank tests indicated that all of the carbon dioxide was scrubbed from the entering air by the train for removing the carbon dioxide, and further blank tests showed that hydrochloric acid could be used for acidifying the sample without danger of carrying over acid in the gas stream to the barium hydroxide.

It will be remembered that means were provided on this apparatus for carrying out a regular phenolphthalein-methyl orange titration or a Winkler titration. Since the evolution method only determines the carbonate it was necessary to do this in order to secure a value for the hydroxide.

The accuracy of the apparatus was tested and the method was compared with both the phenolphthalein-methyl orange and the Winkler titrations, using samples very carefully prepared to contain known concentrations of carbonate and hydroxide. Every precaution was taken to insure an accurate knowledge of the concentrations of these samples.

The values obtained with a series of hydroxide-carbonate samples titrated by the A.P.H.A. method or the method using phenolphthalein and methyl orange are shown in Table 1.

* $CaSO_4$ added in solution.

The titrations were carried out under conditions superior to those usually surrounding control titrations of boiler waters. Loss of carbon dioxide from the sample during titration was obviated by introducing the acid near the bottom of the sample. Since the titration was carried out in a closed system all error due to atmospheric carbon dioxide was prevented. The values calculated for CO_3 by the customary method of interpretation (1)[5] are, however, consistently high and rather irregular, particularly for the lower concentrations. As a result of this arbitrary method of calculation, high values for CO_3 lead to slightly low values for OH.

The titrations shown in the table were made on distilled-water solutions containing no impurities. In the analysis of boiler waters it is doubtful if the relative accuracy shown here could be expected, since salts of slightly dissociated acids other than carbonic acid may be present, and the solutions may be in general more or less colored.

* Solution of calcium sulphate used to make sulphate concentration of sample about 700 p.p.m. SO_4.

The results of titrations by the barium-chloride or Winkler method on a series of samples of known concentration are shown in Table 2. These samples were treated in a variety of ways as indicated by the number in the column headed "Procedure in titration." The details of each treatment and the reasons for the results noted need not be considered here, but it should be noted that in all cases where calcium sulphate was added to the solution the results are high.

In general the barium-chloride titration will yield the best results when a considerable excess of the chloride is used. Letting the sample stand or heating it before titration does not increase the accuracy. When a considerable amount of sulphate is present in the solution, the barium-chloride titration gives high values for carbonate, and consequently, slightly low values for hydroxide.

The results of the direct-absorption method for the determination of carbonate are shown in Table 3. These results were se-

[5] Numbers in parentheses are for references at the end of this article.

cured on the first absorption apparatus which has just been described. They are very close throughout the range of concentrations investigated, the method is accurate at low-carbonate concentrations, and the presence of calcium sulphate introduces no error. It is to be expected that the presence of most impurities would have little effect when it is remembered that the actual titration for the carbonate is conducted in a distilled-water solution containing only barium hydroxide and suspended barium carbonate resulting from the absorption of carbon dioxide evolved from the original sample.

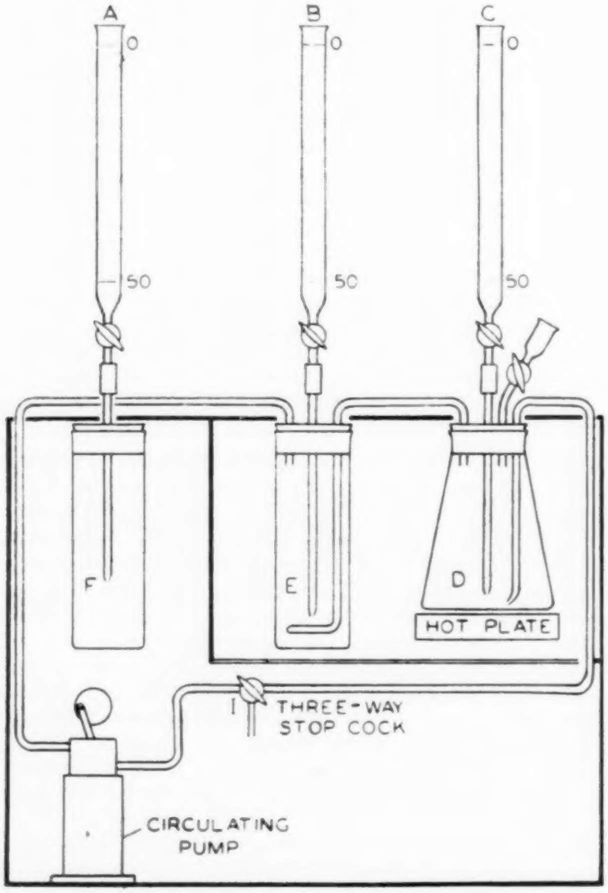

FIG. 1 EVOLUTION CARBONATE DETERMINATION APPARATUS

In contrast to the uncertain results obtained with the customary titration methods, the absorption method for total carbon dioxide shows consistent results, particularly in the case of the lower concentrations of carbonate, and it may be expected to serve as satisfactorily for actual boiler waters as for pure solutions. The only source of possible misinterpretation of the results would be the presence in the boiler water of sulphides, sulphites, or some organic salts which might yield a volatile acid in the direct absorption determination.

As carried out in the apparatus described the chief disadvantage of the absorption method was the complicated equipment and the time required for analysis, which was approximately one hour for each sample.

IMPROVED EVOLUTION APPARATUS

The disadvantages of the absorption method just described arose from the complicated apparatus used. An effort at improvement or simplification resulted in the development of an improved apparatus which requires a relatively short time for an analysis of total carbon dioxide, and which may be operated satisfactorily by a person not familiar with the chemistry of the process or particularly skilled in the manipulation of such apparatus.

The essential difference between the original and the simplified absorption apparatus is the manner in which the carbon dioxide is absorbed. In the simplified apparatus the sample flask and the absorption flask are a part of a closed system in which the air containing carbon dioxide is circulated continuously by a small pump until absorption is complete, thus eliminating the need for a scrubbing tower on the absorption flask. Absorption is hastened by the use of a device to produce many small bubbles in the absorption flask, although this is not essential to the satisfactory operation of the apparatus.

The apparatus consists of a box equipped with daylight bulbs and a ground-glass panel for uniform illumination. Inside of the box are fastened three stoppers connected to the buretted and air-circulating systems as shown in Fig. 1. The evolution flask *D* containing the sample is attached to the right-hand stopper and is supported in place by a small electric hot plate which is swung up beneath it. The absorption tube or flask *F* is filled with 0.03 N barium hydroxide from the burette on the left-hand stopper and is then attached as at *E* to the middle stopper for the absorption and subsequent titration.

The air outlet from the absorption tube *E* is connected directly to the suction side of a small air pump. The delivery side of the pump is connected back to the sample flask *D* as shown. The air line from the pump to this flask is provided with a three-way stopcock with one connection open to the atmosphere to make it possible to vent air from the system before and after an absorption in order to relieve pressure differences. The bubbling device shown inside the absorption tube is a perforated platinum disk sealed in glass.[6] The purpose of this disk is to break up the gas stream into fine bubbles so that the carbon dioxide may be more readily absorbed by the barium hydroxide. A small air condenser, not shown in Fig. 1, is placed between *D* and *E* to prevent condensate from *D* from collecting back of the disk on the bubbling device and stopping the air flow. The circulating pump, which may be driven by any convenient means, consists of two sliding sleeves sealed with mercury to prevent the possibility of any air escaping.

The supply bottles for acid and barium hydroxide are mounted on a shelf formed by the projecting base of the box, and are connected to the burettes by glass tubes. Rubber bulbs are also connected to the supply bottles to allow rapid filling of the burettes by air pressure. Excess acid above the zero mark of the burette is automatically siphoned back into the supply bottle on release of pressure. The outfit is entirely self-contained, and may be moved readily.

The operation of this apparatus is extremely simple. The measured sample is placed in flask *D*, and this flask is held in place by the heater as shown in Fig. 1. The absorption tube is filled with 0.03 N barium hydroxide and put in position at *E*. The sample in *D* is then titrated to give a value for the hydroxide. Excess hydrochloric acid equivalent to 2 cc. of normal acid is then added to the sample and it is heated just to the boiling point. The carbon dioxide evolved from the sample is swept by the circulating air into the barium hydroxide, where it is precipitated as barium carbonate. During a 10-min. absorption period the gas is passed through the hydroxide about 15 times, insuring practically complete absorption. The excess hydroxide in *E* is then titrated, the phenolphthalein used as indicator being contained in the 0.03 N acid added. From the acid equivalent of the hydroxide originally introduced into tube *E* and the amount of acid used for the final titration, the amount of carbon dioxide evolved from the sample is calculated. In alkaline solutions where the pH value is in the range above 11, the total carbon dioxide as determined by the absorption method may be assumed to be equivalent to the CO_3 concentration of the solution. For less alkaline solutions, the concentrations of CO_3 and HCO_3 may be calculated conveniently from the total carbon dioxide and pH value by the method outlined by McKinney (6).

---

[6] Supplied by the Fisher Scientific Company.

Eight samples of known concentration prepared from pure standard sodium-carbonate solutions were analyzed in the manner described. The results as shown in Table 4 were very consistent and considerably more accurate than were the results obtained on the more complicated apparatus first described.

* $CaSO_4$ added to sample to give 298 p.p.m. $CaSO_4$.

A series of determinations was also run on solutions containing sodium sulphate, sodium phosphate, and sodium hydroxide as well as the carbonate. The results for these analyses are shown in Table 5. The accuracy of the method, as is seen, is extremely good.

All of the solutions used in these analyses were made up with double-distilled water which had been boiled for 20 min. and cooled in a flask protected from carbon dioxide by ascarite. The bottles in which stock solutions were stored were also protected by ascarite, and the portions taken out to make up the samples for analysis were pipetted from the bottle through a stopcock, which was immediately closed when the pipette was full. All solutions other than the carbonate solution were made up to be carbonate free and blanks were run to make sure that they were free of carbonate. The sodium hydroxide was made from metallic sodium by dissolving it in water under a layer of ether as described in Clark's "Determination of Hydrogen Ions" (3). The sodium carbonate was made by heating bicarbonate in a jacketed crucible at 270 to 300 deg. cent. for $^1/_2$ hr.

The apparatus was standardized to make allowance for the carbon dioxide in the air in the system at the start of each analysis and tests were run to determine if there were any danger of boiling hydrochloric acid from the sample flask over into the barium hydroxide. With hydrochloric-acid concentrations up to twice that used in the regular analysis no evidence of acid being boiled over was noticed.

The results obtained in the direct absorption determination are probably more accurate than those given by any standard titration method, especially when applied to impure waters. Although approximately 20 min. of elapsed time is required for one complete determination, in many cases it would seem better for control purposes to have a single accurate analysis rather than any number which cannot be relied upon.

It should be remembered that the absorption apparatus determines only the total carbon dioxide present in a sample of water, regardless of the form in which it may exist in solution. Where precision is necessary in experimental work, the activities or concentrations of HCO_3 and CO_3 (in the original sample) may be calculated from the dissociation constants of carbonic acid. For practical purposes the total carbon-dioxide content of the alkaline water from a boiler may be assumed to have been present in that water usually as carbonate, although in the case of natural waters in contact with the air such an assumption would lead to highly inaccurate conclusions.

PLANT STUDIES

After the development of the improved evolution apparatus for the determination of carbonate, permission was obtained to carry out a series of tests on one of the 125-lb. pressure W-type Stirling boilers in the Congress Street heating plant of The Detroit Edison Company. This boiler was conditioned with sodium carbonate for the prevention of scale. The make-up was about 70 per cent, and Detroit city water was used as the feedwater. As a result of the rapid hydrolysis of carbonate in the boiler water, it contained a low concentration of CO_3 and a relatively high concentration of OH.

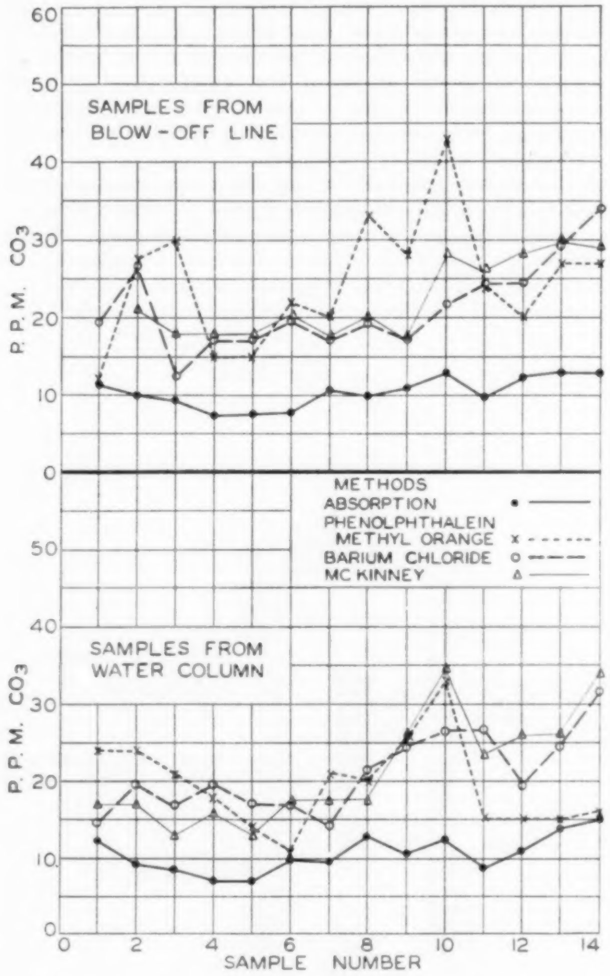

Fig. 3 Carbonate Found in Boiler by Four Methods

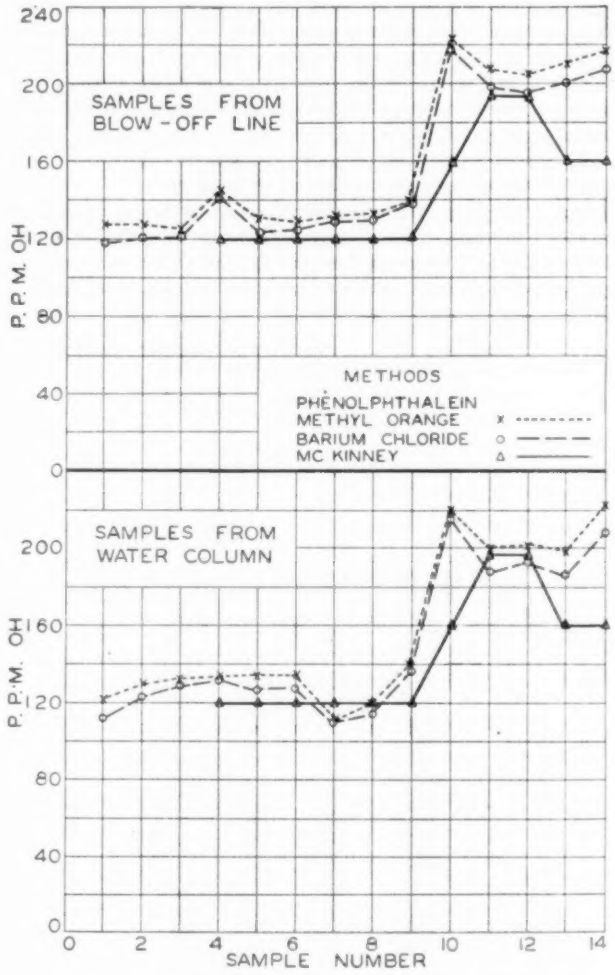

Fig. 4 Hydroxide Found in Boiler by Three Methods

The results of the tests indicate the great need for extreme care in sampling boilers, and they also indicate some of the inaccuracies in the various methods of analysis investigated.

The samples of boiler water in the plant studies were obtained by using the copper-screen type of filter, as shown in Fig. 2. In this device the sample runs through several layers of fine-mesh copper screen. The suspended particles in the boiler water are trapped between the layers and form their own filter medium. This system is fundamentally correct as long as the character of the solid phase in the boiler does not vary. This filter was inserted in the sampling line between the boiler and the cooling coil.

Comparison of Values Obtained for Carbonate and Hydroxide in the Plant Studies

Fourteen sets of boiler-water samples were taken during three successive days for a comparison of various methods for determining carbonate and hydroxide. Each set consisted of two samples, one from the mud drum and one from the steam drum. All of these samples were filtered at boiler temperature and pressure through filters such as have been described, and were not filtered in the laboratory. All samples were analyzed immediately.

Values for carbonate were determined by four different methods: first, the direct-absorption method, using the improved or simplified apparatus described in this report; second, the Winkler barium-chloride method; third, the titration with phenolphthalein and methyl orange; and fourth, the abridged equilibrium calculations of McKinney (6), based on the amount of acid required to titrate the sample between pH values of 8.5 and 5.0. The titration with phenolphthalein and methyl orange was made in flask *D* of the absorption apparatus shown in Fig. 1, prior to evolving the carbon dioxide.

The values for carbonate calculated from the results of the four methods of analysis are shown in Fig. 3. Great reliance is placed on the accuracy of the values obtained by the absorption method, which vary above and below an average value of 10 p.p.m. CO_3. The values indicated by all three of the other methods are high, deviating with no apparent consistency by amounts ranging from a few per cent up to 300 per cent. The results from the barium-chloride titration are only slightly better than those from the titration with phenolphthalein and methyl orange. McKinney's method is subject to the same difficulties encountered with the other titration methods when the end points at pH 8.5 and 5.0 are determined colorimetrically.

If it is granted that the accuracy of the absorption method is established by the tests on solutions of known composition which have been shown, it is evident that none of the other methods for carbonate investigated during the plant tests was sufficiently precise for the purpose of boiler-water control.

Values for hydroxide were calculated for the 14 sets of samples in three ways: (1) from the barium-chloride titrations; (2) from the phenolphthalein-methyl orange titrations; and (3) from the pH of the original sample, using the conveniently tabulated values of McKinney (6), for the activity of hydroxyl ion at different pH values. The activity coefficients necessary to convert the activities into concentrations were estimated as 0.89 for the samples through number 9 and 0.85 for the subsequent samples.[7]

The values for hydroxide obtained by the three methods of calculation are shown in Fig. 4. It is seen that the two titration methods agree fairly well, the barium-chloride method yielding values consistently somewhat lower than those indicated by the titration where phenolphthalein and methyl orange were used as indicators. The hydroxide concentrations calculated from pH measurements fall still lower, with considerable deviation in the case of a few samples. Since the three concentration levels on the curve (Fig. 4) representing the results obtained using this method represent pH values of 11.8, 11.9, and 12.0, respectively, it is obvious that a slight uncertainty or error of judgment in placing the pH of samples 10, 13, and 14 at 11.9 instead of 12.0 might have been responsible for the larger deviations in the case of these samples. An error of 0.1 in the estimation of pH by comparison with standards at intervals of 0.2 is quite possible with either of the sets of standards used.[8]

While the method of calculating hydroxide concentrations from pH values proposed by McKinney for boiler-water control is theoretically sound, its rigorous application necessitates a complete analysis of the water and a determination of pH by some more accurate means than is afforded by ordinary colorimetric methods. If, as in the case of the present tests, the composition of the water is estimated from incomplete data and pH is determined colorimetrically, the values may vary in rather large jumps which will increase in size as the hydroxide concentration and hence the pH increases. On the other hand, it was shown in the first part of this paper that both the phenolphthalein-methyl orange and the barium-chloride titrations yielded results which were within 10 per cent of the true value for hydroxide in solutions of known composition. Even this accuracy is better than might be expected from the calculation of the hydroxide from the pH of the sample if the pH determination is made colorimetrically.

DETERMINATION OF HYDROXIDE

Although it has been shown in the investigation of the method for determining carbonates that both the barium-chloride method and the titration using phenolphthalein and methyl orange as indicators yielded results of fair accuracy, it was felt that further study might increase that accuracy and at the same time answer some questions regarding the effect of interfering ions.

This investigation then may be divided into two parts: (1) that in which an attempt was made to use a precipitating agent to remove the interfering ions before making the titration, and (2) that in which direct titration was made.

USE OF A PRECIPITATING AGENT

The ions present in boiler waters which generally interfere with the direct titration of the hydroxide are CO_3 and PO_4. In attempting a titration of the hydroxide alone these ions should be removed from the field of action. This may be accomplished most readily by precipitation.

The carbonate, as in the Winkler method, may be precipitated as barium carbonate. The use of barium for the precipitation of carbonate in boiler-water samples has two very serious objections. First, since barium carbonate is more soluble than barium sulphate it is necessary to precipitate all of the sulphate before any of the carbonate will come down. Boiler-water samples are usually extremely high in concentration of sulphate as compared to that of the carbonate, so that such treatment results in a high degree of turbidity in the sample, which might be avoided by the selection of another precipitating agent. This makes the determination of the end point exceedingly difficult, and jeopardizes the accuracy of the titration even if the color change of the indicator used in the determination of the end point is absolutely accurate. The second objection is the great tendency of both barium carbonate and sulphate to occlude or adsorb many salts from solution. In the case of the carbonate this occlusion or adsorption would not be serious since the amount of barium carbonate present is extremely small. In the case of the sulphate, however, the seriousness of occlusion or adsorption becomes much greater. Such occlusion or adsorption of the hydroxide would result in a low indicated value for the hydroxide and a high value for the carbonate. This error may be responsible to some considerable extent for the high carbonates shown by the Winkler method.

Since strontium salts are in general very similar to barium salts the use of strontium chloride as a precipitating agent was tried. Strontium carbonate comes down in a very crystalline form and has little tendency to occlude or adsorb other salts that may be present in the solution. Strontium sulphate is much more soluble than the carbonate so that by proper adjustment of the concentration of the strontium ion in the solution it should be possible to precipitate all of the carbonate without precipitating any material amount of the sulphate. This would result in a solution for titration in which there was very little suspended matter, making the observation of the end point easy and accurate, and remove the possibility of any serious error from occlusion or adsorption.

TABLE 6 RESULTS OF THE STRONTIUM CHLORIDE METHOD FOR THE DETERMINATION OF HYDROXIDE

33	2000	44	268	267
40	4000	17	403	403
46	4000	350	403	402

A large number of samples containing hydroxide, carbonate, and sulphate were treated with strontium chloride and the hydroxide determined by titration to the phenolphthalein end point with standard acid. A few of the results are shown in Table 6. The accuracy as is shown is extremely high. These samples are representative of all of the determinations made. In no case did any error occur which was greater than 1 per cent.

The method of treating the sample for these determinations was somewhat different from that used in the case of the Winkler method. In the first place, the amount of strontium chloride added should not be greatly in excess of that needed for the precipitation of the carbonate. After the addition of the strontium chloride the sample is heated to boiling, allowed to stand for a few minutes to permit the precipitation of the carbonate, and then cooled and titrated. These differences in treatment arise mainly from the fact that it is not advisable to use a large excess of the strontium chloride in precipitation.

---

[7] While a complete analysis of the boiler water was not made during the present tests, it was possible to estimate $\Sigma c\nu^2$ rather closely from the determined values for CO_3, OH, and SO_4 by assuming concentrations of Na, Cl, Ca, and Mg in line with those shown in previous complete analyses of the water. Since the feedwater is quite constant in composition, the error in determining $\Sigma c\nu^2$ in this manner is probably less than that in the colorimetric determination of pH or the application of the Debye-Hückel equation to the calculation of the activity coefficient.

[8] Both Hellige-Klett permanent glass standards and LaMotte solution standards were employed in this work.

Due to the fact that the determination of hydroxide by this method gave such extremely accurate results some further investigation of the determination of carbonate by the use of strontium chloride was carried out. In order to make use of this method for the determination of carbonate as well as hydroxide, it was necessary, of course, to combine the titration of the sample from which the carbonate had been precipitated with a second titration which would determine the hydroxide plus some fraction of the total carbonate. Such a determination might be made by titrating the sample directly to some definite pH value, but in general this did not seem to offer great possibilities since the titration would be carried out in the presence of carbonates which act to some extent as buffer salts. The result would be an end point which might not be extremely sharp. In order to remedy this difficulty of sliding end points, the addition of an excess amount of acid, boiling off the carbon dioxide, and back titration was resorted to. The actual details of the titration need not be considered here, but the results for the determination of carbonate were a great deal more accurate than those shown by either the method using phenolphthalein and methyl orange as indicators in the titration or the Winkler method. For a method involving direct titration of the sample the results at low carbonate values were extremely good, although not quite as accurate as the absorption or evolution method.

Due to the fact that the determination of carbonate by this method would be susceptible to error from various impurities in the sample, as are all of the direct titration methods, and to the fact that it is not a great deal shorter than the evolution method, its use cannot be recommended for routine control work; at least not without checking against the evolution method. Its most promising field of use seems to lie in the determination of hydroxide alone or for the determination of hydroxide and carbonate where the equipment to carry out an evolution determination is not available.

The samples so far investigated using strontium chloride as a precipitating agent have contained, besides the hydroxide, only carbonate and sulphate. Since strontium phosphate as well as the carbonate is quite insoluble, it would seem that the addition of strontium chloride to a sample would remove the phosphate from solution as well as the carbonate.

A series of hydroxide determinations was made on solutions containing sulphate, phosphate, carbonate, and hydroxide. The results indicate that errors no greater than 2 per cent were obtained. The method is not quite as accurate as in the presence of the carbonate alone.

The actual precipitation of the carbonate and phosphate is carried out exactly as described for the carbonate alone. After the sample is cooled it cannot be titrated very well to the phenolphthalein end point since strontium phosphate is appreciably soluble in a solution whose pH is about 8. This solubility causes a fading end point. In order to correct this the sample was titrated to the end point of LaMotte Purple, which has a pH range of from 9.6 to 11.2.

It may be noted here that in precipitating strontium phosphate from solution there is more danger of occlusion or adsorption of the hydroxide than in the precipitation of the carbonate alone. The strontium phosphate may under certain conditions come down as a basic salt. This in general would not be serious in boiler-water samples since the concentration of phosphate is extremely low. In the present investigation no appreciable error was found although phosphate concentrations up to 100 p.p.m. of PO_4 were investigated.

The use of strontium chloride makes it possible to determine the hydroxide content of a boiler-water sample directly in the presence of both phosphate and carbonate. It is not necessary to know the concentration of either of these interfering ions.

Titration to the Phenolphthalein End Point

In spite of the fact that by the use of strontium chloride a satisfactory determination of the hydroxide could be secured, it was felt that the method was exceedingly cumbersome for use in regular plant practice. Other precipitating agents might be used, but in general it will be found that practically all of them introduce difficulties characteristic of the particular ion used.

Electrometric titration curves for both carbonate and phosphate show a fairly rapid change in pH with each addition of acid or alkali to the sample at a pH of 8 or 9. This rapid change, as well as the low concentrations of phosphate and carbonate generally present in boiler-water samples, makes it seem possible that a fairly accurate determination of hydroxide concentration could be obtained by titrating to the end point of phenolphthalein alone since this indicator becomes colorless at about the desired pH. When such a titration to one end point is used it is necessary to know the concentrations of phosphate and carbonate, and to apply a correction to the value obtained in the titration in order to obtain the hydroxide concentration.

21	4000	80	94	274	317	41.0	276

The results for a series of samples containing known concentrations of hydroxide, carbonate, phosphate, and sulphate, which were titrated in this manner, are shown in Table 7. The accuracy is extremely good. No difficulty was experienced in these titrations with sliding end points. The apparent hydroxide concentration was calculated directly from the total acid used to the phenolphthalein end point. The deduction or correction was calculated from the known concentration of carbonate and phosphate.

In the case of a boiler water which is treated with sodium carbonate, the pH of the sample will be above 11 and the total carbonate content of the sample may be assumed to be present as CO_3 and the correction may be calculated on this basis. Each 10 p.p.m. of CO_3 calls for a correction of only 2.83 p.p.m. of OH. In the case of the phosphate it cannot ordinarily be assumed that it is all present as PO_4. By a rough determination of the pH, however, the fraction that is present in the form of PO_4 may be determined from the curves compiled by McKinney (6). Ten parts per million of PO_4 calls for a correction of 1.79 p.p.m. on the OH concentration.

Since, as will be noticed, the corrections on the hydroxide concentrations are rather small when compared to the concentrations of the ions causing this correction, small errors in the determination of the carbonate and phosphate will not create any large error in the indicated hydroxide concentration. This is, of course, merely due to the fact that the equivalents of phosphate and carbonate present in a boiler water are usually extremely low as compared to the equivalents of hydroxide present. For the same reason it will not be necessary to know the pH of the sample with an accuracy greater than 0.7 to find the fraction of phosphate that is present as PO_4.

This titration to the phenolphthalein end point for the determination of hydroxide requires that the sample be free from the presence of any considerable amount of either silicates or aluminates. These salts will interfere in practically all direct titrations, and it is necessary to take special steps to remove them or correct for their presence. It might be noted here that the use of strontium chloride offers some possibilities in the removal of silicate since strontium silicate is quite insoluble. Barium cannot be used for this purpose as its silicate is fairly soluble. The removal of silicates by precipitation with strontium chloride will be investigated further, however, in order to determine the possibility of the use of this precipitating agent in the determination of the hydroxide concentration in boiler water.

DETERMINATION OF PHOSPHATE

The phosphate determination like the carbonate has been the subject of much discussion and work in various fields of pure and applied chemistry. Several distinct and different methods have been developed for the determination of phosphate in its various forms, and an almost endless discussion of details, modifications, and revisions of each of the methods has been given.

Methods for the determination of phosphate are found which may be classified as gravimetric, volumetric, colorimetric, or nephelometric, or combinations of these classes. The gravimetric determination or a gravimetric separation combined with a volumetric determination, and purely colorimetric determinations are most generally used in the determination of basic phosphates.

In boiler-water chemistry the purely gravimetric determination with its necessity for accurate weighing is out of the question for routine work even if the method were rapid and simple, which it is not. The purely gravimetric determination has been modified to a gravimetric separation of the phosphate and a volumetric determination of the amount of the phosphate salt so separated. This does away with the necessity of weighing, but the time required for such a determination puts it way beyond the bounds of any possible use for routine determination of phosphates in boiler waters in its present form. Even if the method were rapid, a great number of difficulties surround the separation of the phosphate as ammoniumphosphomolybdate, the form in which it is separated in the gravimetric method. It is difficult to secure a precipitate which contains all of the phosphate and which is not contaminated by impurities. The acidity of the sample, the concentration of all the salts present, the concentrations of reacting substances, the temperature, and the time allowed for precipitation must be very carefully controlled to secure an accurate determination. Even with all these precautions, however, the ideal composition of the precipitate, as represented by the formula, is seldom realized and a correction is applied. The difficulties of the gravimetric separation are so manifold that some investigators (5) after extensive work with the method have stated that it is simply a method of balancing errors.

A method which is essentially gravimetric and which has been used in boiler-water chemistry involves the precipitation of the phosphate and a rough measurement of the volume of the precipitate as a means of estimating the amount of phosphate present. The measurement of the precipitate is often carried out by simply allowing it to settle in a tube and noting the height of the settled precipitate. This modification obviously sacrifices much of the accuracy of the determination in order to make it rapid. The accuracy of the measurement of the precipitate might be increased by the use of the centrifuge, but such a method would be rather complex for use in routine work. Any increase in accuracy of measurement of the precipitate would not remove the difficulties inherent in the original precipitation, and would still leave the determination open to considerable error from this source. These errors might become very serious in control work where the tendency toward quick determinations and slighting of all the precautions necessary to secure accurate determination is always present.

As the phosphate concentrations in boiler water seldom run as high as 100 p.p.m. of PO_4 it would seem that some of the colorimetric methods might be used for this determination. The low concentration ranges are those which are generally best adapted for colorimetric determination.

Phosphate concentrations in boiler samples are often determined colorimetrically, using hydroquinone (2) as the reducing agent to develop the color. This method works with entire satisfaction in some samples. It has two disadvantages, however: first, the color development with hydroquinone is rather slow, and, second, the presence of silicates in the solution interferes with the determination. In searching for a means of overcoming these difficulties aminonaphtholsulphonic acid was substituted for hydroquinone. The results were exceedingly satisfactory.

USE OF AMINONAPHTHOLSULPHONIC ACID IN THE DETERMINATION OF PHOSPHATE

The hydroquinone method, as well as the use of 1, 2, 4-aminonaphtholsulphonic acid in the determination of phosphate, was originally worked out and used in the field of biological chemistry. The originators of the method using the amino acid were primarily interested in finding a reagent that developed its color more rapidly than hydroquinone (4). They also noted that the color development of this acid is not interfered with by low concentrations of silicates. The application of this method to boiler-water analysis did not involve any radical departure from the method used in the biological field.

The details of the method will not be considered here, but a general outline which will serve to indicate its simplicity and rapidity will be given. The boiler-water sample is treated first with a solution of ammonium molybdate and then with an aminonaphtholsulphonic acid in a sodium-bisulphite, sodium-sulphite solution. After the addition of these reagents the sample is allowed to stand about 5 min. and then is compared in a colorimeter with a standard solution containing a known amount of phosphate, and which was treated with the same reagents as the boiler-water sample. This comparison gives the amount of phosphate directly. The whole determination, from the time the boiler-water sample is measured out to the time the phosphate concentration is known, requires about 10 min.

One of the disadvantages of the amino-acid method, when this method was first used, arose from the fact that the aminonaphtholsulphonic acid had to be carefully purified before it could be used. The Eastman Kodak Company now manufactures a purified grade of the amino acid, which has been compared with the acid purified in the laboratory and has been found to be entirely satisfactory.

RESULTS OF THE AMINO-ACID METHOD FOR THE DETERMINATION OF PHOSPHATES

A very large number of determinations of phosphate have been made by the amino-acid method on solutions containing known concentrations of phosphate, carbonate, hydroxide, sulphate, chloride, and silicate. The results of a few of these determinations are shown in Table 8. In practically all cases the error is less than 0.3 p.p.m. of PO_4. None of the ions which were introduced into the sample caused any appreciable error.

It should be noted that all of the results shown were secured by comparison of the solutions in a colorimeter. A Bausch & Lomb Duboscq type was used. Some investigation of the

TABLE 8 RESULTS OF THE ANALYSIS OF SOLUTIONS OF KNOWN PHOSPHATE CONCENTRATION

Sample number	Known conc. p.p.m. PO_4	Conc. found p.p.m. PO_4

36	40.0	40.1

phosphate determination by the amino-acid method in which the solutions are compared in comparison tubes is to be carried out. This modification of the method is certainly not to be recommended for referee work. It must be recognized that the results of such comparisons will not be as good as those secured in the colorimeter.

A good colorimeter is, of course, rather expensive, but for routine control work where a large number of determinations are run and where much time and effort are spent in making these determinations it would seem that the use of poor equipment, which jeopardizes the accuracy of all of the determinations, could not be justified.

One of the chief advantages resulting both from the use of the amino-acid method, which develops its color rapidly, and from the use of a colorimeter is the fact that the intensity of the color of the sample will not remain constant if there are any ions present in the solution which are interfering with the color development. This materially cuts down the danger of whole series of determinations being in error due to the presence of some unknown ions in the solution which interfere with the determination. If such ions are present the method warns the operator by the fact that the intensity of color continues to change. The use of color tubes would make the possibilities of the detection of such errors very slight since the eye is not sensitive enough to detect small differences in intensity unaided.

Conclusions

In concluding this report it is the desire of Subcommittee No. 8 of the Boiler-Feedwater Studies Committee to again call attention to the fact that the aim has been to present herein data as briefly as possible and yet of a sufficiently convincing nature that it will be clear that, first, exhaustive comparisons have been made of the known methods for the determination of carbonates in boiler water, second, that the studies so far carried out have pointed out the characteristics of the commonly used methods for hydroxides, and have indicated the course of further study pertaining to the determination of this ion and such other ions as are known to influence its apparent concentration and the method of test, and, third, that three methods for the determination of the phosphate ion have been considered.

From the considerations presented it is possible to summarize the essential facts as follows:

1 It is apparent that, no matter what analytical methods are used, a representative sample must be secured or the results will be meaningless. A satisfactory way to accomplish this, in the case of obtaining samples from an operating boiler, is to filter the sample at boiler temperature and pressure and cool it at boiler pressure before it is passed into the sampling bottle.

2 The determination of carbonate by either of the standard methods, the A.P.H.A. or the Winkler method, does not give accurate results in solutions containing low concentrations of carbonate and high concentrations of hydroxide. An evolution method for the determination of carbonate has been worked out which will give accurate results, and which can be used in routine control work as well as for referee work. The accuracy of this method is not affected by any ions which are encountered in boiler waters.

3 The hydroxide concentration of a sample may be determined by precipitation of the interfering ions, phosphate and carbonate with strontium chloride, and direct titration of the hydroxide; or if the concentrations of both phosphate and carbonate are known it may be determined by titration to the phenolphthalein end point alone. These methods will give results more accurate than those obtained by either the A.P.H.A. or the Winkler method, and can be considered as suitable for referee work.

4 By the use of aminonaphtholsulphonic-acid method for the determination of phosphate and a colorimeter, an accuracy of 0.3 p.p.m. of PO_4 may be secured on samples containing less than 40 p.p.m. of PO_4. On samples containing up to 80 p.p.m. the error should not be more than twice this value. The determination is extremely rapid and simple. It is not interfered with by any of the ions commonly found in boiler waters. This method can be considered as suitable for referee work as well as plant control work.

It is the hope of the subcommittee that many will try these methods, if possible in comparison with the more commonly used procedures for testing, and submit their comments to the chairman.

Discussion

Joseph D. Yoder.[9] The equipment described for determining the carbonate alkalinity by the evolution and absorption of CO_2 is ingenious. Where exceedingly accurate determinations are to be made as required for determining chemical equilibria with varying amounts of carbonate and sulphate radicals in the presence of calcium, it is evident from the data submitted that neither the A.P.H.A. nor Winkler methods would be sufficiently accurate. It is interesting to note that the A.P.H.A. method, Table 1, was found consistently more accurate than the Winkler method, Table 2.

From the standpoint of protecting boilers from scale, of either the sulphate, carbonate, or silicate variety, the writer has not found the refinements described in this report to be necessary. Granting that when carrying exceedingly low carbonate alkalinity in the boiler water the A.P.H.A. and Winkler tests give relatively large inaccuracies, it is noticeable that if the carbonate alkalinities in the boiler water are in the range that showed large percentage errors (Table 1), as substantially less than 30 p.p.m. CO_3, the alkalinity is too low to generally prevent calcium silicate and carbonate scales. When the carbonate alkalinity is carried high enough to prevent the calcium-carbonate-silicate scales, the percentage errors reported when making the determinations with methyl orange as an indicator are not sufficient to cause any serious difficulty.

---

[9] Cochrane Corporation, Philadelphia, Pa. Mem. A.S.M.E.

If a minimum concentration of 30 to 50 p.p.m. of PO_4 radicals is maintained within the boiler, it is then possible to prevent the formation of scale with the lowest carbonate alkalinities reported in Table 1; but when a suitable concentration of phosphate radicals is maintained, it is of little or no value to make exacting determinations of the carbonate radicals present. It is possibly for these reasons that the writer has never observed a need for greater accuracy than the methyl-orange indicator for determining the proper alkalinity of boiler water in the absence of interfering organic matter. If, as a result of some particular contamination of the feedwater, there is interfering organic matter present, then the Winkler method would seem to fulfil all practical requirements.

The advantage of the method proposed for determining carbonate alkalinity therefore seems applicable to a study of the theory of scale formation rather than to actual practice in the protection of boilers from scale.

Authors' Closure

Before considering directly the discussion submitted by Mr. Yoder, it will be well to reiterate briefly the object of the present report. Its primary purpose is to place before the Boiler-Feedwater Studies Committee and those members of the A.S.M.E. who are interested such data as have been secured concerning the relative accuracy of certain procedures for the analysis of boiler waters. The recommendations in this report are those of the authors and are not those of Subcommittee Number 8. It is hoped that the results of this investigation will lead to methods which may be recommended by the subcommittee as standard, but the present progress report does not attempt to do this.

In the case of the determination of carbonate, the laboratory investigations indicated that in certain ranges of concentration either the phenolphthalein-methyl orange method or the Winkler method gave very inaccurate results. Since these laboratory samples were made up of distilled water and contained no unknown impurities, it would be expected that even larger errors than found in the laboratory samples might occur in boiler-water samples which may be quite highly contaminated. In a boiler water containing appreciable concentrations of such ions as aluminate or silicate, the usual interpretation of the titrations for alkalinity in terms of OH and CO_3 would give a highly inaccurate idea of actual boiler-water conditions.

It has been found in work with an experimental boiler at the university that both the phenolphthalein-methyl orange and the Winkler methods can show inaccurate results for carbonate in the range in which they might be expected to be accurate. In one particular series of samples these methods showed carbonates from 60 to 80 parts per million of CO_3 when the concentration found by the evolution method was from 9 to 12 p.p.m. This points to the necessity of checking the phenolphthalein-methyl orange method or Winkler method from low to fairly high concentrations or carbonate.

The discussion has noted the fact that the phenolphthalein-methyl orange method is seriously interfered with by some kinds of organic matter, but goes on to state further that the modified Winkler method might not be subject to errors from this source. The assumption that the modified Winkler is the all-magical method which removes most of the errors in the analysis of boiler-water samples for carbonate seems to be very general. While it is true that it would not be expected to be as susceptible to error from buffer salts (which may be organic salts) as is the phenolphthalein-methyl orange method, it is certainly a long way from being free from error from this source. This is clear if it is remembered that, with these buffer salts present, it may require the addition of a large amount of acid to change the pH value even slightly. Practically this may result in very indefinite end points, and if the carbonate is calculated in the usual way for the Winkler method, the resulting values may be quite meaningless. All titration methods for the determination of carbonate, depending on measurements of the pH of the original sample for the end points, either electrometrically or by means of indicators, are open to this objection. This is one of the reasons that makes the authors believe that the evolution method for carbonate will be found more satisfactory in many cases.

The statement was also made in the discussion that "the A.P.H.A. method, Table 1, was found consistently more accurate than the Winkler method, Table 2." The authors would like to correct this statement; the Winkler method may be quite accurate in the case of samples free from sulphate, as seen in Table 2 under reference numbers 7 and 19, analyzed by procedure (3). The Winkler method of titration is inaccurate in the presence of sulphate.

If a boiler water is conditioned with phosphate, there is really little necessity for determination of its carbonate content. Determination of the CO_3 is, however, necessary as a control when soda ash is being used as a conditioning chemical for scale prevention. When a boiler is fed with a naturally alkaline or zeolite-softened water, an accurate knowledge of the CO_3 concentration may also be important from the standpoint of embrittlement prevention.

Hydrolysis of carbonate in a boiler water proceeds rapidly. When a boiler is conditioned with soda ash, this results in low carbonate concentrations and high hydroxide concentrations. The attempt to add an excess of carbonate in order to prevent scale may result in hydroxide concentrations sufficiently high to cause danger from embrittlement. The result will be that a balance will have to be struck between the amount of carbonate which must be present to prevent scale and the maximum amount which can be fed without causing danger from embrittlement. In this case the necessity of controlling the carbonate is apparent, and since in general it must be low, it would seem that the evolution method would best satisfy the requirements.

The plant studies described in the report were made on a boiler water nearly free from organic or inorganic constituents which would affect the alkalinity titrations. Nevertheless, Fig. 3, showing the results of these plant tests, indicates that both the phenolphthalein-methyl orange and the Winkler methods gave values for CO_3 which were consistently about 100 per cent too high, and at times 300 to 400 per cent too high as compared with the results for the evolution method. An error of 100 to almost 400 per cent is certainly not negligible. In fact, the authors are tempted to believe that if one evolution analysis were made on a sample of this boiler water, the carbonate could be guessed from then on, with considerably more accuracy than would be secured by titration using either the phenolphthalein-methyl orange or the Winkler method. Since the evolution method has shown itself accurate in every case in which it was tested, and since by the very nature of the method it is not susceptible to interference by such ions as might exist in boiler-water samples, the difference between the results obtained by the use of the evolution method and those obtained by the use of the other two methods examined must be ascribed to inaccuracies in these other two methods.

It may of course be contended that the particular boiler from which these data were secured contained low carbonates, and that in this range the ordinary methods of analysis show comparatively large errors, whereas if the concentrations become higher, the comparative errors are smaller. This is true, but in how many actual boilers does the true CO_3 concentration exceed 30 p.p.m.? Mr. Yoder speaks from a wide experience in the practical control of boiler waters, but this experience has been based upon methods of analysis which are now known to give consistently high values for CO_3.

The point that Mr. Yoder strives to make is that refined methods of analysis are all very well for the research laboratory, but that the practical engineer has no need for them. The trend of engineering development is, however, always in the direction of more accurate control. The engineer must base his conclusions upon data, and his conclusions can rarely be more sound than the data from which they are derived. For example, Mr. Yoder states that if the carbonate alkalinities in the boiler water are substantially less than 30 p.p.m. CO_3, "the alkalinity is too low to generally prevent calcium silicate and carbonate scales." Is it not probable that this conclusion is based upon numberless analyses by the standard titration methods, and that these analyses, even though made with scrupulous care, were inaccurate by from one hundred to several hundred per cent?

The discussion as to whether 30 p.p.m. of carbonate is too low to prevent calcium carbonate and calcium silicate scale is perhaps beside the point in a report which attempts to deal with analytical methods, yet with the few data available and a large share of these based on analytical methods which may be very greatly in error, it would seem that the establishment of this figure at any particular value would be rather premature. This problem would no doubt be worth considerable investigation, and it is hoped that when such an investigation is undertaken care will be exercised to use accurate analytical methods.

Tungsten-Carbide and Other Hard Cutting Materials

Progress Report No. 3 of the Sub-Committee on Metal-Cutting Materials[1] of the A.S.M.E. Special Research Committee on the Cutting of Metals

By COLEMAN SELLERS, 3d,[2] PHILADELPHIA, PA.

Shortly after this sub-committee's Progress Report No. 2 in June, 1930, the activities were broadened to include not only tungsten-carbide but other hard cutting materials. In April, 1931, a second questionnaire was sent out to the leading manufacturing establishments of the country, with a letter asking all that had had experience with tungsten- and tantalum-carbide or other new alloys to answer the questions as far as possible. It was thought that the information thus obtained might help to determine the present status of the use of these materials and perhaps lead to the enlightenment of some as to their possibilities and limitations.

This questionnaire was sent out thirteen months after the first one. It is interesting to note that the answers show that considerable progress has been made, not only in the number of users, but in that many of those that had been using a little have found it worth while to extend the use. Furthermore, much has been learned in the methods of use.

Over 100 replies were received, of which 85 gave the information on which this report is based, and 2 more answered the first question only. The remainder of the letters stated they did not use the materials or did not feel they had had sufficient experience to be able to give reliable information. The first questionnaire brought in 75 replies, of which 50 could be used in the report. This increase of 70 per cent is very gratifying, particularly since many firms have discontinued all experimental work on account of the condition of business.

The questionnaire is divided into two parts; the first deals with general questions, and the second asks for information on typical applications. This report covers a digest of the first part, including the comments of some of the users. The second part cannot be handled in the same manner, but some of the important points are mentioned, and a few of the more complete applications are given in tabular form.

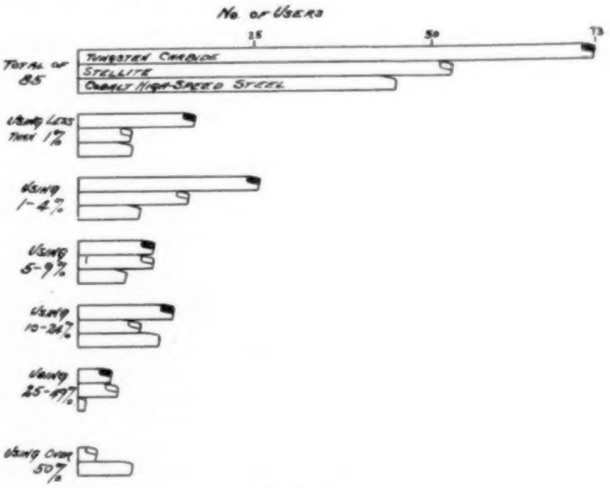

Fig. 1 Relative Use of Tungsten Carbide, Stellite, and Cobalt High-Speed Steel

A copy of the questionnaire, with the letter that accompanied it, is attached to this report.

1 Extent of Application

There were 73 firms that used tungsten-carbide tools. The percentages varied all the way up to 48 per cent, but only 20 used over 5 per cent.

Cobalt high-speed steel was not used by as many, but those that did, used a higher percentage. The figure was 45 users, and 22 used over 5 per cent. The maximum percentage used was 85, and 8 used more than 50 per cent.

Only 7 reported the use of tantalum carbide; 2 used 3 per cent, 1 less than 1 per cent, and 4 were experimenting with this material.

Stellite was used by 53, of which 32 used 5 per cent or under.

---

[1] The personnel of this sub-committee is as follows:

F. C. Spencer, *Chairman*, Assistant Superintendent of Manufacturing Development, Western Electric Company, Kearny, N. J.

Coleman Sellers, 3d, *Secretary*, Executive Engineer, William Sellers & Co., Inc., Philadelphia, Pa.

G. H. Ashman, General Superintendent's Department, General Electric Company, Schenectady, N. Y.

A. H. Bainton, Works Manager, Brown & Sharpe Mfg. Co., Providence, R. I.

O. W. Boston, Professor, Department of Engineering Research, University of Michigan, Ann Arbor, Mich.

T. G. Digges, Associate Metallurgist, U. S. Bureau of Standards, Washington, D. C.

M. Judkins, Firth-Sterling Steel Company, McKeesport, Pa.

R. D. Prosser, General Manager, Widia Department, Thomas Prosser & Son, New York, N. Y.

F. C. Ritner, Assistant Sales Manager, Carboloy Company, Detroit, Mich.

C. M. Thompson, Jr., in charge of engineering and manufacturing of Carboloy equipment, Henry Disston & Sons, Inc., Philadelphia, Pa.

W. A. Wissler, Union Carbide & Carbon Research Laboratory, Inc., Long Island City, N. Y.

[2] Executive Engineer, William Sellers & Co., Inc. Mem. A.S.M.E. Mr. Sellers was graduated from the University of Pennsylvania, Mechanical Engineering Department, in 1915, and entered the shops of William Sellers & Co., Inc., immediately thereafter. He worked in various parts of the shop and finally became foreman of a fitter gang. After two years he became associated with the Midvale Steel Company, in charge of repairs to machine tools in all eight machine shops. On Jan. 1, 1919, he returned to William Sellers & Co. as assistant superintendent, and has been there since, his present position being executive engineer in charge of the engineering and production departments.

Contributed by the Sub-Committee on Metal-Cutting Materials of the A.S.M.E. Special Research Committee on the Cutting of Metals and presented at the Machine Shop Practice Session at the Annual Meeting, New York, N. Y., Nov. 30 to Dec. 4, 1931, of The American Society of Mechanical Engineers.

The maximum percentage used was 81, and this was the only firm reporting the use of over 50 per cent.

The diamond as a cutting tool was not popular, but 9 reported its use—3 at 2 per cent, 3 at 1 per cent, and 3 at less than 1 per cent.

The chart in Fig. 1 was made up to show the relative use of cobalt high-speed steel, tungsten carbide, and stellite among the firms which answered the questionnaire. The chart has no particular value, but is interesting as it is based on information given by a number of the leading machine shops of the country.

2 Types of Operations Found Successful With Tungsten or Tantalum Carbide

There are 80 that report turning, 62 report boring, 11 planing, 14 milling, 6 drilling, 1 sawing, and 1 shaping slots.

At the time of the last questionnaire there were practically nothing but lathe and planer tools. Evidently milling cutters, saws, and drills are now coming into use.

3 Types of Material on Which Tungsten Carbide Is Used Successfully

The replies to this question show a wide variety of materials. There were 69 that found success on cast iron, 46 on bronze, 23 on aluminum alloys, 14 on soft steel, and 12 on hard steel. Fig. 2 shows these figures in chart form. Among the other materials were malleable iron, vanadium iron, babbitt, forged brass, experimental bearing metal, nickel silver, 50-per cent semi-steel, phenol plastic, asbestos, bakelite, hard rubber, resinous products, hardwoods, stellite, high-speed steel, stainless steel, 18-8 nickel alloy, and heat-resisting alloys.

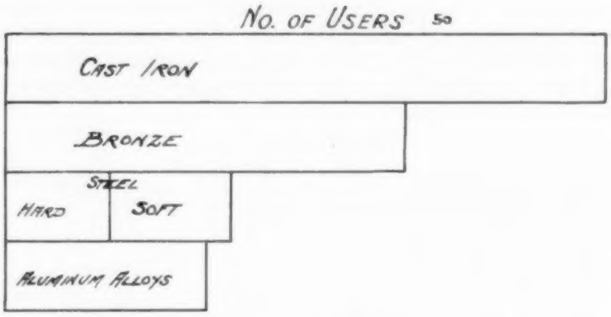

Fig. 2 Relative Successful Use of Tungsten Carbide on Different Materials

4 Types of Material on Which Tantalum Carbide Is Used Successfully

Not many replied to this question, and it is evident that the use of tantalum carbide is not widespread. There were 14 that reported success on steel (8 of these on soft steel and 5 on hard), 4 reported success on bronze, 3 on aluminum alloys, 5 on cast iron, and 1 on stellite; 4 others reported carrying on experiments, and 2 reported no success.

5 Grinding of Hard Cutting Material Tools

(*a*) As to the type of machine, 54 reported they used a pedestal grinder and the tool is held by hand; 15 of these used no other method. There were 28 that used a pedestal grinder with the tool clamped on angle-setting slide, 45 used a universal tool grinder, 30 used a surface grinder, 17 used a face-mill grinder, and 1 used a drill grinder.

Evidently there is no uniformity in the method used in grinding. However, it is apparent that the importance of machine grinding is being realized, and the methods have improved since the time of the sub-committee's first report, when only 13 shops reported machine-ground tools.

(*b*) In answer to the question as to who ground the tools, 41 reported tools ground by machine operator, 21 by tool crib attendant, 35 by grinding-machine operator, and 28 by a specialist. In 9 cases the grinding-machine operator was the specialist. Several replied that the machine operator ground high-speed tools and the tungsten-carbide tools were ground by the grinding-machine operator. In one case the machine-tool operator ground all but the form tools.

It is interesting to note that of the 30 firms using 5 per cent or more tungsten carbide, only 4 reported tools ground only by machine-tool operator, and 1 of these was in tool crib. In other words, where they have had sufficient success to warrant the purchase of a number of tools, they realize the importance of careful grinding.

(*c*) As to the place where the tools are ground, 44 reported the tools were ground in the maintenance tool room, 34 in the tool crib, and 1 ground by supplier. There were 45, including many of the foregoing, that had tools ground in the shop; in some cases they specified this was only the high-speed tools.

(*d*) There were 38 firms that used a straight wheel only in grinding their tools, and of these all but 1 ground on the periphery; 12 ground on the side of a cup wheel, and 37 used both types. Only 1 used a disk.

(*e*) The size of the wheels used varied greatly, the minimum being $3^{1}/_{4}$ in. in diameter and the maximum 26 in. in diameter. The face varied from $^{1}/_{4}$ in. to 4 in. The most popular was 10 in. in diameter, as 27 were equipped with that size, 24 used 8 in. in diameter, and 15 used 6 in. in diameter. The remainder were scattered among the various sizes. There were 10 firms that reported a large variety, but gave no sizes.

(*f*) As to specifications the grain, grit, and bond varied almost as much as the size of the wheel. There were 5 that specified that they used the same grain and grade for roughing and finishing; 2 of these used universal tool grinders, 1 used a surface grinder, and the 2 others used a pedestal grinder. There were 4 of the 5 that used a 60-grain wheel, and the other used 80. There were 39 that used a different wheel for finishing than they did for roughing; 11 specified the wheel for roughing only, and 20 the wheel for finishing only.

For roughing, the grain used varied from 20 to 200 and for finishing from 24 to 220. By far the most popular were 60 to 80 roughing and 100 to 120 finishing. The actual figures were 47 using grain 60 and 17 grain 80, 17 grain 100, and 21 grain 120.

There seems to be little doubt that silicon carbide is the abrasive to use, but the hardness varies. The majority favored G and H on the scale used by some manufacturers and S and R on the other scale. These four letters represent very little difference in hardness.

(*g*) On the method used to test cutting edge, 11 reported inspection made with a magnifying glass, 9 others judged by appearance, 2 used a microscope, 3 used a protractor, 2 used dial indicators on milling cutters, 2 used a gage, and 1 a surface plate. There were 9 that tested only by use, or by cutting action and life, and 8 specified no method.

(*h*) On the question of grinding wet or dry, 67 answered that they used the dry method only, 9 ground wet only, and 14 used both methods. Evidently either is acceptable.

(*i*) The time of grinding varied from 1 minute to 2 hours for lathe and planer tools, but the majority ran between 3 and 20 minutes. The time does not mean much unless the size and condition of the edge are known. One prominent manufacturer using a fairly high percentage of tungsten-carbide tools stated that a $1^{1}/_{4}$ in. square tool would take 5 minutes to resharpen if dull. If it was chipped, the time would be 15 minutes, and for a new tool the first sharpening would take 25 minutes. There were 8 other firms that stated times from 4 to 40 minutes for this size of tool, with the average about 15 minutes.

There were 4 answers that gave the time for a $^3/_8$ in. square bit as an average of 8 minutes, and 7 reported on $^5/_8$ in. by $1^1/_4$ in. as an average of 11 minutes, although the times varied from 3 to 30 minutes.

Milling cutters required from 15 minutes to 10 hours, depending upon the size. Some of these were: 6 in. diameter by $2^1/_2$ in. face, 27 minutes; 8 in. diameter by 1 in. face (20 teeth), 45 minutes; 8 in. diameter by $2^1/_4$ in., 25 minutes; 9 in. diameter (24 teeth), $1^1/_2$ hours; 12 in. diameter (36 teeth), 3 hours.

Drills required from 1 minute to 5 hours. One firm reported 1-in. drill, 3 minutes; another, 2-in. drill, 3 minutes; another $1^1/_2$-in. drill, 5 hours, and one stated that a $^1/_2$-in. drill required $2^1/_2$ minutes to grind and lap.

Among the special tools was a form tool $3^5/_8$ by $^1/_2$ by $^1/_2$ in., which required 30 minutes, and a circular form tool requiring 10 minutes.

(*j*) This question was "Do you have any difficulty with tools cracking from grinding?" Most of the answers were negative, but 3 answered "yes," 2 answered "some," 2 answered "not much," and 1 stated "a little, with tantalum carbide."

6 Lapping and Honing

There were 2 that answered that they lapped all tools, 3 lapped 75 per cent, and 3 lapped 50 per cent of the tools, 7 more lapped 10 per cent or less, and 31 did no lapping. Of the 15 that lapped, 9 lapped finished tools only.

Honing is much more generally practiced. There were 15 that reported that they honed all tools, and 8 more honed 15 per cent or more. Only 7 reported no honing.

Of 37 shops reporting honing, 22 honed both roughing and finishing tools; 1 firm honed all roughing tools and lapped all finishing tools; 1 reported honing tungsten-carbide tips frequently while in the machine to retain a sharp edge, claiming that this practice increases the number of pieces machined between grinds.

The lapping disk in the majority of cases was cast iron, but silicon carbide, bakelite, swedish iron, wood, and both iron and steel with copper insets were also used.

(*d*) and (*f*) The lapping disk in 70 per cent of the answers was charged with diamond dust or the latter was used as lapping compound, but flour of emery, carborundum, crystollon powder, boron carbide, and tripoli were also mentioned.

(*e*) All but one used oil for a vehicle with the lapping compound, and the majority reported it was olive oil. The one exception used water.

(*g*) The amount removed by lapping averaged 0.0003 in., although the answers varied from 0.0001 to 0.005 in. One firm merely removed the tool marks.

(*h*) The time for lapping ran from $^1/_2$ minute to 3 hours, but the majority required between 5 to 15 minutes without regard to size.

The specifications of the hone used varied from 150 to 500 grain crystollon or carborundum stones. All but 3 would be included in a range between 180 and 300; 4 reported using India oil stone, giving no other data.

7 Question of Leaving Less Metal on Work

It is interesting to note that on the question of being able to leave less metal on the work for finish because the new cutting materials can cut scale more readily, 37 found this to be the case and 35 did not. Of those that answered negatively, several admitted that they had no experience or had not attempted to change the amount of finish.

8 Detecting Hard Spots

There were 10 that reported difficulty because hard cutting materials cannot detect hard spots in finished surfaces; 65 answered no difficulty.

9 Handling Chips Commercially

There were 8 that reported difficulty in producing chips that could be commercially handled, and 67 answered "no" or that they do not use tungsten carbide on steel.

10 Protection From Flying Chips

On the question of protection against chips, 30 reported using goggles or glasses, 24 guards or screens, and 5 others did not mention the kind of protection. There were 15 that reported having no protection and no difficulty; 1 reported that if the tools were ground with chip breaker, there was no protection required.

11 Obtaining Desired Finish

There were 62 that had no difficulty in obtaining the desired finish on their work with the hard cutting materials and 3 reported a better finish. However, 14 reported that they did have trouble, and 1 had difficulty with reaming operations only; 1 stated that it was possible to obtain a smoother cut with stellite than with tungsten carbide.

12 Suggestions or Additional Information

Among the miscellaneous comments and additional information the following is interesting to note:

A manufacturer of gear-cutting machinery states that he finds cobalt–high-speed-steel tools work best in their shop as they have short runs and the tungsten-carbide tools are too "fussy." Also on heat-treated S.A.E. 3140 steel, the cobalt tools stood up better.

Another machine-tool builder who makes his own tools reports that the tips are formed before the tool is made up, which reduces the grinding to a minimum.

A prominent manufacturer states that very good speeds to use with tungsten carbide are 160 to 200 ft. per. min. for continuous turning and 100 to 140 for intermittent cutting.

An automobile manufacturer reports that he uses tungsten carbide for all operations on aluminum pistons and for finish cuts on cast iron. For roughing cast iron he uses tungsten carbide on new set-ups and where increased production is required, but in the majority of cases he obtains the required production using stellite and high-speed steel. The excessive price of tungsten carbide does not warrant its use until a higher production is required.

A tool manufacturer states that the use of tungsten-carbide tips on precision jig-boring machines has not proved profitable. He was unable to finish-bore with the tool as the cutting edge lost its keeness due to chatter in performing the roughing operation.

An automobile manufacturer reports that tungsten carbide can be used on steel where the job and tool can be held rigid and a light cut taken with a fast cutting speed.

Actual Examples

The second part of the questionnaire dealt with typical successful operations. There were 37 companies that gave definite figures, including savings in money, hours, or percentage and several gave more than one example.

Among these were 11 machine-tool builders, 6 builders of other types of machinery, 4 automotive plants, 2 electric companies, 2 manufacturers of plumbing equipment, 2 ball-bearing and roller-bearing makers, 2 chain manufacturers, and 7 miscellaneous, including manufacturers of ships, hoists, instruments, and tele-

phones. This shows quite a diversification in product from which the examples were selected.

Many others gave part of the information, but did not have the figures available to give the complete story.

It is difficult to summarize all the answers as in the first part of this report because the information is such that part of it is practically meaningless unless connected with all of the other data. It seems best therefore to tabulate some of the typical examples in full, spreading them over the various operations and materials. All were with tungsten carbide.

Before presenting these, however, there are several questions which can be discussed generally.

METHOD OF TIPPING

All tips were brazed, and in addition 12 were dovetailed.

ANGLES OF CLEARANCE AND RAKE

The reports show that the clearance angle varied from 2 to 14 deg. There were 15 that reported 4 deg., 10 reported 6 deg., 11 reported 7 deg., and 4 reported 8 deg., although only 2 of these were successful, 1 on aluminum and 1 on cast iron; 1 used a clearance from 10 to 20 deg. for cutting babbitt.

The top front rake varied considerably. There were 10 that reported 0 deg., 4 reported 4 deg., 8 reported 6 deg., 4 reported 12 deg. The others were scattered among the numbers between 1 and 20 deg.

The top side rake varied from 0 to 18 deg., but the average was approximately 6 deg.; 6 reported 0 deg., 10 said 4 deg., 12 reported 6 deg., and 5 stated 12 deg.

The radius at the point of the tool is evidently not important, as successful tools were ground with a radius from $\frac{1}{32}$ to $\frac{3}{8}$ in. The most popular was $\frac{1}{16}$ in., to which 13 of the tools were ground; 8 other tools were ground to $\frac{1}{8}$ in., 3 to $\frac{3}{16}$ in., and 4 to $\frac{1}{4}$ in.

The condition of the machine tools was good for 28 of the successful applications, fair for 10, and poor in 1 case.

There were 24 applications that were on machine tools motor-driven and 17 driven from a countershaft.

In motor drives the drive was through silent chain, V-belts, flat belts, gears and worm and wheel so that practically all types are represented.

METHOD OF MOUNTING TOOL

A square turret type of tool holder was used in 16 cases and plain tool post in 7 cases. The remainder used boring bars, drill spindles, special tool holders, box tools, etc.

All tools were clamped by setscrew except that 3 had clamps, 1 a wedge, and 1 used a bolt through the shank.

Table 1 shows 4 applications on engine lathes—1 on steel, 1 on hard bronze, and 2 on cast iron.

The increases in cutting speeds and increases in number of tools per grind are extremely good.

Table 2 shows 4 applications on turret lathes with 4 different materials. The tool used in application 7 is shown in Fig. 3, as it is unique.

Application 8 is interesting in that no more pieces per grind were obtained than with stellite. However, the difference in cutting speeds permitted a net saving of $9.10 per 100 pieces.

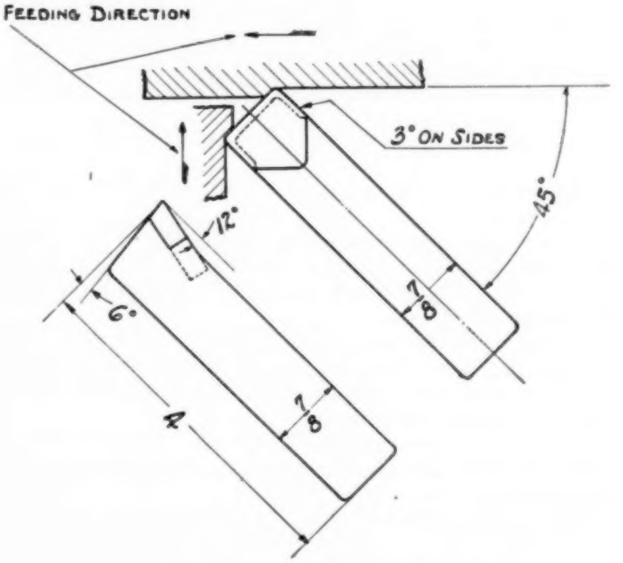

FIG. 3 TOOL USED IN APPLICATION NO. 7

Table 3 covers 3 applications on automatic lathes.

Application 9 is interesting, as it shows the elimination of the finishing cut.

Table 4 covers applications on vertical boring mills. These are nearly all large jobs.

Table 5 outlines milling-machine applications. One of the cutters used in application 20 is shown in Fig. 4. It milled on an

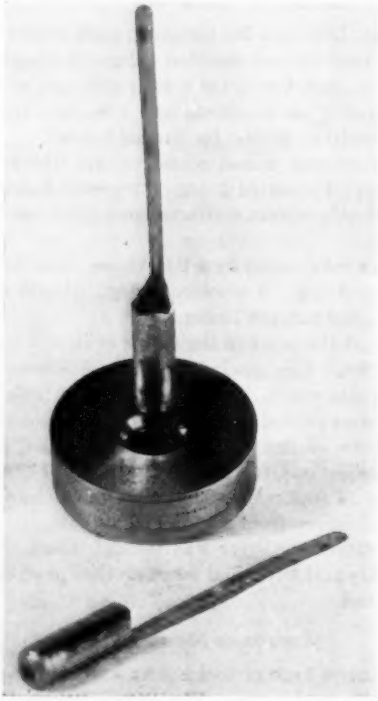

FIG. 5 DIE WITH TUNGSTEN-CARBIDE INSERT

thick was supported on all sides by a hardened shell. The surface produced was a considerable improvement over the high-speed-steel die. The number of pieces per grind was 600,000 against 15,000 with the previous die. The die is shown in Fig. 5.

One machine-tool manufacturer states that the management is a strong believer in tungsten carbide and that the concern is able to create remarkable savings. There are more than 30 milling cutters from 3 to 14 in. in diameter in use in the shop.

One company reports experimenting with tipping small air-gun chisels with stellite, but without success so far. It was about to try another grade that is designed to withstand shock and hopes to have better results. This same concern has experimented in resurfacing copper commutators for generators, cutting the time in half as compared to high-speed-steel tool or grinding. The cutting speed used was 5000 ft. per min.

One firm reports great success sawing insulating material with a tungsten-carbide-tipped saw. A tool manufacturer states that the application of tungsten carbide to saw teeth and knife edges is a proved fact.

This same company has great success cutting steel files with tungsten-carbide-tipped chisels. The chisels are machine driven, making 900 to 1900 blows per minute and from 30 to 40 impressions per inch on the file. The hardness of the file is from 8 to 28 on the Rockwell C scale. The tungsten-carbide-tipped chisels cut from 40 to 60 dozen files before becoming dull, while the high-speed-steel chisels could only cut about 1 dozen.

One manufacturer of machine tools finds the angles of the tools have to be much greater than the tungsten-carbide manufacturers recommend. Quite often a 20-deg. hook in the tool is found. This concern finds 350 ft. per min. on cast iron the proper cutting speed, but the lathes used with this material must be kept in practically perfect shape, and the size of the driving belts has been doubled to provide sufficient power.

This same concern finds the first cost of the tool relatively unimportant. It says that a $40 tool, used properly, will pay for itself in 20 hours. If the men in the shop could be induced to use the tungsten carbide on all possible jobs, the cost of the machine work could be cut to about one-third the cost of the same work with the best cobalt high-speed steel.

UNFAVORABLE COMMENT

One concern using about 20 per cent tungsten carbide states that it does not use more for the reason that the foreman and the machinists are against it because it is new. It was the management's experience that it always takes from four to five years to introduce any new cutting material in a shop.

Another company that has made several successful applications states that it is not sold on anything even approaching a general application of this material because it does not definitely show economy in operation, if unbiased accounting is applied to the problem and all factors are taken into account. This concern finds the reasons for the failures are lack of machine rigidity, poor bonding of the tips, excessive overhanging of the tool, intermittent cuts, etc. Tantalum carbide was not successful in any case. It believes that the conditions in the average shop are not favorable to the use of carbide material and that not much progress will be made until existing machine-tool equipment is replaced by tools properly designed to accommodate the material.

Several companies think that the present price level is one of the most important factors in retarding the use of tungsten carbide. They feel that it should be brought to the level that obtains in Germany and England and suggest that the committee renders its opinion of the present prices.

One manufacturer says he cannot take advantage of the material because the set-up time is so great compared to machining. He also feels that there is insufficient knowledge available as to feed, speed, and depth of cut. He suggests that a series of experiments be conducted such as Frederick W. Taylor conducted with high-speed steel. All the information now available is believed to be unreliable. He also claims that the material is being placed on the market with a minimum amount of information regarding its correct use and only in isolated cases are the results being obtained which are inherent in the material.

SUB-COMMITTEE'S ACTIVITIES

This, of course, is well known by this sub-committee, and it is one of the objects of this second questionnaire to obtain some definite data that are authentic. The sub-committee also has had in mind for two years the experiments suggested, but it is a large task and one that is difficult to get any one to undertake or to finance. If all of those interested to this extent would be willing to contribute to a fund for such a purpose, the proposition could be put across, and this would be the best means of obtaining the desired information in the shortest time.

The members of the sub-committee have been reporting progress of the companies with which they are connected, and a number of interesting developments are under way. For instance, the Union Carbide and Carbon Research Laboratory, Inc., is conducting a series of experiments correlating red hardness and cutting quality. Dr. Boston, of the University of Michigan, is at present conducting a series of tests with cobalt high-speed steel. The General Electric Company has purchased for Schenectady and Lynn especially designed lathes for the purpose of determining accurate and conclusive data pertaining to the use of tungsten carbide and tantalum carbide as a cutting medium. The lathes are about ten times more powerful than standard makes of the same nominal size, and will give an opportunity such as was never before afforded to learn the possibilities of these cutting materials. At the time this report is being prepared they are negotiating with vertical-boring-mill manufacturers with the same object in mind.

CONCLUSION

It is evident that considerable has been learned about tungsten carbide in the past year and a half. There is a great deal more to be learned, and scientific data are needed most. It seems that machine-tool manufacturers have not made much progress, probably because of the lack of definite information as to how far they should go and along what lines they should proceed. The pioneer work being done by the General Electric Company should help much, and others should follow this lead.

The sub-committee wishes to take this opportunity to thank the many companies for their ready response to the letter sent out and for their carefully prepared replies.

Appendix

LETTER ACCOMPANYING QUESTIONNAIRE

Dear Sir:

In March, 1930, the Sub-Committee on Tungsten-Carbide Cutting Materials of the A.S.M.E. Special Research Committee on the Cutting of Metals sent out a questionnaire to the leaders of the metal-cutting industry. This questionnaire dealt with the use of tungsten carbide in actual practice and enabled the committee to prepare a report which was of great interest to the users of this material as well as to machine-tool builders.

Since that time much has been learned about tungsten carbide, tantalum carbide, and other alloys, and it was felt that the sub-committee, whose activities have now been broadened to cover all hard cutting materials, should undertake the compilation of a second report. By this it is hoped to determine the present status of the use of these materials.

Accordingly, a second questionnaire is enclosed, and you are earnestly requested to have the man in your organization in charge of the introduction of these tools fill out the blanks and return them before June 1, 1931.

Please note that the form of this questionnaire is such that it will be much easier to fill out than the first. Many questions may be answered by checking the proper item, eliminating the necessity of writing out an answer. The questionnaire is divided into two parts. The first is general and is intended to determine the scope of application, etc. The second part covers several specific uses and will help to determine satisfactory practice for various operations on different materials.

The response to the first questionnaire was very gratifying, and it is hoped that the second will be as well received. Copies of the report will be mailed to all those who answer and who desire to study the data prepared.

The names of the concerns furnishing this information will not be published.
Kindly address communications to the Sub-committee on Metal Cutting Materials, American Society of Mechanical Engineers, 29 West 39th Street, New York, N. Y.

Chairman, Sub-Committee on Metal Cutting Materials,
F. C. Spencer, *Chairman.*

QUESTIONNAIRE ON THE USE OF NEW CUTTING ALLOYS

1 Extent of Application. State percentage of your total operations that are carried on with:

- *a* High-speed steel
- *b* High-cobalt steel
- *c* Stellite
- *d* Diamond
- *e* Cemented tungsten carbide
- *f* Cemented tantalum carbide
- *g* Other high-speed cutting material

2 Types of Operations Found Successful With Tungsten or Tantalum Carbide

- *a* Turning
- *b* Boring
- *c* Planing
- *d* Milling
- *e* Drilling
- *f* Sawing

Note: Please give details of at least six typical applications on sheets which follow. More sheets will be forwarded upon request.

3 Types of Material on Which Tungsten Carbide Is Used Successfully

- *a* Cast iron
- *b* Soft steel
- *c* Hard steel
- *d* Bronze
- *e* Aluminum alloys
- *f* Other material (state nature)

4 Types of Material on Which Tantalum Carbide Is Used Successfully

- *a* Cast iron
- *b* Soft steel
- *c* Hard steel
- *d* Bronze
- *e* Aluminum alloys
- *f* Other material (state nature)

5 Grinding of Hard Cutting Material Tools

- *a* Type of machine
  - 1 Pedestal (work held by hand)
  - 2 Pedestal (work clamped to angle slides)
  - 3 Universal tool-grinding machine
  - 4 Surface-grinding machine
  - 5 Face-mill-grinding machine
- *b* Who grinds your lathe and planer tools?
  - 1 Machine operator
  - 2 Tool-crib attendant
  - 3 Grinding-machine operator
  - 4 Specialist
- *c* Where are tools ground?
  - 1 Tool crib
  - 2 Maintenance tool room
  - 3 Shop
- *d* What kind of wheel used?
  - 1 Cup (grinding on side)
  - 2 Straight (grinding on periphery)
- *e* State size of wheel used
  - 1 Diameter
  - 2 Face
- State specifications of wheel
  - 1 Roughing
    - *a* Grain
    - *b* Grade
    - *c* Bond
  - 2 Finishing
    - *a* Grain
    - *b* Grade
    - *c* Bond
- State method used for testing cutting edge
- Do you grind?
  - 1 Wet
  - 2 Dry
- *i* What is average time required for grinding?
  - 1 Lathe or planer tool
  - 2 Milling cutter
  - 3 Drill
- *j* Do you have any difficulty with tools cracking from grinding?

6 Lapping and Honing

- *a* What percentage of tools do you
  - 1 Lap
  - 2 Hone
- *b* Do you lap (or hone) both roughing and finishing tools?
- *c* Of what material is lapping disk made?
- *d* What material is lap charged with, if any?
- *e* What vehicle (oil, etc.) do you use with lapping compound?
- *f* What lapping compound do you use?
- *g* How much metal do you remove by lapping?
- *h* How long does it take to lap a tool?
- *i* State specifications of hone:
  - 1 Grain
  - 2 Grade
  - 3 Bond

7 Do You Find That It Is Possible to Leave Less Metal on Your Work for Finish Because the Hard Metals Can Cut Scale More Readily?

8 Do You Encounter Difficulty Because Hard Cutting Materials Cannot Detect Hard Spots in Finished Surfaces?

9 Have You Had Difficulty in Producing Chips That Could Be Commercially Handled?

10 How Do You Protect Workmen From Flying Chips?

11 Do You Have Difficulty in Obtaining the Desired Finish on Your Work With the Hard Cutting Materials?

12 Suggestions or Additional Information

Please fill in these blanks for typical applications of tungsten or tantalum carbide tools. Application No.

A Kind of Material Cut

- *a* Type
  - Cast iron
  - Steel
  - Brass
  - Aluminum alloy
  - Other material
- *b* Analysis (if steel, give S.A.E. specification)
- *c* Rockwell or Brinell hardness
- *d* Heat treatment, if any
- *e* Condition of surface
  - Hard scale
  - Sand
  - Blowholes
  - Pickled
  - Sand-blasted
- *f* Cutting quality
  - Soft
  - Stringy
  - Good
  - Hard
  - Very hard
  - Abrasive

B Machine Equipment Used

- *a* Type of machine tool
- *b* Size (capacity)
- *c* Condition
  - Good
  - Fair
  - Poor
- *d* Nature of drive
  - Countershaft
  - Motor
  - Flat belt
  - Multiple V-belt
  - Silent chain
- *e* Horsepower
  - 1 Capacity of motor drive
  - 2 Actually used on job

C Tool Used

- *a* Material
  - Tungsten carbide
  - Tantalum carbide
  - Other material
- *b* Trade name
- *c* Dimensions of shank
- *d* Method of tipping
  - Dovetailed
  - Brazed
  - Other (state nature)
- *e* Dimensions of tip
- *f* Shape of nose
- *g* Angles of tool (state amount)
- Clearance angle
  - Top front rake
  - Top side rake
  - Radius at corner
- *h* If milling cutter, state
  - Diameter
  - Width of face
  - Number of teeth
  - How held

D How Tool Was Used

- *a* Method of mounting tool
  - Plain tool post
  - Square turret
  - Boring bar
  - Other
- *b* Method of clamping
  - Setscrew
  - Clamp
  - Wedge
- *c* Operation
  - Turning
  - Facing
  - Parting
  - Forming
  - Planing
  - Milling
  - Slotting
  - Shaping

E Grinding of Tool (method covered under general questions)

- *a* Time consumed for grinding
- *b* Time consumed for lapping or honing

F Roughing Cuts. Comparison of this tool with tool previously used (state cutting material)

- *a* Cutting speed (ft. per min.)
- *b* Feed (in. per rev.)
  - Feed (in. per stroke)
  - Feed (in. per min.)
- *c* Depth of cut (inches)
- *d* Metal removed (cu. in. per min.)
- *e* Was cut continuous or intermittent

G Finishing Cuts. Comparison of this tool with tool previously used (state cutting material)

- *a* Cutting speed (ft. per min.)
- *b* Feed (in. per rev.)
  - Feed (in. per stroke)
  - Feed (in. per min.)
- *c* Quality of finish produced

H Economies Shown. (Comparison of this tool with tool previously used)

- *a* Number of pieces per grind
- *b* Number of grinds per tool
- *c* Purchase price (of tool or cost)
- *d* Time per piece
- *e* Savings in labor cost over previous method
  - Per piece
  - Per 100 pieces
- Net increase or decrease
- In cost per piece or 100 pieces

(Taking into account increased cost of tool and grinding)

Discussion

W. S. Huson.[3] On going over the progress report on metal-cutting materials there is much that invites consideration and discussion, for it shows continued endeavor to find a cutting edge that will stand up satisfactorily under the stress of separating a chip from the stock. There is no reason to feel that, because experience broadens and the breakdown point is reached, an ultimate has been finally found, although some of the answers to the questionnaire seem to indicate this. That interest centers about tungsten carbide, Stellite, tantalum, or in fact any other hard substance that will excel high-speed steel, shows there is determined effort not to sidetrack the information and data already available. It may well be that out of it all may come a material or alloy that will help solve the limitations of cemented compounds; and although the high speeds claimed now may be modified, the ultimate result will be more profitable—for as long as a cutting edge has to depend upon a relatively weak bond, there will be a breaking away of the cutting grain, no matter how efficient it may be in hardness and durability.

The item on the construction of super-powerful machine tools leads to the thought that the mere making of heavier tools will not solve the question of the life of a cutting tool, for some seem heavy and powerful enough now, until the cutting tool in itself will prove it can stand up in continuity of acceptable machining. There is, however, this thought—that with heavier machines and the elimination of chatter and other features that have been accountable for cutting-edge failures, there will come tools in which the high-speed steel will give a higher percentage of output. A way may be found to incorporate in a homogeneous mass, say as in high-speed steel, the cutting features of the more or less segregated cutting points as now held in a cementing bond. When this comes, such tools as milling cutters, for instance, will have an ability that may tax the strength of the heaviest tools that can be devised. It is not to be wondered at that machine-tool builders hesitate in trying to devise tools that will be within the range of reasonable purchase and give a profitable return on the investment.

Roger D. Prosser.[4] It is interesting to note the greatly increased use and improved methods of application of tungsten carbide during the last year.

One point that stands out from the paper is the great length of time required to grind tungsten-carbide tools in the average shop. This emphasizes the fact that proper grinding methods are not being employed by most shops, and it shows the need of a greater study in this respect by manufacturers who wish to effect the greatest possible savings with tungsten carbide or other hard-metal-composition tools.

It is apparent that when all tungsten-carbide tools are ground in a special department, where a study of the proper grinding methods has been made, the results obtained are far superior to those in shops where each machine operator is allowed to grind his own tools. It is difficult to instruct the general run of machine operators in the proper grinding methods, and at this time it seems that it is only through careful instruction of a few expert men that the desired results can be obtained.

The grinding of intricate tools, such as milling cutters, forming tools, etc., of course requires somewhat more time than for similar high-speed-steel tools, due to the great hardness of the cemented carbide. On the other hand, simple lathe tools, such as compose the majority of the cemented-carbide tools in use at this time, should require only very little longer time than required for similar high-speed-steel tools. The average time required to grind such a tool at the plant of the Krupp Works, where thousands of these tools are ground daily, is less than 3 min., and this is accounted for by the fact that large wheels are used, with ample power, and wet grinding. The wet grinding permits much faster grinding, and the use of a large roughing wheel for taking down to size, with only a light touching up of the edge on the finishing wheel, is also a factor in attaining the desired results.

The grinding of the average cemented-carbide tool is very simple if a little study is given to proper methods and equipment.

Author's Closure

Mr. Huson's comments are very timely. Cemented carbides have improved and are likely to continue to do so. Heavier machine tools may not give greater possibilities, but who can say so definitely, as the machine development for these materials has just started? Very high speeds are now used successfully with light feeds. If the latter be increased, the amount of metal removed in a given time will increase tremendously. More heat, of course, will be generated, tending to limit the production. On the other hand, tantalum carbide shows the peculiar property of conducting heat away from the cutting edge very rapidly, and this tendency may lead to remarkable advances in the near future.

Mr. Prosser hits the nail on the head when he says that grinding is a serious problem with the carbides. This is the reason that so many questions on the subject were included in the questionnaire. It is true that the times reported in many cases are too high. With further experience will come improved methods, but the important points to note are that more care is being taken in grinding carbide tools and that machine grinding is being more generally adopted.

---

Development of Wood Adhesives and Gluing Technique

By T. R. Truax,[1] Madison, Wis.

Study of adhesives used in furniture and other relics of earlier civilizations yields little of value to present-day craftsmanship. This paper therefore discusses only the more recent developments in glues and the technique of using them. While some glues were of ancient origin, the modern large-scale production and the more precise controlled methods have resulted in glues of higher and more uniform quality than the ancient glues from the same sources. Standardization of tests and testing methods is important. Joint tests constitute the principal means for determining the suitability of glues for woodworking. Tests that can be made directly upon the glues rather than upon glued joints may be developed.

Furniture and other relics of earlier civilizations attest the gluing of wood (9)[2] as an art of long standing, but they furnish little authentic information that is of practical value to the craftsman of today as to kinds and quality of adhesives used or of methods or processes. Because of mechanical and chemical progress, it is doubtful that even reliable and complete historical records would add much of practical value to present-day gluing operations. Consequently, this paper will discuss only the more recent developments in glues and in the technique of using them.

Development of Glues

It is a common assumption that the joints in chests and other articles recovered in recent times from ancient tombs were glued with adhesives that were superior to modern glues. The fact that the joints have endured for many centuries is, however, no positive evidence that the adhesives were superior to present glues. On the other hand, the fact that the wood in these particular articles was not damaged leads us to believe that the surrounding conditions were not extremely severe. In other articles recovered there has been more or less damage, presumably to both glue and wood. Adhesives are available today that might reasonably be expected to withstand permanent exposure to conditions where wood is not deteriorated.

Animal and fish glues were undoubtedly of ancient origin and may have been used by the craftsmen of 20 or 30 centuries ago. Certainly they were the best known and most extensively used a few centuries ago. Blood-albumin glues are reputed by some to have had an early origin and perhaps casein glues were also known to the ancients. Large-scale production of glues under efficient and refined methods, however, is a development of modern times. Manufacturing under more precise, controlled methods has resulted in glues that are probably of higher and more uniform quality than the ancient glues from the same sources. Coincident with better manufacture, improvements have occurred in the testing and grading of adhesives and better technique has been developed in their use.

In the United States it has been only within the last 20 years that animal and fish glues have had serious competitors in the woodworking field. Starch glues, suitable for wood joints, were developed about 1912, and during the World War casein glues came into use on a commercial scale in the woodworking trade. Both starch and casein glues have grown in importance during intervening years. Vegetable protein glues were developed commercially subsequent to the World War, and they, too, have grown rapidly in importance. Though the protein glues have a vegetable source, they are more analogous to the casein glues than to the starch glues in properties. Animal, casein, starch, and vegetable protein glues have been quite fully discussed elsewhere; (13)[3] hence only adhesives that have not yet come into general use in woodworking will be discussed here.

Miscellaneous Adhesives

There are many kinds of adhesives, such as blood-albumin, phenol-condensation products, rubber cements, cellulose esters, silicate of soda, waxes, asphalts, and gums, which have been used to some extent or proposed as glues for wood. Blood glue has been used considerably, and others may eventually become important. So far as is known no extensive tests ever have been made on most of the foregoing miscellaneous adhesives. Samples of many of them, however, have been tested at the Forest Products Laboratory in order to obtain some idea of their value and suitability for making joints in wood. The results of these preliminary tests indicate that some have outstanding properties.

Blood-albumin glues are the best known of the miscellaneous group. They have been used more extensively in European and Asiatic countries than in the United States, but their use appears to be diminishing rather than increasing. They have been used principally in plywood, but casein glues at present appear to be taking their place in part, both here and abroad. High water resistance is the most valuable property of blood-albumin glues; the necessity for hot-pressing is the chief disadvantage. Because the cheaper cold-press method of gluing prevails in the United States, the blood-albumin glues have been used here only in a few plants. Attempts to produce a cold-press blood-albumin glue have met with only partial success.[4]

Phenol-Aldehyde Adhesives. By heating a phenol with an aldehyde it is possible to produce hard, strong adhesive substances that appear to be unaffected by moisture in any form. Adhesives of this type that have been produced commercially have yielded joints in wood of high strength when tested both dry and wet. Phenol-aldehyde adhesives are apparently more water

[3] See also papers on these four classes of glues presented at the Sixth Annual Meeting of the Wood Industries Division of The American Society of Mechanical Engineers.

[4] A blood-albumin glue, which can be cold pressed and which is recommended only for light-weight woods, has been developed at the Forest Products Laboratory. See U. S. Department of Agriculture Technical Bulletin No. 205, page 54.

resistant than any of the glues now in common use. They are, however, several times as costly as the common woodworking glues, and the necessity for hot-pressing in order to produce the characteristic bakelite reaction is a disadvantage particularly under prevailing methods of manufacture in American factories. Unless the phenol-aldehyde adhesives can be produced more cheaply, they will be restricted to special uses. Tests made in Germany indicated that similar adhesives of this class (8) became brittle in wood joints when dry, but this characteristic was not found to be objectionable in the tests at the Forest Products Laboratory.

Adhesives From Rubber. Joints can also be made in wood by hot-pressing with adhesives made from rubber. Two commercial products of this type have been tested at the Forest Products Laboratory. The joints were strong both dry and wet, but the adhesives are expensive. They may find limited uses for special purposes.

Cellulose Esters. Cellulose cements have been suggested at various times as adhesives for wood, and tests have been made on several products. Most of them are too thin and require more than one application to make good joints in wood. When so used, they are slow drying, and they are also relatively expensive. It is reported that joints of good strength and high water resistance have been made with them in Germany. (8) Cellulose cements can be cold-pressed, but their cost and difficulty of use appear to make them impractical at present for general woodworking purposes.

Silicate of Soda. Silicate of soda makes joints in wood of fairly high dry strength. It is cheap, easy to apply, and finds a large use in fiber containers, but the joints are weak when wet. Silicate of soda changes in properties with age and is therefore not considered a permanent binder.

Waxes, Gums, and Asphalts. Waxes, gums, and asphalts have been proposed as adhesives for wood. So far none of them has proved to be satisfactory.

Dry Glue Films

Attempts have been made from time to time to produce a dry film of glue that could be used in place of a liquid adhesive. The advantages of such a process are obvious, especially in laying thin veneer, but as yet a material of this kind has not come into commercial production in the United States. Some work was done in 1918 at the Forest Products Laboratory on a dry-glue process, and a film was produced experimentally using blood albumin as a base. (1, 11) So far as is known, this material is not being produced commercially. Recently published accounts of tests in Germany indicate that attempts are being made in the same direction abroad. (8) Films made from cresol-formaldehyde and from cellulose esters are reported to give good results. The dry-glue films, so far produced, require the use of a hot press. No information is available as to cost, but the dry films of these materials are undoubtedly more expensive than common glue mixtures.

Testing Glues

Progress and development in the manufacture of glue are necessarily related to its testing. Some means of measuring quality is essential to determine the value of new products and the improvement of old ones. Not only is glue testing necessary to the manufacturer, but it is also important to the user. It is his means of determining whether he gets value received for his money, and, still more important, it helps to insure the value and quality of his own products. A table, a chair, a door, or an airplane wing beam is no better than the joints it contains.

Manufacturers commonly have their own methods of checking the quality of their raw materials and their manufactured glues. Consumers and others, likewise, use one form or another of test in an effort to check the quality of glues and to determine their suitability for a particular job. This has led to many forms and kinds of tests, all of which are aimed at essentially the same purpose. Standardization of tests and testing methods is therefore important to a common understanding. A considerable amount of work has been done upon standardization, but much remains yet to be done.

The testing of animal glues has reached a higher degree of perfection than the testing of other types of adhesives. A number of workers have investigated the physical and chemical properties of animal glues and methods of measuring them, and, as a result, clearly defined and reasonably accurate tests of the glues themselves are available. The National Association of Glue Manufacturers, comprising a considerable number of animal-glue makers, has adopted uniform testing methods (4), and the U. S. Federal Specifications Board has recently incorporated these methods in a specification for Government use in the purchase of animal glue for woodworking. (6) In Germany a committee on glue testing of the (German) Society for Testing Materials has recently carried out investigations with the object of setting up a uniform procedure in that country for testing animal glues. (7) Investigators in Russia and other countries are also studying the testing of animal glue.

There is general agreement among research workers that viscosity and jelly strength are the most reliable criteria for judging the quality of an animal glue, and one or the other or both are usually the basis for grading. In Germany viscosity is regarded as the more reliable of the two properties (7), while in the United States both are considered essential for defining the grade of a glue. (4) Other characteristics commonly considered of some importance in an animal glue for woodworking are moisture content, reaction (acidity or alkalinity), tendency to foam, and odor or keeping quality. Joint tests in glued wood blocks have been a part of most all glue-testing investigations, but they are less accurate and less satisfactory for testing the quality of animal glues than are the physical properties of the glues themselves. (14)

There are at present no generally accepted physical and chemical tests for blood-albumin, casein, starch, and vegetable-protein glues. In the absence of more refined testing methods, the strength of joints of all of these adhesives and the water resistance of joints of blood-albumin, casein, and vegetable-protein glues are the properties most often tested. Joint tests, therefore, constitute the principal means thus far available for determining the suitability of these glues for woodworking.

Forest Products Laboratory Joint Tests. The Forest Products Laboratory during the World War developed two types of joint tests for aircraft glues. (1) The tests were later used on starch and other kinds of adhesives. They are known as the block-shear and plywood-shear tests and have been described in several publications. (13) The block-shear test is adapted to thick pieces and the plywood-shear test to veneer. Both tests have since been used in the same or slightly modified forms in several other countries. (2, 5, 9, 10, 15) Both tests are simple, and with proper equipment and care can be quickly made with a moderate degree of accuracy.

All forms of joint tests involve a gluing operation, and this may have a most important effect upon the results. Poor gluing may result in weak joints with high-quality adhesives, while careful gluing may result in fairly strong joints with medium- to low-quality glues. In addition to the gluing operation, the variable properties of the wood are factors that may lead to erroneous conclusions unless careful selection of material is made. With proper care in selecting and making joints, however, the block and plywood tests will show fairly consistent differences between weak and strong glues and will enable the selection of a glue or glues satisfactory for a particular job. Other tests on blood-albumin, casein, starch, or vegetable glues, such as the viscosity and working life of the mixed glue, may give supplementary information of much value. It is to be hoped, however, that in the course of time complete tests will be developed for each of these glues that can be made directly upon the glue rather than upon glued joints.

Developments in Gluing Technique

The third phase of the development of glues involves the details of their use and the technique of joint making. Only the principles of handling glues and making joints that have undergone important changes will be described here.

Preparation of Glue for Use. In preparing glue for use the necessity of producing a glue mixture of uniform and proper consistency, in which the raw materials are completely dissolved or dispersed is of primary importance. The animal glue must be all softened and melted, the starch all "converted," the casein, vegetable protein, or albumin all dissolved in order to produce a uniform mixture. It is also important that the mixing or conversion be done without the inclusion of large amounts of air. Outside the character of the glue itself, the speed of stirring and the type of mixer govern the amount of air, or foam, included. Suitable types of equipment are available for preparing the different kinds of glues, and with reasonable care in the operation good glue mixes can readily be prepared.

An old tradition has been that an animal glue must be boiled to prepare it for use. Furthermore, it has been common practice to keep prepared animal glue boiling or near the boiling point during use. The injury to the glue and the wastefulness of such practice have been clearly shown by many investigators. (13) It is unnecessary to go any further into this subject than to point out that the most desirable temperature conditions are known and that commercial practice has been largely changed to conform to improved practice. Equipment manufacturers have been very helpful in bringing about this change by providing glue converters and pots in which the temperature is easily or automatically controlled.

Temperature control is somewhat less imperative for blood-albumin, casein, starch, and vegetable glues than for animal glue, but is nevertheless important. The quality of a starch glue and the working life of casein and vegetable-protein glues depend to some extent upon temperature. Manufacturers of starch adhesives usually recommend the temperature conditions most satisfactory in mixing, and temperature recommendations are also made by some manufacturers of casein and vegetable-protein glues. Heating blood-albumin glues and certain other adhesives during preparation above their coagulating temperatures alters their adhesive properties.

Spreading. To make a satisfactory joint it is important to spread an adequate amount of glue evenly and quickly over the surfaces to be joined. Machine spreading is quicker, more uniform, cheaper, and more economical of glue than hand spreading and is recommended on work adapted to it. Speed is essential in many operations in order to get uniform results. It is important to spread the right amount of glue—that is, a sufficient quantity to make a strong joint, but not enough to add excessive water to the glued members. The required amount of glue to spread has been worked out experimentally (13) and is fairly well established in commercial practice. Spreading both sides of a joint uses more glue than single spreading and is ordinarily not justified.

An important development in gluing technique has to do with the consistency of the glue mixture at the time of pressing. Here again, with respect to animal glue, an old tradition has been inherited to the effect that the glue mixture must be relatively thin when pressed, that the wood must be hot, and that the solution must penetrate the cells to make a strong joint. Gluing methods and practices for several decades and perhaps centuries had been built upon this principle. It is not surprising, therefore, that the results of investigations showing that glue need not penetrate deeply into the wood cells, that relatively thick mixtures give better results than thin mixtures, and that strong joints can be made with animal glue on unheated wood should be regarded as revolutionary and accepted very slowly by the craftsmen. Although these principles have been checked and verified many times in commercial practice, there are still some who regard them with suspicion.

The Forest Products Laboratory undertook, somewhat more than a decade ago, a detailed study of the factors that affect the strength of a glued joint. Two general principles were formulated as a result of these investigations: First, that glue adheres tenaciously to wood substance and that mechanical adhesion, such as exhibited by the holding power of nails, is of secondary importance; second, that the making of strong joints involves a close correlation of the amount of pressure applied and the consistency (viscosity) of the glue mixture at the time of pressing. (3, 12, 13) Since the publication of the results of these studies, similar investigations have been undertaken in other countries, including Germany, England, and Russia, and the results recently appearing in foreign publications indicate that our conclusions are being verified by the workers of other countries. (2, 8, 10, 15)

Working out the interrelation of factors for different gluing operations and different species of wood required the making of many thousands of tests and several years of work. The kind of glue and proportion of water in the mixture, the quantity of glue spread, the temperature of the glue and the room and the wood, the lapse of time between spreading and pressing, the amount of pressure, the length of the pressure period, and the species of wood were all investigated. The interrelation of these factors is complex, each depending upon the others, resulting in a large number of combinations of conditions that give good results and a like number that give poor results. However, from these investigations it is now possible to set up recommendations for gluing different species of wood with different kinds of glue that are applicable to different commercial gluing operations. (13)

In general the most satisfactory joints are made by the use of relatively thick mixtures of glue and high gluing pressures. These two conditions are necessary to bring the contact surfaces of wood together, to force the air and excess glue from the joint, to spread the glue uniformly throughout the joint in a thin continuous film, to force the glue into intimate contact with the wood substance, but not excessively into the cell cavities, and to hold the joint in correct position while the glue sets. Excessive warming of the wood keeps an animal glue too thin for immediate pressing and favors starved joints, a condition in which there is not a continuous film of glue in the joint.

In quick clamping, such as in edge-joint gluing and certain assembly operations, the glue must be mixed relatively thick or, as in the case of animal glue, permitted to come to the proper consistency by cooling. Wood at 70 deg. fahr. normally requires no further warming in operations where the pressure is applied within one minute after spreading. Gluing pressures of 100 to 200 lb. per sq. in. of joint are best; the lower pressures for lighter woods and the higher pressures for heavy woods. These recommended pressures are higher than those that still generally prevail in many operations.

Time-saving machinery and devices also have brought about important changes in the gluing room, as related to the technique of gluing. Mechanical spreaders, rotary clamp carriers, and hydraulic presses have had a marked effect on the time element in gluing—a most important factor in joint production. They have tended toward higher gluing pressures, have made it inadvisable in many operations to warm the wood, have brought about shorter clamping periods and the need for quick-setting glues, and have made it necessary to mix glues relatively thick. These developments have generally contributed to a more uniform and higher standard in glue joints, but to take full advantage of them the gluing operator must make certain that he controls the details of the operation in harmony with the changed conditions.

Merits and Applications of Animal Glue to Veneer Work

By WILBUR L. JONES,[1] MADISON, WIS.

The growing use of crotch, burl, and stump veneers has added to the technical difficulties of fine-furniture manufacturing. Animal glue, for manufacturing fancy veneered work, has properties commending it to the plywood maker, such as (1) its fluidity, giving a moderately large spread in highly concentrated solution; (2) its neutral reaction and chemical inertness, which make it incapable of staining delicate face veneers; and (3) its quick-setting and fast-drying tendencies, which permit prompt pressing. Modern processes of sizing and gluing are described. The veneering operation is analyzed from the standpoint of (1) the large area of wood surface to be covered with glue, (2) the large proportionate amount of moisture absorbed by the wood from the glue, (3) the short distance from the glue line to the surface to be finished, (4) the comparatively long assembly time, (5) the emphasis on beauty of appearance in the fabricated article, (6) the need for speed of production, and (7) the importance of quick and proper drying. The conclusion is reached that animal glue has kept pace with the industry and is well qualified for the highly decorative, if somewhat difficult, veneering processes of today.

MANUFACTURE of veneered work makes rigorous demands on the adhesive used. The glue requirements of veneering are more exacting than those of heavy joint work. Even in such relatively difficult branches of heavy joint work as chair manufacture and automobile-body building the two chief qualities sought in glue are strength and durability. The plywood maker, however, is interested not only in these, but in many other properties as well. The so-called lower-grade glues are used more often in veneering than in heavy joint work, but the adhesive requirements of veneering are the more difficult to fulfil.

Some people have felt this so keenly that they have expressed the opinion that the ideal veneer glue has not yet been invented, and perhaps they are right. What they probably have in mind is that a glue, in order to be perfectly satisfactory for veneering, ought to be strong, elastic, fluid, moderately quick setting, fast drying, water resistant, non-staining, foam free, easy to prepare, lump free, non-injurious to cutting tools, unaffected by heat, reasonably priced, usable at a very low water-glue ratio, chemically inert, thoroughly reliable, and absolutely uniform as to quality. Considered by this list of requirements, animal glue makes a surprisingly good showing.

The principal technical differences between veneering and heavy joint work are (1) the larger area of wood surface to be glued; (2) the larger proportionate amount of water absorbed by the wood from the glue; (3) the shorter distance from the glue line to the surface which is to be finished; (4) the generally longer assembly time; (5) the greater emphasis on beauty of appearance in the fabricated article; (6) the need for speed of production; and (7) the importance of quick and proper drying. Let some of these points be considered further.

1 LARGE AREAS TO BE COVERED

The area of wood surface to be covered with glue is likely to be but a few square inches per unit in heavy joint work, whereas it may easily run up to 25 or 50 sq. ft. per unit in veneering. Hence there is need for mechanical equipment, such as glue spreaders and hydraulic presses, that the work may be handled as expeditiously as possible. The glue is practically always applied by corrugated roll spreaders, the contents of which are kept warm when animal glue is the adhesive.

There are many advantages in having a glue which is perfectly fluid. Veneer sheets are often slightly wrinkled and wavy. This is particularly true of crotch, burl, and stump veneers, which are almost always thin and therefore too fragile to be flattened forcibly between the rollers. Since the spreading must be accomplished in haste, there is no time to correct the inequalities of the machine spreading by hand. Therefore a glue that will flow a little and by its very fluidity cover up the dry spots on the sheet is less likely to encourage the formation of blisters and loose edges than a glue which is so thick that it stays exactly where it is put. Furthermore, sliced and rotary-cut veneers have an "open" side—that is to say, a side on which there are innumerable tiny checks, caused by the bending of the sheet away from the cutting knife. Since this "open" side is usually laid toward the glue, it is desirable to have a solution that is thin enough to enter these cracks and hold the face firmly to the crossband or core.

A degree of fluidity is desirable in the press, too, for the glue there is subject to redistribution under the influence of pressure. Certain types of glue, if they are too stiff at this point, may crumble rather than "give," and thus lead to the production of areas of poor adhesion.

Mechanical spreaders have a tendency to whip air into glue if it is a potential foam former. The causes of foaminess are not well understood, but fortunately the cure is. Certain sulphonated oils and greases and other agents are effective in reducing the foaminess of animal glue to a point at which it is quite negligible. No well-manufactured animal glue will give any trouble on this score.

On account of the large areas of wood to be covered, the cost of the glue is a factor. When veneers are laid with animal glue, the so-called lower grades are generally used. These are not only moderately priced, but are desirable for other reasons which will be explained later.

---

[1] Consulting Glue Chemist. (This paper was prepared in collaboration with the National Association of Glue Manufacturers, New York.) After graduation from the Engineering School of New York University, Mr. Jones was engaged for four years in testing miscellaneous materials at a New York City municipal laboratory. In 1920 he joined the Forest Products Laboratory at Madison, Wis., to conduct investigations of glue-using in the woodworking industries and the development of water-resistant and other new adhesives. In the course of this work he became chairman (1923–1924) of the technical committee on glue of the Federal Specifications Board. In 1924 he opened a testing and research laboratory at Madison, Wis. His specialty is adhesives and adhesive problems. Mr. Jones has contributed numerous articles on woodworking glues, other adhesives, and their use in the industries.

Presented at the Sixth Annual Wood-Industries Meeting, Winston-Salem, N. C., Oct. 15 and 16, 1931, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

The lower grades of animal glue are made from the same kind of stock as the higher grades. Sometimes they are simply the later runnings from stock that has yielded the very choicest glues. The processing which they receive results in a lowered viscosity, a lowered jelly strength, and a greater fluidity, which in turn makes it possible to use them at a very high concentration—a great advantage in veneering, where it is essential that the minimum amount of water be transmitted to the veneer. The processing by which the so-called low-grade animal glues are made does not affect their potential adhesive strength to the same extent that it affects their fluidity. In fact, any reduction in adhesive strength that may have been brought about by the processing can safely be ignored in veneering, because the shearing strength of even the lowest grades exceeds that of the wood by a comfortable margin.

High-grade animal glue has the highest tensile strength. The strength of the low grades, though not quite as great, is such that strength values of 3500 lb. to the sq. in. have repeatedly been obtained in the standard shear-block test whenever the wood was able to stand so high a load. It is hardly ever possible to go higher than this, because the shearing strength of wood is the limiting factor in the test, just as it is in use.

The National Association of Glue Manufacturers has in recent years devised a system of evaluation whereby hide and bone glues alike are graded according to their viscosity and jelly strength.[2] Thus the purchaser who specifies some particular grade of animal glue is assured of getting an adhesive uniform in properties and constant in effect. With a graded animal glue it is unnecessary for the veneer manufacturer to experiment with every new lot of glue to determine its water-taking requirement. The uniformity of graded animal glue banishes the danger of too much water on the one hand or of too stiff a glue on the other hand.

2 Absorption of Water by Veneers

The amount of water added to wood in the course of the gluing process varies. Although it is usually less than 1 per cent in heavy joint work, it may rise to 30 or 40 per cent in plywood manufacture. Veneers are sheets of wood which seldom exceed $^1/_4$ in. in thickness. In fabricating them it is customary to coat at least one of their two surfaces with glue. In the case of crossbands and cores both surfaces are generally spread with glue.

It is considered good practice to redry veneers just prior to laying them, and this of course tends to keep the final moisture content low. A moisture content of about 5 per cent is the one sought in the redrying treatment when the work is most exacting. It is not advisable, however, to dry fancy veneers lower than this on account of their fragility.

Because most of the veneers used in furniture manufacturing today are quite thin, the weight of glue relative to the weight of wood is exceedingly high. Since the glues most commonly used in veneering are solutions varying in concentration between 28.5 and 40 per cent, it can readily be seen that water is their major ingredient. Consequently, when veneers are laid, a large amount of water is enclosed in the panel. Most of this water must make its escape by migration through the wood. In doing so it causes swelling, which is the root of nearly all evil in plywood manufacture.

The amount of moisture added to wood in gluing can be estimated by a simple calculation, the formula being as follows:

$$M = \frac{12(n-1)}{62.3} \times \frac{r}{s} \times \frac{1}{n_a t_a d_a + n_b t_b d_b + n_c t_c d_c} \quad \ldots\ [1]$$

where

M = per cent of moisture added

n = total number of plies

r = number of pounds of water per pound of dry glue in the solution used

s = spread, in square feet of single glue line per pound of dry glue

n_a, n_b, n_c = number of plies of species a, b, and c

t_a, t_b, t_c = ply thickness, in inches

d_a, d_b, d_c = specific gravity[3] of species a, b, and c.

When the panel is homogeneous (that is, consists of plies of only one species and one thickness), formula [1] reduces to:

$$M = \frac{12(n-1)}{62.3\,n} \times \frac{r}{s} \times \frac{1}{dt} \quad \ldots\ldots\ldots\ldots\ [2]$$

Given a certain type of panel to make, it is obvious that the thickness, the specific gravity, and the number of plies are predetermined. The only chance of controlling the amount of moisture added lies in the factor r/s. Inspection of formulas (1) and (2) shows that the added moisture varies directly as r and inversely as s. In keeping this factor as low as possible lies the hope of obtaining minimal swelling, which is the aim of every good worker in veneers.

These quantities cannot be varied entirely independently of each other. The nature of the glue itself sets limits to the changes which can be effected in the factor r/s. That is to say, if the water-glue ratio is materially reduced, the glue becomes heavy and tends to pile up on the sheet so that it cannot be spread as far as before. Thus r and s decrease at the same time and the factor r/s does not decline to a minimum. On the other hand, when the denominator s is increased to make the fraction r/s small, r has to be increased in order to give the glue the necessary fluidity. A highly fluid glue will permit a large spread at a low water-glue ratio, thus giving rise to minimal moisture change and minimal swelling. But the reverse is true of a non-fluid glue, for it will tend to give a moderate spread, even at a high water-glue ratio.

Animal-glue solutions by reason of their being used at an elevated temperature are the most fluid of all the common veneer glues. Hence it is possible to use them at an exceedingly low water-glue ratio without loss of spreading power. From this standpoint alone animal glues are worthy of consideration by those alive to the danger of face checks and the other consequences of a high moisture content.

Sometimes ill-advised attempts are made to decrease the amount of water-absorption by making use of a very scanty spread. These attempts, undertaken to further the interests of economy, often have the contrary effect, because thin spreads of glue dry rapidly, may become non-adhesive in spots, and result in the formation of blisters, which lead to costly repairs, if not to rejections.

Furthermore, when certain other types of glue are made up for scanty spreading, they are prepared at comparatively high dilution. Thus it happens that when the glue solution is thin enough to cover a large area it is also thin enough to strike through the face veneer and cause staining. It is advised, therefore, to have a moderate spread of glue and a fairly concentrated, though fluid, solution, both of which are obtainable in animal glue.

Very briefly, the newer method of cementing fancy veneers is as follows: The cores are prepared in the usual manner, with of course careful drying before planing in order to avoid sunken joints. Then the cores are crossbanded on both sides, taking the precaution to have the "closed" or "right" side of the crossband uppermost. A moderately long assembly time may be allotted to this operation, but the crossbands should be in prime condition and the covered cores well dried before proceeding.

[2] *Industrial and Engineering Chemistry*, vol. 16, no. 3, p. 310, 1924.

[3] In the absence of exact data on the specific gravity of the wood at its moisture content at the time of gluing, the specific gravity (oven dry, based on volume when air dry), which is given in U. S. Department of Agriculture Bulletin No. 556, table 2, can be used.

The next step is carried out according to either of two preferred techniques. In one of them the face veneer is glue-sized by dipping it in a dilute animal glue solution or else by double-spreading it with the same. After the dipping process any unabsorbed solution on the surface is removed by wiping or passing the veneer through a sort of wringer. Then the faces which have been sized are dried in racks and finally between warm, flat basswood boards, or else between spare sheets of basswood or other suitable veneer. When the glue-sized faces are down to 5 per cent moisture content, they are ready for attachment to the covered cores.

An alternative method of strengthening the faces and sealing them against glue penetration is to back them with a thin sheet of some suitable veneer, which is glued to the face parallelwise. For backing fancy faces in this way, animal glue is preferred because of its fluidity and because it is non-staining.

The final step in the making of the panels consists in attaching the glue-sized or veneer-backed faces to the crossbanded cores. For this purpose a fairly concentrated animal glue solution is best. The glue is spread on the crossbands, and then when the glue has chilled slightly or has become "tacky," the faces are laid on and the whole panel pressed between warm caul boards. The panel backs, of course, are laid at the same time; but when veneer-backed faces are used, it has been found possible to leave off the conventional panel back. This is done for reasons of economy; and although it violates the time-honored principles of balanced plywood construction, some firms have found it not to be a cause of warping when properly performed.

3 Effect of Thin Faces

The distance from the glue line to the surface which is to be finished is very small, being of course the thickness of the face veneer. Face thicknesses are rarely more than $^1/_{16}$ in. or less than $^1/_{40}$ in. It is extremely difficult to prevent glue solutions from coming through the thin faces which modern furniture styles have decreed by reason of their insistence on the use of highly figured wood surfaces.

The texture of the wood has an influence, in that the more porous species allow glue solutions to seep through to the surface with greater facility than the more compact species. In veneers thinner than $^1/_{20}$ in. there is always danger of some seepage. The difficulties arising from the seepage of glue through face veneers are staining, clogged surface pores, and the sticking of paper and wooden cauls.

Sizing the faces with animal glue serves to lessen the trouble from this source. Glue-sizing is particularly effective in the case of fancy veneers, because the grain in them does not run in orderly fashion, as it does in many plain veneers, but wanders about in every conceivable direction. Oftentimes there is a certain amount of end grain in fancy veneers. This is likely to offer an unobstructed passage for the glue from one side of the sheet to the other.

Glue size is a 1-to-8 or a 1-to-10 solution of animal glue. Applied either by dipping or by roller-spreading, it impregnates the sheets thoroughly, strengthens them so that they will be less fragile, and closes the pores, sealing them against subsequent penetration by whatever glue may be used in cementing the panel. Indeed, sizing sets up a bar against moisture as well as against glue and prevents them both from reaching the surface of the panel.

Wood is subject to staining by certain glues. A glue does not need to be fluid in order to stain, since it is not absolutely essential that the glue gets to the surface in order to discolor it. In some instances the glue remains in the joint approximately where it was put, but the moisture strikes through to the surface, carrying with it chemicals extracted from the glue. If these chemicals are alkaline, they are almost certain to discolor the surface. Some species of wood are quite seriously affected by alkalis. Therefore if the veneer faces are thin, cross-grained, and easily marred, it is advisable to choose animal glue for the adhesive, because animal glue is practically neutral in reaction and inert chemically.

Animal glue solutions, used at about 140 deg. fahr., have an appreciable vapor tension. Consequently they lose water and increase steadily in concentration. A glue that was, say, a $33^1/_3$ per cent solution to begin with will become somewhat more concentrated by the time it is spread on the panel. There it continues to lose moisture both to the air and to the wood. As it rises in concentration its chilling point rises. In consequence of this it may gelatinize very soon after spreading. Its initial warmth enables it to penetrate and secure a foothold; its increasing concentration as it loses moisture to the wood enables it to solidify before reaching the surface of the panel. Cold glues, on the other hand, remain more nearly constant in concentration because their evaporation loss is negligible in comparison. They gelatinize less promptly, since with them setting occurs primarily as the result of drying. With animal glues, however, chilling checks penetration, thereby lessening the danger of plugging the surface pores of the veneer.

4 Assembly Time

Speed is one of the distinguishing marks of gluing operations in thick lumber. Plywood is handled in large sheets and pressed in bundles. Naturally the time interval is much longer. As was pointed out in section 2, considerable amounts of moisture are added to plywood in the course of spreading and considerable swelling results. This swelling does not occur all at once. A piece of glue-coated veneer will swell at a gradually decreasing rate for more than an hour if not confined. Putting it under pressure, though, will reduce both the rate and the total amount of its expansion. Since the swelling during the gluing process accounts for checking during the drying process, it is evident that fine plywood should be made in the briefest possible assembly time. Assembly time of 20 min. is not uncommon in making ordinary plywood, but it would be well to reduce this to 10 min. or less in making fine plywood. One firm strives to get the panels under pressure within 4 min. after spreading. This means of course that the panels are pressed in small bundles, and there is a great advantage in so doing.

It has often been noticed that when severe checking occurred it was the panels on the bottom of the press that suffered the most. Such checking is correctly attributed to an overlong assembly time for the first panels in the lot, since they obviously were absorbing water and expanding while the later panels were being spread. High bundles are apt to cause checking, especially if they prolong the assembly time of any of the units in them. Sometimes the bundle size is limited to 12 panels for the sake of rapidity and minimal expansion.

Long assembly times (that is to say, long delays before going to press) operate to the disadvantage of the veneer maker, no matter what the glue. There are four types of defect which they tend to cause: namely, face checks, open veneer joints, blisters, and dislocation of the set glue, with consequent weakness. Animal glue is not immune to the difficulties resulting from overlong assembly times, but the knowledge that animal glue will set soon probably serves to put the veneering crew on their mettle and furnishes an incentive to get the panels under pressure before the glue has become too stiff.

It often happens, however, that the spread glue solidifies before the panels are pressed. This has led to the use of hot cauls. The misuse of hot cauls has occasionally made animal glue the object of unmerited criticism. The glue in the panel is apt to be a jelly at the time of pressing. Heat from the cauls reliquefies the glue and makes it subject once again to evaporation, extrusion, and seepage. If the heat is too intense, these processes will go too far. Cases have been known where cauls that were too hot drove the glue out of the joint in spots or dried it prematurely, giving rise to blisters.

The function of the hot caul is simply to melt the glue so that it will make contact with the dry face ply. The glue will probably be fluid enough for this at 100 deg. or thereabouts. Undoubtedly there is some loss of heat in transmission through the face ply. The thicker the face, the greater the heat loss. The caul temperature ought to be dependent on the face thickness, being lower for thin faces than for thick ones. If provision is made for this, and the further precaution is taken to heat the cauls to a measured temperature (and a low one), hot cauls should be a help to the veneer maker and not a hazard.

5 Proper Surfaces for Finishing

The primary purpose of veneers is to enhance the beauty of the object to which they are added. The increasing use of rare and highly figured woods and advances in the art of finishing are weather vanes indicating the tremendous importance which attaches nowadays to fineness of appearance. There is no object in facing an article with a decorative layer of wood if blemishes are left as a result of the veneering process. Faulty methods of construction result in marred surfaces because of sunken corestock joints; ripples due to poor planing of the core; checked crossbanding, resulting from the use of moist, poorly cut, or wrong-sided veneer; defective cauls; moist faces; bad taping; lapped joints, due to long assembly time, resulting in expansion in the press; blisters; wrinkles; clouded finishes, on account of glue penetration; uncemented edges, etc. In addition to these there are defacements that are due primarily to the glue itself. These have been touched upon in the preceding sections. They are attributable, mostly, to the presence of a highly alkaline glue, although the danger and the damage can be lessened materially by measures designed to keep the glue extractives from reaching the surface of the sheet. But in order to insure the product against any chance of discoloration from this source it is best to use a strictly non-alkaline binder, of which animal glue is the outstanding example. The old-fashioned cabinetmakers used to demand an opaque glue (that is, an animal glue containing whiting, zinc oxide, or the like) in order to get an invisible glueline in their joints. How much more important, then, it is for their modern successors to place in proximity to the surface of the still more beautiful products of today a glue that is all but invisible and entirely without injurious effect.

6 Production Rate

Since veneering represents additional handling, labor costs mount, and there is need for a high rate of production in the plywood department. The greatest speed consistent with sound workmanship should be the goal of every maker of veneered furniture. Adequate mechanical equipment, planned operations, and a quick-setting, fast-drying glue are the driving wheels of the efficient veneer room. A glue that sets by virtue of cooling from 140 deg. fahr. to room temperature is bound to be swift in action. It grips whatever surfaces it may be in contact with when it chills and holds them with an ever-increasing firmness until dry, when its binding force exceeds the strength of the wood itself.

7 Panel Drying

The selection of an adhesive that will stand drying is advisable, because the use of panel kilns is becoming more and more common in the industry. Animal-glue panels come from the press with the lowest moisture content. The water-glue ratio of the solution as prepared is low to begin with; it decreases steadily by reason of evaporation on the spreader and on the sheet. The use of hot cauls induces a gentle warming and drives out still further amounts of moisture. The glue at the time of leaving the press has a comparatively low moisture content and needs but little drying. Therefore it can stand mild heating at once and the full temperature of the kiln in a few hours. Good animal glue is not harmed by dry heat. Glue in solution must of course not be heated above 140 deg., but dry animal glue can be heated to at least 200 deg., without injury.

Conclusion

The increasing use of fancy veneers and the growing appreciation of the fundamental principles of veneering construction have established the place of animal glue in the furniture factory. It is not a one-purpose glue, but a many-purpose glue, and as technical difficulties multiply, the many-sided properties of animal glue give it wider usefulness.

Although effective at any task of holding wood to wood, there are places where animal glue compares favorably with other materials which are low priced because of their abundance in nature; and there are branches of plywood manufacture where there is little need for as fine and versatile an adhesive as animal glue.

But the veneering of fine furniture demands a more delicate touch in coping with its gluing problems. Animal glue is perfectly adapted to the glue-sizing of crotch, burl, and stump veneers. Its chemical inertness and its freedom from staining effect, its perfect fluidity at the relatively low concentrations used in sizing, its speed of setting and drying, and its strengthening and moisture-excluding effects make it an ideal glue for the purpose.

Its fluidity at low moisture content, its quickness of setting and drying, its freedom from alkaline extractives and staining effect, its graded uniformity, and its dependability are the chief advantages which commend it to the manufacturer of fine veneered work. Oldest of the glues, it is as up to date as the newest of them.

Vegetable Glues

By ALBERT B. MAINE,[1] LANSDALE, PA.

This paper gives essential information about vegetable glues and the gluing of wood with them, considering veneer glue, joint glue, and liquid glue. There have been recent developments in vegetable joint and liquid glues that are not generally known, and the paper covers these in a practical rather than in a technical manner, intending to be of assistance in commercial operations. Vegetable glue is any adhesive made from a base or substance of vegetable matter. The paper describes vegetable glue that has a carbohydrate as its base and is a practical vegetable glue for use in the woodworking industries.

PLYWOOD operations reveal numerous advantages to be derived from the use of vegetable glue. It can produce joints as strong as or stronger than those produced by other glues. Vegetable glue has a great spread, and as it is applied cold, the warming of stock and the heating of cauls are eliminated, and thereby the hot glue room necessary when certain other glues are used. There is no deterioration in the dry state nor after it is converted.

Vegetable glue is practically odorless. It is easily mixed, and then requires no watching to see that is is not too thick or too thin for use. Being a glue rather than a cement, it is not as hard on cutting tools as some adhesives.

Though water resistance is not claimed for vegetable glue, it is sufficiently moisture resistant for all practical purposes in the making of furniture, pianos, and other high-grade work.

Staining in glue joints and face veneers in panel work is frequently objectionable. There are vegetable glues which may be used to the complete elimination of any stain even in the most delicate cabinet-wood veneers.

Preparing Vegetable Glues

Most vegetable glues, as received by the buyer, appear in a dry powdered form resembling wheat flour. They are prepared by three different methods. First, by mixing the flour with cold water, stirring the mixture until free from lumps and of a uniform consistency, and then adding a predetermined amount of caustic soda in solution. The mixture is then heated while being constantly stirred. A second method is the combining of flour with water and then adding a predetermined amount of caustic soda. In this case a sufficient amount of caustic soda is used to heat and agglutinate the mixture to the desired consistency, and no artificial heat is employed. The third method is to combine the flour and water without caustic soda and to convert the glue by the action of external heat.

The third method does not make a glue capable of producing the highest quality joints and is not much used. The second method produces a glue high in alkaline properties with a strong tendency to stain and is mostly used in making box shooks, mirror backs, or similar work. It is used in high-grade plywood construction where the face veneers are thicker than commonly used in furniture and like work. The first method is most generally used and produces the most satisfactory joints.

The proportions of water and dry glue used in all three methods vary from $1^{1}/_{4}$ parts of water to 1 part by weight of dry glue to $4^{1}/_{2}$ parts of water to 1 part by weight of dry glue depending on the particular kind of glue and the work on which it is to be used. The amount of caustic soda commonly used is equal to 3 per cent by weight of the dry glue. There are, however, some special-purpose vegetable glues where the amount of caustic soda is varied depending on whether one is gluing plywood where no stains must show or fire-resistant wood or some other special work.

Using Vegetable Glues

The types of vegetable glues used in plywood construction are very viscous and stringy and so are not readily applied by hand or brush methods. Most plywood making is on reasonably large-scale production which makes mechanical spreading advantageous, and the vegetable glues are handled economically on roller spreaders. This is accounted for by the ease in regulating a light spread, and also by the fact that the glue may remain in the spreader indefinitely without spoiling in any way.

The liquid vegetable glues are intended for brushwork in general cabinet work and repairing, but they may be used in any gluing machine. The joint vegetable glues are intended for building up lumber joints and are used on plate and roll joint glue spreaders.

The making of a good joint requires the even and quick spread of an adequate amount of glue on the surfaces to be joined. Hand spreading with liquid vegetable glues is practical on any job, and particularly on small or irregular surfaces. The veneer and joint vegetable glues require machine spreading, which is the method used for applying most of the glues used.

Pressure is required to bring the surfaces of the joint into contact, to force excess glue and air from the joint, to force glue into the wood cells, to hold the joint in position while glue sets, and to prevent warping. Hand and power presses are used, but the best results are obtained where power presses, on which exact pressure is recorded, are used. The amount of pressure required to make satisfactory joints has been the subject of many debates. In practical work for all-around use in building panels, 100 lb. per sq in. has been found most satisfactory, but there are conditions in the use of different kinds of woods and construction where better results would be obtained by using more or less than 100 lb. pressure. Conditions surrounding the particular work involved determine the amount of pressure to be used, and the experienced operator knows what to do.

Uniform pressure is absolutely necessary, and to that end the pieces to be glued must be true, must fit accurately, and in plywood construction each piece must be of uniform thickness in all its parts. A thick caul should be used at the top and bottom of glued plywood. Before the introduction of vegetable glue it was customary to use a hot caul between each panel. With the use of vegetable glue the hot caul is eliminated and fewer cauls are used in the stack.

[1] Sales Manager, Perkins Glue Company. Mr. Maine has been with this company for 17 years, the last 10 years of which he has served in his present position.

Presented at the Sixth Annual Wood-Industries Meeting, Winston-Salem, N. C., Oct. 15 and 16, 1931, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

The length of time that glue joints made with vegetable glue should be left under pressure depends on the work being done and on the type of glue used. For safety purposes when the regular veneer vegetable glues are used the panels are left under pressure overnight. Such a long time is seldom necessary, but was adopted as a standard precautionary time. Quick-setting glue makes it possible to remove stock from pressure in two hours, and in the case of joint glue even a shorter period is possible.

Preparation of Wood for Gluing

Too much emphasis cannot be laid upon the importance of the proper preparation of wood for gluing. Drying, conditioning, and machining may be more responsible for the successful building of glued-up stock than the glue used. These facts are assumed to be generally known. It is believed, however, that the question of moisture should be given consideration. Moisture changes in wood make stresses which favor warping, checking, and even separation of plies, and should therefore be avoided as far as possible.

The range of moisture content of dry wood in service is covered in "The Gluing of Wood,"[2] by T. R. Truax.[3]

The builder of panels having highly figured face veneers seriously considers the amount of water used in his glue as well as the spread and the quick-setting qualities of the glue used, because he desires above all things to avoid the reactionary stresses. Some figures on the amount of moisture absorbed by veneers serve to show the necessity of careful handling of all veneered work.

These calculations assume that all water in the glue is absorbed by the wood and that none evaporates into the atmosphere during assembly. The percentages of moisture added are based on the weight of air-dry wood.

Since the percentage of moisture added depends very considerably on the density of the wood, the calculations have been worked out for birch, which is an average dense wood weighing about 44 lb. per cu. ft., and for poplar, which is an average light wood weighing about 27 lb. per cu. ft. Both weights given represent the average for lumber in an air-dry condition.

Moisture absorption has been calculated for three glue spreads for each glue having a certain water ratio. The spreads used would correspond to a moderately light, a medium, and a moderately heavy application. The coverage for such spreads is given in gross square feet of single veneer covered by glue made from 1 pound of dry-glue base.

The spreads of vegetable glues are approximately proportional to the weight of the liquid glue made from one unit of glue base. If the spreader is set to spread a $2^1/_8$ to 1 glue at the rate of 45 sq. ft. per pound of glue base, and then without changing the spreader adjustment another glue having approximately the same consistency but with a different water ratio is put on the spreader, the spreads would be roughly as follows: For a 1.2 to 1 glue, 31.6 sq. ft.; 1.5 to 1, 36 sq. ft.; 2.12 to 1, 45 sq. ft.; 2.5 to 1, 50.5 sq. ft.; 3.5 to 1, 65 sq. ft.

Tables 1 to 5 show the moisture added by the glue. To obtain the total amount of moisture in the finished plywood the amount of moisture in the wood before gluing would have to be added.

Laying Linoleum

Linoleum tops, etc. are laid with vegetable glue as an adhesive in what is termed two operations. The first operation is the ordinary building of three-ply construction using the regular core lumber and cross-banding veneer. These cross-banded cores are handled through gluing, drying, and sanding operations like commercial three-ply work. The second operation consists in laying the linoleum face and a suitable back veneer. This is done in quantity production by running the cross-banded core through the spreader and building up a bale for pressure as usual. No cauls are used, the work being laid face to face and back to back. Pressure of 100 lb. per sq. in. is sufficient. When removed from pressure, the tops, or panels, are carefully piled with $^1/_8$-in. stickers between linoleum faces and $^3/_4$-in. stickers between backs. As the linoleum faces are impervious to moisture, the drying action must come through the edges and back. So it is best not to try to hasten the drying through use of a panel dry

kiln, but dry with air circulation only, at factory-room temperature. To complete the building of the tops they are trimmed after drying and banded all around with a wood veneer band equal in width to the full thickness of the top. While there is a decided advantage in using a low-water-content quick-setting glue on such work, it is done successfully with the regular glues.

Laying micarta, formica, and similar materials is done with vegetable glues in the same manner as laying linoleum.

Gluing Fire-Resistant Wood

The question of gluing fire-resistant wood will no doubt become more and more important because of the constantly growing interest in and use of such wood in building construction in the large cities. The gluing of this wood requires a special technique. The chemicals which are used for impregnating the wood and making it fire resistant render it difficult to get a satisfactory joint with any type of glue. Special types of vegetable glues will glue this wood as good as any glue. The best results are obtained from the quick-setting, low-water-content vegetable glue.

Joint Vegetable Glue

In lumber gluing, particularly on edges, the desired speed of production usually requires a quick-setting glue. Such a vegetable glue has been introduced within the last two years, and is increasing in use very rapidly. It is of special value at the glue-clamp carrier where production in core construction is required. While developed especially for lumber joint work, it can be used for veneering. Advantages in the use of joint vegetable glue over other joint glues are the same as in the use of veneer glues. Actual first cost and final cost receive chief consideration, but the elimination of continuous heat in gluing operations makes more contented workers and is a factor not to be overlooked.

The joint vegetable glue is mixed in the same manner as veneer vegetable glue. When converted it has a creamy color. Its working life is indefinite if kept covered when not in use. It is best applied with a roll-joint glue spreader with the roll operating at 45 r.p.m. It can be used on the plate spreader, but not on the ordinary plate as applied for use of hot glue. A special plate is made for vegetable joint glue work.

The water ratio used in this type of glue is from 1.3 to 1.6 parts of water to 1 part of glue by weight, depending on the time of setting required, strength desired, and drying conditions. Removal of stock from clamps in less than 30 minutes is possible, but not generally recommended. Conditions in the plant determine that point. The spread for joint glue on edge gluing is from 24 sq. ft. per lb. to 30 sq. ft. per lb., depending on the amount of water used. It would be possible to spread more or less, but the spread mentioned will give a light bead for the squeeze-out. An excessive squeeze-out shows a waste of glue and retards the set.

For pressure on joint work the average clamping methods are used, but as in the use of other glues caution must be exercised against the use of excessive pressure. Enough pressure should be used to hold the stock firmly together. A starved joint is just as possible and perhaps more dangerous in a lumber joint than in a veneer joint.

The time under pressure required for lumber gluing depends entirely on the conditions. The most important of these affecting the time required for pressure are, listed approximately in the order of their importance, as follows:

(1) Degree of contact at glue joint; edges to be joined must be cut square and true.

(2) Moisture content of lumber; not over 6 per cent if speed in setting is desired.

(3) Tendency of lumber to twist on removal from clamps or in drying. Such so-called soft woods as bass, poplar, and chestnut require a shorter pressure period than some of the harder woods, because of their lesser tendency to twist.

(4) Quantity of glue spread; use only enough to give a small, beady squeeze-out with the pressure used.

(5) The water content of the glue; the lower the water content the quicker the setting.

(6) Clamp-carrier drying conditions; artificial heating and ventilating aid in shortening the time needed for pressure.

Lumber Preparation for Joint Gluing

Owing to warpage and uneven surfaces it is sometimes difficult to obtain strong lumber joints. This is especially true in edge gluing where there is more strain and less glue contact surface. With lumber gluing it is extremely important to obtain the best possible degree of contact between the surfaces to be glued. The full strength of a glue is developed only by lumber cut by the best commercial methods; if not, the joint may show a variation in strength of from only a few pounds to more than 1000 lb. per sq. in., depending entirely on the degree of contact.

It is not good practice to joint lumber and allow it to stand for any length of time before it is glued. Lumber continually works and twists under the strains produced by changes in moisture, and for this reason better contacts and consequently better joints are produced when the surfaces of the lumber to be glued have been freshly prepared.

Based on comparison of glue strength made with both sawed and jointed lumber, it has been found that there is not much difference between smooth-sawed joints and those made on the jointing machine; but if sawed joints are rough, irregular, and out of square, it is impossible to make good joints. The ordinary circular rip saw will rarely make a joint good enough to glue. With a miter or planer saw properly filed and fitted, smooth sawed joints can be made.

Obtaining Maximum Joint Strength

Joint glue when compared with any other vegetable glue having the same body will show a superiority in both strength and set. The most important variables affecting the strength of the joint are, listed in the order of importance, as follows:

(1) Degree of contact; the better the contact, the more strength.

(2) Body and water ratio of glue; the heavier bodied and lower water ratio glues develop greater strength.

(3) Moisture content of lumber; preferably not over 6 per cent.

(4) Time under pressure; average for safety 35 min., minimum under good conditions 25 min.

(5) Degree of pressure; use only enough pressure to hold stock firmly together.

Vegetable Liquid Glues

While the vegetable liquid glues have been under laboratory and practical observation for several years, they have come to the attention of the woodworking trade only recently. These glues are used on the cabinet makers' bench and in repairing, and displace the hot-glue pots and steam coils in cabinet and assembling work. Also they are used in making joint work on equipment such as the Linderman machine and replace hot glue on that operation. These glues are in liquid form and do not deteriorate. They are readily spread with a brush by hand methods. No special technique is required in their use.

Correcting Defects in Gluing Operations

It is possible to misuse any glue or to have defective work in gluing operations, regardless of what glue is used. By a knowledge of the cause of such defects the intelligent operator either will avoid trouble or will discover the reasons of his particular trouble when it occurs. It would be well if every plant had a competent personnel to check up on gluing defects, which seldom result from one condition alone, but from a combination of circumstances. The inspection of a defective sample in itself cannot always determine what caused the trouble, but such inspection, together with a full knowledge of the manufacturing process, should enable one to solve the problem accurately. It is not possible to present a complete key to the causes and remedies for all gluing defects. A number of the more common causes are given in "The Gluing of Wood," by T. R. Truax, Department of Agriculture Bulletin No. 1500.

Casein Glue

By W. F. LEICESTER,[1] NEW YORK, N. Y.

Casein glue, made from soured skim milk, then dried, ground, and blended, has been in use in Germany for 50 years and in the United States for 30 years, but it was not until the World War period that it came into general commercial use. It was then that easy-to-use formulas of standard type were developed for the production of waterproof plywood in airplane construction. It now has general use in the woodworking industry. Casein glue in the past has relied upon harsh alkalis as a waterproofing agent. The casein glue of the future for veneering will be relatively only slightly alkaline, but will be high in water resistance through the addition to the dissolved glue of a chemical solution. The smaller user will have a glue that will carry overnight without loss of strength, will be quick setting and strong, and that will have sufficient water resistance for ordinary needs.

USE of casein glue in industry is familiar to all in a general way. Casein is a dairy product. It is the same as cottage cheese in that it is the curd formed in skim milk when it sours. Commercially, casein is made in centralized creameries by natural or acid souring of skim milk. When dried, ground, and blended, it is the raw material from which is made the casein glues used by the woodworking industry. Centralization and conservation in the milk industry of the United States have resulted in a large increase in the production of casein, freeing this country from dependence upon imported supplies. Forty to fifty million pounds of casein are used industrially in the United States each year. The chief use is in the coating of paper; the next is as adhesives for wood, fiber, paper, etc.; other uses are for sizing veneers, walls, and wallboard and as the binding and waterproofing ingredient in plastic paint, calcimine, and whitewash. Solid casein in various colors is fabricated in rods, tubes, and sheets, from which it is remanufactured into buttons, drawer pulls, pens, and various novelties.

While casein glue has been used in Germany for upward of 50 years and in the United States for 30 years, its general commercial use dates from the World War period, when easy-to-use formulas of standard type were developed for the production of waterproof plywood in airplane construction. When as a result of the wartime record of casein glue the woodworking industry seized upon this new product as the solution of gluing problems, it was not quite ready for such commercial development. The formula in use at that time was highly alkaline, so that the glue affected the skin of workmen, and it stained acid woods, such as oak, mahogany, walnut, etc. When the glue set, it was very hard on machine knives. In general, it was difficult to handle, and a prejudice which existed for several years was developed against casein glue. Today, with wider chemical knowledge and with greater facilities for laboratory and factory experiments, the sphere of usefulness of casein glue has greatly widened, the old-time prejudice has disappeared, and the product is generally accepted by the woodworking industry. One now thinks of casein glue as not merely a glue or cement for exposed work where water resistance is paramount, but as an all-around adhesive to be used wherever great strength combined with high or low resistance is required. It has become possible to fit the formula to the job; to produce not just one casein glue, but a wide range of glues; to meet all wood-gluing needs from the veneer fuselage of the globe circling "Winnie Mae" airplane to the gluing of $^{1}/_{32}$-in. imported walnut, hardwood, or other modern veneers; from the laminated bowling pin to leg blocking.

A modern casein glue is easy to mix and easy to use. It comes to the user as a dry powder which has only to be mixed in cold water to form a liquid glue. It is quickly prepared for use without the addition of chemicals or the application of heat. It finds favor with both large and small factories because it meets the needs of both. The plant that uses one or two pails of liquid glue daily mixes a pailful at a time, either with a hand-operated mixer or merely in a pail with a stick. The larger factory uses a power-driven mixer of from 8 to 75 gallons capacity. In each case the mixing procedure is the same. The cold water is placed in the mixer, and the glue powder is sifted in while agitation proceeds. Then the mixing stops for 15 minutes, during which period the casein and chemicals soak up the water, thicken, and begin to dissolve. Mixing for 5 minutes finishes the dissolving process, so that at the end of about 20 minutes the liquid glue is ready for use. The consistency of dissolved casein glue may be compared to that of thick cream. It spreads readily by brush or by machine spreader. It can be used safely for the gluing of softwood or hardwood joints and for gluing any type of veneer. Summing up, the modern casein glue is easily mixed and spread, is strong enough for any gluing job, is usually highly water resistant, is quick setting, is reasonably free from stain, and offers no special tool problems in the machining operation. As to cost in the glue line, casein glue lies between that of vegetable and animal glue. It is difficult to give a specific cost figure because of the wide formula range which depends upon the work to be done and the results required.

The present use of casein glue in the woodworking industry is as wide as the industry itself. The original and most obvious use is in the fabrication of airplanes, not a large-volume business today. This is one place where metal is displacing wood, and not necessarily to the improvement of the airplane, but chiefly to the lowering of cost. Casein glue does a good job in the laminating of hardwoods for auto-body parts. Laminated and block flooring, glued with casein glue, is finding a widening field of use, and in this work it has been proved over a period of more than ten years that a casein-glued joint will stand up perfectly under conditions of hard usage and more than usual exposure. Church furniture and seating, especially plywood seating, is widely done with casein glue. This type of furniture leads a fairly strenuous life; plywood seats must stay tight right up to the unprotected edge. Doors and millwork constitute a fairly obvious field for water-resistant glue. Used at first only for outside doors, casein glue is today generally used for all veneered doors, for the core sections, the panels, and for the veneering of stiles and rails. One of the

Presented at the Sixth Annual Wood-Industries Meeting, Winston-Salem, N. C., Oct. 15 and 16, 1931, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

latest developments is a glue for the dowel assembly operation which works in the automatic dowel gluers.

Coming to the consideration of casein glue in the furniture industry, at first it may be thought that here is no field for water-resistant glue because furniture stays within the home and lives a quiet life. There is an increasing use of casein glue in this important branch of woodworking, not only in Grand Rapids, Rockford, and other Northern points, but also in the South. The manufacturer of high-grade furniture uses casein glue for veneering in order to safeguard the quality of the goods, as an insurance against loose veneer which might be caused by conditions of use or climate beyond his control. Furniture manufacturers generally use casein glue for overlay and for core and block gluing, for reasons of convenience and economy. Throughout the industry there is a trend toward using water-resistant glue for important veneering such as tops and fronts, the parts that have unprotected edges. Leaving the matter of whether it is good policy to use water-resistant glue, look into its use in the furniture factory and see if it functions smoothly in production and if it removes any of the troubles that are so often inseparable from the veneering department. To begin with, casein glue promotes quick assembly of panels between the spreader and the press; and this is a basically good thing, because it gives the trouble maker, glue moisture, less time to get in its work. A load of casein-glued panels should be under pressure 15 minutes after the load is started; 10 minutes is better. The shorter the period, with any glue, the better. Here is what short assembly with casein glue means: a thin spread of a heavy-bodied glue; a minimum of glue moisture going into the veneer; minimum expansion of the crossbanding due to thin spread, and quick pressure, thus a lessening of internal stresses in the panel and consequently less tendency to checking and warping. Some day there may be realized the ideal of a dry gluing process, but with modern casein glue the industry is moving in that direction. Other advantages are quick setting (pressure can usually be safely released in three hours), quick redrying, and elimination of glue stain through thin veneers due to the thin spread of heavy glue not penetrating to the face, and to short period of pressure. An average size load of panels can be built in 10 to 15 minutes with casein glue because the glue, being free flowing and easily spread, the glue-spreader rolls can be run relatively fast, thus speeding up the entire veneering operation. As to glue spreaders, spiral corrugations rather than the conventional lateral corrugations are recommended for the spreading of casein glue. The spiral corrugations, cut 12 to the inch and 0.03 in. deep, spread a very fine and economical film of glue, which on the veneer almost has the appearance of having been brushed out by hand. The spreading of a fine, even film of glue is more important today in the furniture industry than ever before, because the light or natural finishes now used do not allow for the covering up with stain or shellac of veneer imperfections due to glue stain or blisters. If the spread of glue consists of alternate hills and hollows, and the hollows dry out before pressure is applied, the result is blisters in the water-staining operation, which become visible when the finish is applied and which necessitate expensive repairs. Water stain is a real test of the veneer-gluing job, and it is of course obvious that a well-built casein-glued panel should come through this operation without blistering or loose edges. Casein-glued panels can safely be treated with a water-bleaching solution, if required. Some manufacturers that use casein glue remove veneer tape from the surface of glued panels with a steam jet, thus cutting down the drum-sanding operation and preserving a greater thickness of face veneer. Another operation, well done with casein glue, is overlay gluing. A thin film of heavy-bodied glue is applied, resulting in minimum squeeze-out and speedy setting. Turning to joint gluing, casein glue is being extensively used in blocking, core gluing, and banding. It is applied by brush or single-roll spreader, can be removed from pressure quickly, and soon thereafter machined. The fact of its wide use in blocking work which has to be turned proves the statement that modern casein glues are not hard on knives. Other furniture uses are in gluing formica and other bakelite veneers to wood. The use of these durable materials is increasing; they are hard to glue, but casein glue holds them permanently. In bending and gluing veneers in one operation, the quick set of casein glue permits frequent reuse of forms, and the stiffness of the casein-glued joint when set gives bent work desirable rigidity. Another use is in the sizing of thin, delicate veneers such as crotches and burls. By a special treatment these veneers are given strength combined with flexibility, which makes them glue and finish better and helps to prevent checking.

A final word might well deal with present and future developments in the manufacture and use of casein glues. In the field of use it is to be noted that mixing and spreading machines are being improved. There are the spiral corrugations, already successful. The latest veneer spreader has the lower glue box adjustable so that the last of a batch of glue can be brought right up to the lower roll and so used up entirely without waste. Casein-glue-mixing machines are now available with a sifter built in, which is driven off the shaft, and beats the glue powder through a sieve, thus preventing lumping and producing an extremely smooth, varnish-like glue. A two-speed mixer is being developed which will allow rapid mixing while the glue powder is being added, and which can thereafter be run at slow speed while the batch is dissolving, thus speeding and improving the mixing operation. Chemically, the tendency is toward more complicated glues for large-scale use and toward simpler glues for smaller use. The casein glue of the past has, generally speaking, relied upon harsh alkalis as a waterproofing agent. This has caused stain, hardness on tools, etc. The casein glue of the future for veneering will be relatively only slightly alkaline, but will be high in water resistance through the addition to the dissolved glue of a chemical solution. The smaller user will have a glue which need not be used up the same day as mixed, which will carry overnight without loss of strength, and which with this conveniently long life will be quick setting and strong, and will have sufficient water resistance for ordinary needs.

WDI-54-5

Blood Albumin and the Woodworking Industry

By C. B. SMITH,[1] CHICAGO, ILL.

Blood-albumin glue is probably the latest commercial adhesive. Its first use apparently was in the making of plywood canoes. The World War created an intensive demand for water-resistant plywood glues, and much of it was used in airplane and boat construction. Its source is beef blood as a by-product of the packing-house industry. It is essentially a hot-press glue. There are several types, all a mixture of blood albumin, water, and an alkali.

COMMERCIAL blood albumin, as its name signifies, is a material obtained from beef blood as a by-product of the packing-house industry. It is a complicated mixture composed mainly of hemoglobin, serum albumin, and serum globulin, together with small amounts of sugars, fats, salts, coloring matter, and other substances normally found in blood. The main characteristic of blood albumin is its ability to form an irreversible gel when its water solution is heated to 160 deg. fahr.

The manufacture of blood albumin will be briefly described, and more time will be given to a discussion of its uses in the woodworking industry. Beef blood from the killing floor of a modern packing house is collected in tanks, in which it clots. The clot-forming protein, or fibrin as it is called, is removed from the liquid blood, and the latter is pumped to the drying plant to be dried in shallow pans in tunnel driers. The temperature of the drying air is kept below 130 deg. fahr. at all times in order to avoid any possibility of coagulating the blood albumins. The dried flakes contain 5 to 7 per cent of moisture and are deep red, almost black in color. They easily dissolve in water, after a preliminary soaking of about one hour, to form a dark red solution with properties similar to the original blood. In the flake form they may be kept for a reasonable length of time, although if kept in a moist and warm place they gradually lose some of their solubility. In water solution, they are food for bacteria and will decompose in time unless properly preserved.

It is difficult to determine when blood albumin was first used as an adhesive, although it probably was much later than many other glues. It is known that the early Chinese used a mixture of blood and lime as a protective covering for wood, but it is doubtful whether it was used as a glue at that time. About 1910, reports were prevalent in this country that a water-resistant blood glue had been discovered in Russia, but early experiments met with little success, and much plywood was spoiled in attempts to use blood as an adhesive.

Several years later Messrs. Haskell and Beiger together did the first recorded work with blood-albumin glues in this country. After a successful formula had been evolved, their first project was the making of plywood canoes. Shortly thereafter, the World War created an intensive demand for a water-resistant glue, and blood albumin came forward as an answer to the problem. Several large plants worked day and night turning out water-resistant plywood for the Government and for many private concerns. Practically all of this plywood went into airplane and boat construction, and it can be safely said that it was the most water-resistant glue obtainable for the purpose. Since then this unusual war demand has fallen off, and blood-albumin glue is not used for plywood to as large an extent in this country today, although it is admirably suited for many purposes and conditions of service and is still used by several large manufacturers. It has been a source of much pride to one such manufacturer that his plywood was used exclusively in many noted planes, such as Col. Charles Lindbergh's "Spirit of St. Louis," and the planes of Byrd, Chamberlain, and many others equally famous. In many countries of Europe, blood albumin is still extensively used in water-resistant plywood, although it is commonly mixed with other albuminous adhesives, such as casein or soy-bean flour. It is probable that such mixtures will soon be favored in this country, as they tend to lower glue costs, and if properly used give results comparable to those obtained with straight blood-albumin glues.

Blood-albumin glue is essentially a hot-press glue. Several years ago wood technologists at the Forest Products Laboratory discovered a cold-process formula which may be found in several of their publications, such as Bulletin No. 1500. As this formula, to the best of knowledge, is not used on a commercial scale, discussion will be limited to blood-albumin glues requiring the application of heat.

In searching through the patent literature one finds several types of blood-albumin glues. One of these early patents refers o a mixture of blood albumin, water, and silicate of soda, while later patents use lime and ammonia as the required alkali. Repeated tests have demonstrated that maximum water resistance is acquired through using a mixture of blood albumin, water, and a very small amount of a weak alkali such as ammonia, borax, or soda ash. In other words, a heat-coagulated albumin is more insoluble and water-resistant than one coagulated by means of a chemical, such as lime. However, such a glue requires less water in its make-up than others using a stronger alkali, and this fact results in an increased glue-line cost. For this reason, alkalis which act as extending agents are commonly used with blood albumin in order to obtain a lower glue-line cost, even though the water resistance of the resulting plywood is slightly lowered. As an example, in making a straight blood-albumin glue, only about 125 parts of water are required for each 100 parts of albumin. Other formulas, using various alkalis, increase the water content to 200 parts, and in admixture with other proteins, such as casein, the water content is still greater per hundred pounds of dry glue. Following the trend of present-day gluing practices and demands, all manufacturers of water-

[1] Chemical Engineer, Armour Glue Works. The author was graduated in 1913 from Cornell College, Mt. Vernon, Iowa, with B.Sc. degree. Was with Diamond Match Company as chemist from 1914–1920, the last four years as chemist for the Utah plant for recovery of potash salts from Great Salt Lake. Then followed two years as chief chemist for the Salt Lake Potash Company of Salt Lake City, a year with Armour & Co. in Chicago, and five years as Assistant Manager of the Utah plant of the Morton Salt Company. Since 1928, he has been with Armour & Co.'s Research Laboratory, the last two years in research work on blood albumin and its relations to various industries.

Presented at the Sixth Annual Wood-Industries Meeting, Winston-Salem, N. C., Oct. 15 and 16, 1931, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

resistant glues are continually endeavoring to work out better glue formulas which will give maximum dry and wet strengths at the lowest possible glue-line cost.

Applications of some of the glue formulas herein briefly mentioned are ably discussed in publications of the Forest Product Laboratory. There are many factors—such as details of glue spread, assembly time before pressing, temperature, amount and duration of pressing, and the like—which are so dependent on plant conditions and the nature of the wood used that it is not advisable to discuss such variables in a paper of this kind. As with other glues, such factors must necessarily be worked out in each plant for each set of conditions encountered. However, there are several characteristics of plywood made up with blood-albumin glue that are noteworthy and of interest.

As previously stated, plywood made up with blood albumin is of primary importance because of its water resistance. As an example of the practical importance of such a trait, an article by Mr. J. W. Beiger in the March, 1930, issue of *Veneers Magazine*, says: "Our first molded canoe was made early in the fall of 1916. It was made from one sheet of plywood approximately 57 in. wide by 17 ft. long and $^{3}/_{16}$ in. thick. This panel was put over a vat of water and boiled until it was pliable (about 3 hours), then placed on the mold and dried under pressure. Oak stems were placed at each end inside and out, and birch was used for gunwales and thwarts. Seats were hung from the gunwales and the canoe was ready for the water."

Since that time many similar canoes have been made and successfully used under conditions which demonstrate the value of blood albumin as a water-resistant adhesive.

In recent years, one has seen plywood panels made with blood-albumin glue, then soaked in hot water until pliable, and placed in an embossing press and allowed to dry under pressure. Very striking deformations of the wood fibers are made possible by this procedure without affecting in any way the strength of the finished embossing. Imitations of carvings are thus made possible in which chisel marks and other details are faithfully reproduced. It is this property of the coagulated albumin becoming plastic under application of steam and pressure and returning to its original condition when dry that is one of the most striking characteristics of blood albumin.

Another valuable feature of plywood made up with blood-albumin glue is the absence of dulling action on cutting tools, such as saws. This is due to the fact that the glue is organic in composition. In the past, it has been found that such joints had a tendency to become brittle on aging due to the glue becoming too dry, this resulting in a lower joint strength, but the inclusion of hygroscopic materials in the glue mixture has aided in overcoming this trouble.

By this same inclusion of a hygroscopic material, such as glucose, in blood-albumin glue, the Forest Products Laboratory has been able to devise a process for making up plywood from very thin veneers. Strips of absorbent paper are impregnated with glue mixture and dried at a low heat to avoid coagulation of the albumins. These strips are placed between plies of veneer, and the panels are pressed in a hot-plate press in the usual manner. By this method, in which a minimum of water is introduced into the glue line, it is possible to glue up exceedingly thin veneer without checking, warping, or staining.

Discussion up to this point has dealt with glues made from flake-blood albumin. It is also possible to obtain blood albumin as a spray-dried product. In this form, it is a dark red powder with properties similar to the flake form. However, it is interesting to note one use of this product in the wood industry concerning which little has been published. This is in the gluing of green veneer, or wet veneer direct from the lathe. It has long been a dream of woodworking engineers that some time it might be possible to work out a straight-line production of plywood, taking veneer from the cutting lathes directly through a glue spreader, press, and drier in some manner that would be commercially practical. Much plywood has already been made on the Pacific Coast from soft woods by spreading the veneer with a powdered blood-albumin glue and combining the pressing and drying operation in multiple-plate hot presses having grooved plates to allow the escape of moisture as steam. When one considers the savings made possible by a straight-line production of plywood, it serves as an impetus to further research. Even though such production is limited to water-resistant plywood of the cheaper grades, such as box plywood, it seems entirely probable that blood albumin will be the glue responsible for solution of the problem.

Spray-dried blood albumin is also used extensively as a thermoplastic in the molding of small objects such as buttons. In connection with wood products, it is used with cork, sawdust, paper pulp, and the like in the molding of many articles.

The two forms of blood albumin which have been discussed are dark colored. If a light colored blood albumin is desired, it is necessary to use a third form, the so-called light albumin. This is made from beef-blood serum, or blood liquid, from which the corpuscles have been removed in passing through a centrifugal separator. Its chemical and physical properties are quite similar to those of whole blood products. In the woodworking industry, it is used in the edge-gluing of veneer for pieced faces for water-resistant plywood. The exposed glue line in a pieced face thus treated is water-resistant and not discolored by stains.

Besides the uses of various forms of blood albumin in applications of interest to engineers, there are uses of interest to all. Indeed, there are few industries which are not confronted with problems in which the use of blood albumin might be of service.

It is desired to acknowledge indebtedness to the wood technologists of the Forest Products Laboratory and to Mr. Haskell and associates for items taken from their publications.

Oil-Seed-Residue Glues

By I. F. LAUCKS[1] and GLENN DAVIDSON,[2] BLOOMINGTON, ILL.

I. F. Laucks

The paper describes the history, characteristics, uses, and limitations of soya-bean glue, or generically of seed-residue glue. This is the newcomer in the glue field, its use practically dating from 1923. The adhesive base of the seed-residue glues is the cake or meal resulting from the oil-pressing of soya beans, peanuts, cotton seed, etc. In the manufacture of plywood it is stated that the tonnage of the oil-seed-residue glues equals that of any other type of glue. In connection with the soya-bean glues there has been developed the use of carbon bisulphide as an agent to increase water resistance.

Glenn Davidson

Oil-seed-residue glues are glues the adhesive base of which is the residue cake or meal resulting from the oil pressing of soya beans, peanuts, cotton seeds, and the like. These oil-seed-residue glues are newcomers in the plywood field, for prior to 1923 they were unheard of commercially, but by 1929 they had reached such importance that, in the manufacture of plywood, the total tonnage of oil-seed-residue glues used approximated, if not exceeded, that of any other type of glue.

History of the Oil-Seed-Residue Glues

The Pacific Coast served not only as the birthplace but also as the cradle in which oil-seed-residue glues developed into a real member of the glue family.

From the beginning in 1923 until 1926, soya-bean glue faced the typical discouraging and disheartening uphill fight that is faced by most new products until all production problems are solved and the products themselves win the full confidence of the users. One of the most serious problems encountered in the production of commercial soya-bean glue was that of the chemical condition of the soya-bean meal available. The chemical state of the meal under suitable conditions may be rapidly modified by such factors as oxygen, moisture, bacterial and chemical action. This meant that but few lots of the soya-bean meal reached the Pacific Coast with the chemical state of the meal altered only slightly from the state in which it existed in the beans as they were harvested from the fields in China, but in most of the lots there had been considerable alteration, and in some of them this alteration was extremely great. Thus it was found that the lots of soya-bean meal which were presented in the early days as possible sources of soya-bean glue differed among themselves through about the same range of characteristics that a raw egg differs from a fried egg. The standardization of the chemical state of the meal constituted three major steps. First, a working arrangement was perfected with one of the largest Oriental mills producing soya-bean cake which permitted the standardization of their product within certain limits as it left their mill. Second, the meal intended for glue was transported to the United States by the fastest steamships, instead of the old method of shipping by tramp steamer or schooner. Third, a method of chemical treatment to be used in this country was developed which insured the uniformity and stability of the resultant glue. These are extremely necessary characteristics of a base material to be used in the manufacture of a commercial veneer glue.

Aside from manufacturing and standardization difficulties, soya-bean glue had other difficulties to surmount in the form of the natural sales resistance to a new and different product. Soya-bean glue does not possess the typical physical characteristics ordinarily described as "glue like;" that is, it is not sticky, tacky, or sirupy; on the contrary, it is rather "soupy" or "mushy." These physical characteristics were really a blessing in disguise, for today they represent one of the strongest arguments for the use of soya-bean glue. Practical glue men looked at the soupy, mushy liquid in the glue spreader, tested it between their thumb and forefinger for tackiness, which was conspicuous by its complete absence, and then shook their heads, saying such a thing could never stick to plywood This first impression was so strong that many refused to believe that the plywood glued with this glue could really be stuck even after the packages had been opened and the panels found to exhibit very good adhesion.

Another handicap was that no one had ever heard of a water-resistant glue from a vegetable source. The name "vegetable glue" connoted starch glues, and it was well known that vegetable glue was not water resistant.

The year 1926 proved to be the turning point in the life history of a soya-bean glue. Prior to this time there had been an insistent demand for plywood of greater water resistance on the part of automobile manufacturers, who were beginning to buy large amounts of plywood. Finally, the Pacific Coast plywood manufacturers announced through their association that they wished to arrange a series of competitive demonstrations of all water-resisting plywood glues. These demonstrations were made during April, 1926, with nearly all glue manufacturers participating. The results in these tests obtained with soya-bean glues were so outstanding that these glues were almost immediately adopted by all the Pacific Coast plywood manufacturers and have been in continuous use there.

Present Uses of Soya-Bean Glues

The present uses of soya-bean glues embrace the entire fir and pine plywood industry, together with a large share of the plywood

box industry and the furniture plywood industry so far as glass backs, drawer bottoms, and similar panels are concerned, but not tops, drawer fronts, and other plywood where fancy veneers are used extensively. A considerable tonnage is also used in the lamination of insulating board to be used in refrigerators and for other purposes.

So far as fir and pine plywood is concerned, soya-bean glues offer at the same time a most satisfactory, strong, water-resistant, easily used, and low-cost glue. The fir plywood manufacturers will not consider any other than a water-resistant glue. They were the first to use water-resistant glue generally, and now the term fir plywood has come to imply water resistance, whether so stated or not. This is one of the reasons why fir plywood finds such a large use for industrial purposes. Some of these uses are in automobiles, shipbuilding, railroad cars, and refrigeration, besides many uses in buildings and construction. An interesting use which has been developed only lately is for concrete forms. Builders are finding that plywood can be substituted for the old-style concrete form construction, with a very decided advantage in favor of plywood. There are 17 plants in the Pacific Northwest producing fir plywood. The smallest of these will produce about a hundred thousand square feet of plywood per day and the largest about three hundred thousand square feet.

All users of glue are familiar with the fact that certain woods are more easily glued than others with a given glue. In fact, there is no glue known that gives equally good results on all woods. In the case of fir and soya-bean glue it turned out that these two seemed to have a natural affinity—a very fortunate thing for a new glue introduced in the Pacific Northwest. Not only were these advantages in adhesion and water resistance, but also the use of soya-bean glue enabled the fir plants to speed up production, because of the ability of spreader crews to handle stock faster on account of the peculiar consistency of the new glue and also because spreaders could be run at a higher speed without danger of foam.

When one is using glue by hand methods, one can choose the type of glue to be used, with no regard for any of its characteristics other than adhesion. It is quite different with a plywood glue. The latter must fit into a mechanical process, and the production and cost of the process depend to a large extent on how well the glue fits. Properties of the glue such as uniformity, life, foaming tendency, time of setting, consistency, abrasive power, and so on may become nearly as important as adhesion in a plywood glue.

The cost of the glue line is only one item in making plywood, and one of the smallest items at that. If by spending a dollar more on the glue line, the plywood manufacturer can save two dollars elsewhere, he has a net gain of one dollar.

A good example of this is in the plywood box shook field. Here, cost is the prime consideration, and all glues except starch and soya-bean glues are eliminated on this score. Even soya-bean glue would be out on this point were it not for a number of manufacturing advantages which it possesses. These advantages are so great that the total manufacturing cost of the finished plywood shooks is less with soya-bean glue than with starch. In addition, the soya-bean glue produces moisture-resistant plywood.

When soya-bean glue is used, the veneer is glued up at a relatively high moisture content, say 20 to 35 per cent. Single-ply veneer at this moisture content is tough and accordingly does not break easily as is the case with dry veneer such as must be used with starch glue. When single-ply veneer is glued at 20 to 35 per cent moisture content, it is necessary to redry the panels. Experience has shown, however, that single-ply veneer can be dried to 20 to 35 per cent moisture and the panels redried, in most cases, at about the same drying cost for both operations that is required for the single operation of drying the single-ply dry enough to glue with starch glue.

There are many other manufacturing advantages resulting from the use of soya-bean glue. For example, it is usually possible for a given glue crew to "lay up" more stock with soya-bean glue.

The absence of extreme stickiness and gumminess in the soya-bean glue makes the handling of center stock coated with it very similar to the handling of veneer without glue at all. A further advantage of soya-bean glue lies in the almost complete elimination of glue-spreader breakage of thin center stock. Thus it is seen that the very characteristics that were the basis of the early predjudice against soya-bean glues became one of their greatest selling advantages.

In the manufacture of furniture plywood, soya-bean glue is finding considerable use in the manufacture of glass backs, drawer bottoms, and similar panels. The reason for this is its comparatively low cost and its water resistance. Water resistance is more essential for this class of furniture plywood than it is for tops, etc., since these have an extremely protective coating against moisture of high-grade lacquer, while the drawer bottoms, glass backs, etc., enjoy little or no protection of this kind and are so left exposed to ravages of moisture when the furniture is stored in a basement or under similar conditions. Further, many backs and drawer bottoms are finished by dipping in a water stain, and in such cases moisture resistance is particularly desirable.

Water-resistant glues in the United States plywood industry are comparatively a recent development, only dating from the time of the war. Much plywood is still made today with non-water-resistant glues, and the manufacturer of such plywood will generally say that his product does not need water resistance. However, water in some form or other, whether as liquid or vapor, is everywhere present, and there are very few glued products that do not come in contact with it, and frequently to their detriment.

Limitations of Soya-Bean Glues

Practically all of the fancy veneers used in the manufacture of high-grade cabinet plywood are easily stained by alkali. Unfortunately, all of the present commercial soya-bean glues require considerable alkalinity to properly disperse them and to develop good adhesion. This results in an almost, if not quite, prohibitive amount of stain in the case of most fancy veneers. On the other hand, animal glue requires no alkalinity whatever, and accordingly it stains fancy veneers to only a negligible extent. Starch glues can be made up with very low alkalinity and still give fairly satisfactory adhesion. The low alkalinity possible with starch glue does not result in more than a permissible amount of stain in the manufacture of most plywood faced with fancy veneers. Water-resistant casein glues share with soya-bean glues the necessity for higher alkalinity and the resultant stain difficulties. Accordingly, to date, neither casein nor soya-bean glues have been able to make any great progress in the fields where fancy veneers are used and where glue stain is a matter of prime consideration.

The authors have considerable experimental work in progress to the point of developing a stainless soya-bean glue for fancy veneers, and it is hoped that this will become a commercial reality in the next few years.

Miscellaneous

In 1927 the manufacture of commercial veneer glue from American-grown soya beans was begun. Prior to this time, the production of domestic soya beans had been on too limited a scale to render such a venture advisable. However, since 1927, the production of soya beans in the Middle Western states has been rapidly increasing. It is believed that the use of soya-bean meal as a glue base has been a notable factor in encouraging farmers to increase their soya-bean acreage.

A matter of incidental technical interest that has been developed in connection with soya-bean glues is the use of carbon bisulphide as an agent to increase water resistance. This chemical materially increases the water resistance of protein glues and is particularly useful with soya bean and casein glues.

CONCLUSION

Soya-bean glue, although a newcomer in the plywood field, has found many uses in the last eight years, and its tonnage approximates that of all other plywood glues.

It is used for many forms of plywood, with the chief exception of gluing fancy veneers where stain is an important factor.

The chief uses at present are for Pacific Coast fir and pine plywood, where it is used exclusively; box shooks in Eastern and Southern states; drawer bottoms, glass backs, etc., in the furniture field, and for laminating fiber boards.

Manufacture and Uses of Fish Glue

By A. G. BROOKS,[1] GLOUCESTER, MASS.

This paper briefly describes the process used in the manufacture of liquid fish glue. It also mentions the field of application of this glue and the technique for using it.

THERE always have been arguments as to the relative merits of the various kinds of adhesives.

The Greeks and Romans knew that a strong adhesive could be extracted from the skins of certain fish, and used this adhesive for such delicate purposes as fastening precious stones in their setting. This product, however, was made in very small quantities and had to be used immediately. It was not until the last century, some time between 1870 and 1875, that liquid glue was made a commercial possibility by the discovery of means whereby it might be permanently preserved in liquid form.

For many years it was the custom of the producers of salt fish to sell their product whole, stretched out flat and dried hard with the skins and bones all attached. Some years ago, however, the development of the boneless-fish industry, in which the skins were stripped from the dried fish and the bones cut away from the flesh, opened the way for the commercial development of those by-products for which the fish producers had no further use. It was found that liquid glue could be manufactured from all of this material, varying in quality and quantity with the kind of fish and the part of the fish from which the glue was extracted. The development of the liquid-glue industry has utilized all of these salt-fish by-products and has made a firm place for itself in the commercial world.

The heads of certain fresh fish, as well as the backbones, fins, and tails of all salted fish, yield a glue of very good quality which is largely used in such industries as paper coating, envelope manufacturing, shoe manufacturing, bookbinding, box manufacturing, etc. Where the very highest grade of adhesive power is needed, however, nothing ever has been found to equal glue properly made from the salted skins of the cod and cusk. It is this raw material which goes into the fish glue known to the carpenter and woodworker.

The process of manufacturing liquid fish glue, while not complex, requires much skill and experience to result in a uniformly good product. The salt skins as received from the producers of food fish are first washed to remove the salt and any foreign matter which may have become mixed with the stock. Then the skins are cooked very gently in specially constructed apparatus where the gelatin contents are extracted in their purest form.

After cooking and settling in the cookers, this thin gelatin liquor is pumped to evaporating apparatus, where it is concentrated under vacuum to remove the excess water which was used in extracting it from the original raw material.

When the glue has reached the proper concentration, preservatives and scent are added in accordance with a strictly kept formula so that the resulting glue will retain its qualities indefinitely.

Liquid fish glue is claimed to be the strongest adhesive known. A scientific test has recorded the strength of 2375 lb. per sq. in., equal to the estimated holding power of eight nails in the same area. Another test shows a strength of 3015 lb. per sq. in. before breaking.

The chief advantage which fish glue seems to have is its flexibility in operation. Where a joint made with a hot glue must be immediately placed in position without any further motion, a fish-glue joint can be moved back and forth until it reaches its perfect adjustment, without detriment to the strength of the joint. Furthermore, fish glue has a much slower set-up. This means that the glue has a greater chance to penetrate before it reaches its set. It is considered that this is an advantage in a wood joint, for it is the penetration of the fibers on either side of the joint that gives it its strength, and the adhesive which penetrates best is, generally speaking, the best adhesive for the particular condition.

Whereas a user of either animal glue or casein glue is handling something which requires to be used up immediately, or at least in a day if he wishes to avoid the risk of deterioration, the user of fish glue can open his can or tube or bottle day after day and find it substantially the same as it was when he first opened it.

The technique of gluing with fish glue is not essentially different than that of using other glues. It is recommended that a sizing coat be applied to each side of the joint to be made up and that this sizing coat be allowed to become tacky before a final coat is applied and the two elements of the joint are clamped together. In this way maximum penetration is permitted, and it is assured that there will be plenty but not too much glue in the joint as finally built up. We guard against excessive glue by rubbing the elements of the joint together, after the sizing coat has been applied, which brings a uniform film of adhesive over the surface.

Fish glue is to be recommended (1) where its permanently liquid form is a convenience, such as in the journeyman carpenter's tool kit or in the household; (2) where the nature of the joining is such that it is desirable to have the power to move it after the elements of the joint have been brought into contact; (3) where the nature of the wood to be joined is such that penetration would be difficult were an adhesive used which dried immediately.

How Dry Should Wood Be for Various Industrial Uses?

By H. L. HENDERSON,[1] SYRACUSE, N. Y.

The testing of wood for industrial uses is stated to be best made on its moisture content. Much wastage in manufacture is declared to be due to lack of knowledge of this fact, and the consequent antiquated test methods in use in the wood-goods manufacturing industries. The effect of climate on the ideal moisture content is said to count for little. Furniture, flooring, and other products are dried to about 6 per cent, wherever manufactured. A table is given of the equilibrium moisture content of wood at various atmospheric conditions and also a table of the dryness requirements for a wide variety of wood products.

MOISTURE content of wood is the most reliable known criterion of its fitness for use. Lack of knowledge of this important factor has been the direct cause of much wastage in manufacture, of the breakage of wooden articles after being put to service, and of the unwarranted replacement of wood by other materials thought to be more stable in shape and size.

Progressive as these times are said to be, a fairly large proportion of wood is still manufactured and used without any method of testing its fitness for the work in hand, or if any tests are made, they are of the most primitive type. Archaic methods are practiced in many woodworking factories, and conditions are found at their worst in some of the large industries. Such industries, where the manufacture of major products requires many skilled engineers, chemists, metallurgists, or technicians, often have overlooked the wood end of their business entirely. Even sawmills, where the principal output is lumber and finished wood products, often neglect the drying of wood.

Occasionally one can find in practice such methods of testing wood for dryness as cutting the edge of a board with a knife and breaking out a sliver. If it shows a brittle fracture, it is considered dry; otherwise it is left in the kiln a few days longer. Some still employ the senses of taste and smell to determine dryness.

Many factories do not have any means of testing wood for dryness, depending entirely on excessively long periods of drying in the kiln and factory to insure its fitness for use. Some firms, especially in the handle and turning industries, process their wood parts very slowly through their plants, a practice which permits the moisture to evaporate gradually and the wood to shrink to its final stable condition before the articles are finished.

These wasteful methods are slowly disappearing, giving way to modern methods that are more precise and reliable. Free technical information is now available on the best methods of testing wood and on the dryness required for specific purposes. The best method of testing the dryness or moisture content of wood is by the weight method. This is done by cutting a small piece (see Fig. 1) from the board to be tested, weighing it carefully, drying it in an oven until all water is evaporated, and reweighing. The loss in weight will represent the water evaporated.

FIG. 1 METHOD OF CUTTING A BOARD TO MAKE MOISTURE AND CASE-HARDENING TESTS

Since the dry weight of wood is a constant factor, all references to percentage of moisture are based on it. By dividing the weight of the evaporated water by the oven-dry weight of the wood and multiplying by 100, the percentage of moisture is obtained.

The temperature of the oven should not be so hot that the test pieces will be scorched. Between 215 and 225 deg. fahr. is a safe condition. If the test pieces are cut thin (from $^1/_8$ to $^1/_4$ in. thick), they will lose all their moisture in two to three hours' time.

The balance scales to use should be graduated into grams and with a sensitiveness to 0.01 gram. There are several computing scales for this purpose which do not require the use of arithmetic. More recently, electric machines have been developed for testing moisture in wood. They are based on electrical conductivity and resistance. Wet wood is a good conductor of electricity, and of course dry wood is not; therefore, by measuring the resistance to a current passed through the wood, the moisture content in percentage is shown. Since

wood having more than 25 per cent of water still has free water in the cell cavities, these electric instruments will not measure beyond that point, nor are they effective below 7 or 8 per cent, as the resistance is too great with wood so dry.

Wood is a hygroscopic substance, and no effective treatments have been devised to change it. If wood is placed in a dry atmosphere, it gives up its moisture to the air, and this keeps up until it reaches an equilibrium. With the rise in temperature or the reduction in relative humidity, wood has a tendency to give up its moisture, or in other words, loses its ability to retain water. Air, of course, increases its capacity to hold water with the increase in temperature. As its relative humidity increases, however, its power to absorb moisture diminishes, as is shown in Table 1. Many experiments have been made in this field, and it is found that for a given temperature and relative humidity of the air, wood will gradually come to a definite moisture percentage, which is termed the equilibrium moisture content. With this information available, it is possible to predict the exact amount of moisture to be left in wood which is to be used for some specific purpose when the average temperature and relative humidity are known.

For instance, a heated factory in winter might have a temperature of 75 deg. fahr. and a relative humidity of 15 to 20 per cent. Lumber would be at equilibrium at 4 to $4^{1}/_{2}$ per cent. During the spring, summer, and fall, when there is no artificial heat in the building, the humidity will vary from 35 to 75 per cent, with an average of about 45 per cent. This condition would allow 8 to 9 per cent of water to remain in the wood. Since it requires a long period of time for wood that is 1 in. or thicker to reach an equilibrium moisture content, and since its progress through the factory is often rapid, it is usually kiln-dried to some point between these extremes, such as 6 per cent. Before it leaves the factory it is probably filled and given several coats of varnish, paint, or lacquer, all of which tends to make it partially impervious to moisture, and so it never has a chance to dry too low or to absorb too much if air conditions are moist. Some factories do dry their stock to 5 per cent during the winter months, and only to 6 or 7 per cent in summer. This helps to keep the stock flat during manufacture. When a piece of cabinet work is finished and put into service, it has to stand the change in air humidity and temperature from season to season. There usually is a gradual taking on of moisture during the summer months, and then a loss throughout the winter. The varnish coatings retard this greatly, so that under normal conditions the swelling or shrinking will be gradual and not sufficient to warp the wood or to have it crack open at the joints.

While it is easy to determine the optimum final moisture content by a study of the factory air conditions during processing and the air conditions where the wooden article is put into service, it is not so easy to actually get the wood down to this condition. The ends, edges, and surface areas of a board always dry faster and to a lower moisture per cent than the central portions. There might be 4 to 7 per cent difference between them. Sapwood usually dries quicker than heartwood, and quarter-sawn pieces slower than plain-sawn. Specific gravity has something to do with rate of drying, as the lighter pieces dry faster. All of these conditions usually are present in a load of lumber, and thus complicate the process.

Added to these difficulties are the uneven temperature and humidity usually found in the dry kiln and the rate and direction of air circulation. These conditions are bound to produce a variety of moisture conditions in the lumber. It is not difficult to find the moisture content varying during the process as much as 20 to 30 per cent, and at the end of the process varying from 1 per cent in some boards to 18 per cent in others.

With good drying apparatus and intelligent operation, however, it is possible to produce kiln-dried stock that will not vary more than 2 per cent in moisture content. It is also possible to stop the drying at 7, 6, or 5 per cent, depending on which point is desired. It is not so easy to have stock uniformly dried if only 10 per cent is desired. The reason for this is the individual characteristics of boards and variations in rates of evaporation, as well as variables in kiln-drying conditions. There is very little difference in the final equilibrium moisture percentage of different species or textures of boards, but they do vary considerably in the time necessary to bring them to this equilibrium.

The foregoing discussion, then, should suggest a practice which is in more or less use in this industry—namely, holding lumber in dry storage for a sufficient period to permit it to equalize its moisture. There is considerable divergence of opinion as to the length of time necessary to obtain effective results, running all the way from a few days to six weeks. It is a subject that needs further study, and yet any factory might work it out satisfactorily for its own particular conditions.

Another aspect of the situation which needs explanation is that a wooden article might be used in a damp climate or in a position where the relative humidity averages a high percentage, and yet it must be dried to a much lower equilibrium moisture percentage. Numerous instances can readily be cited. Automobile wheel spokes are always dried to a very low percentage so that a slight swelling after assembly into the wheel will keep them always tight. Stock that is to be glued must not change its shape during manufacture, or the joints will be broken or the pieces warped. Caskets must be made with great care so that they will remain in shape with no fracture of joints or warped tops while they are in storage or on display. Wooden dowels are expected to swell a slight amount after use to help to keep them tight. Certain types of brushes, mirror backs, turned handles, etc. have to be dried to 1 or 2 per cent moisture because they are to have enamel baked on under high temperatures. Some cabinet work, automobile bodies, furniture, etc. which have to go through several kiln-drying periods to dry the various coats of paints and varnishes are very carefully dried before assembly.

On the contrary, some articles are not dried as low as they will come to in use, because of certain methods of manufacture.

As one example, the veneer used in bushel fruit baskets is often very wet so that it will bend easily. The same is true of grape baskets. They must be dried after assembly to prevent stain and to reduce weight.

Clothespins and some rough-type turnings and legs for cheap furniture are turned in a green or air-dry condition, mainly because the wet wood machines more easily than dry wood. High-grade turning, however, is done at 6 or 7 per cent moisture, and with the proper knives and turning speeds, good results are obtained.

Stock which is to be bent is usually thoroughly air-dry before it is steamed and bent. There is less tendency to fracture in bending, but this has some drawbacks. Surface checking and honeycombing, as well as some warping, are likely to develop in the final drying process, which is often done with less care and attention to temperature and humidity than in the regular kiln process. In the construction of houses and factories, most joists, studding, and sub-flooring are used at moistures ranging from 15 to 25 per cent. After a year's service in a heated building they will dry to 6 or 8 per cent and shrink proportionately. Cracked plaster, sagging floors, door frames out of plumb, etc. are a result of such practices.

Stock such as shingles is often kiln-dried to a low moisture percentage simply to reduce the freight costs. They will reabsorb more moisture after being put into use. This practice is common with rough softwood lumber.

The data on wooden articles and wood uses in Table 2 were gathered by many personal contacts and experiences in the wood-using industries and by replies to several hundred questionnaires sent out early this year. The minimum and maximum moisture percentages represent the extremes found in those industries, while the average represents a composite picture of the more normal working conditions found, and in most cases can be taken as the ideal moisture condition desired. The percentages of moisture are for conditions just prior to manufacture.

Although one hears much in reference to climate and its effect on the ideal moisture content for any given location, this canvass shows that for any given article geographical location counts very little. Furniture made in New York City, Jamestown, Chicago, Grand Rapids, High Point, or Los Angeles is dried to about 6 per cent. This is also true of flooring, whether made in Shreveport, La., Williamsport, Pa., Tupper Lake, N. Y., Seattle, Wash., or Traverse City, Mich. Extreme cases can be cited against this statement in most any wood-using industry, but it must be kept in mind that there are enormous differences in quality in manufactured articles and that the average to better qualities were the only ones given consideration in this study.

Although air-dry lumber seldom gets below 12 per cent moisture, even after years of exposure, many articles shown in Table 2 as having 6 to 8 per cent have never been in a dry kiln. This is occasioned by the practice of taking well air-seasoned stock into the factory building and storing it in locations that are always warm and dry. After months and sometimes years of such exposure, the wood gradually dries down to an equilibrium moisture content of 5 or 6 per cent, or even lower. This condition of dryness is comparable to kiln-dried stock. Some firms still believe that kiln-drying injures wood structurally, and this accounts for these antiquated methods.

Discussion

Thomas D. Perry.[2] Professor Henderson has made a distinct contribution to the industry, but it is wished that he had dwelt more on the fact that wood is one of nature's growths, the character of which cannot be changed except through processing and conditioning. In other words, we may saw lumber radially or tangentially, i.e., quarter sawn or plain sawn, and have quite different characteristics in the respective boards.

Further, we may vary the moisture-removal treatments all the way from intensive drying green from the saw or a leisurely air drying, with final high-temperature drying before using.

---

[2] Chief Engineer, United Plywood Sales Corp., New Albany, Ind. Mem. A.S.M.E.

Hence it seems that it would be entirely proper to place even more emphasis on using our knowledge of the processing and conditioning of lumber preparatory to manufacturing, since there are so many other factors in its characteristics that we have to take as nature supplies them.

It is the writer's observation and experience that woodworkers are notoriously careless about taking the necessary steps to maintain lumber in prime utilizable condition all the way through the remanufacturing process. It will not be long before we shall be obliged to have manufactured "weather" in all woodworking departments where precision in operation is necessary. This is already extensively practiced in textile operations, paper making, and cigar manufacturing.

This paper does much to hasten the day when such attention will be given to keeping lumber in the condition it ought to be for the ultimate stable product.

Fred F. Bahnson.[3] In the consideration of any engineering problem, it is usual to assume, among a number of variable factors, certain ones as being practically uncontrollable, and try to change the others to suit. As a manufacturer of humidifying equipment, with many years' experience in the control of air conditions in manufacturing plants, my point of view is quite different from the author's. His observations and experience seem to lead him to the assumption that humidities in factories will be very different in summer from those in winter—that is, subject to wide seasonal variations. The writer's experience over many years shows that it is not only possible, but also quite practical, to produce and to maintain, within very close limits, the same humidity the year round in any reasonably well-built factory room.

Excepting woodworkers, practically every industry whose material in process is affected by humidity changes now uses air-conditioning equipment as a matter of course. Textiles, printing, tobacco, ceramics, flour mills, and a host of others do not even try to operate without controlled humidity. Of all the industries now generally using artificial humidification, the printing industry most nearly parallels the woodworking industry. The stock used, paper, is largely composed of wood fibers, and consequently is affected by changes in relative humidity just as wood is affected. It is as important to the printer to maintain his paper uniform in size as it is to the furniture manufacturer to maintain his dimensional stock of uniform size. The printer has found that the only satisfactory way to do this is by maintaining a constant relative humidity. This is so well known throughout the industry that humidification is no longer considered merely as a desirable refinement, but is recognized as an absolute necessity for quality printing. Within a comparatively short time the same attitude will be manifested in the furniture manufacturing industry.

Instead of trying to dry lumber to fit seasonal variations due to humidity variations, that lumber should be dried to approximately the condition of use, or to the best working moisture content, and then the factory should be humidified to keep the predetermined and desired moisture content in the lumber the year round. Why manufacture shuttles, for instance, in a relative humidity of around 20 per cent (moisture content 5 per cent) when the average weave room where these shuttles are used is held at humidities ranging from 75 per cent to as high as 92 per cent (moisture content about 18 per cent).

It would seem that the sensible thing would be to dry lumber to the moisture content corresponding to the average relative humidity of 55 to 60 per cent which prevails over the United States, and then hold lumber storage rooms and factories, from start to finish (except perhaps the rooms where enamels are dried), at that humidity, so that if there are any changes, every piece in a built-up table top, for example, will expand and contract alike. What will happen if a built-up table top is made from several pieces, some of which have been stored outdoors or in an unheated room with humidity around 60 per cent, and from other pieces which have been stored in a factory in winter with a humidity of 30 per cent or less? One will swell in use, the other will shrink, and what about the veneer?

It is the writer's engineering opinion that if woodworking factories would use properly conditioned air the humidifying system would pay for itself very quickly in the saving of culls, checks, and cracks, to say nothing of the better health of operatives and the certainty of having dimension stock stay put.

The time element in the response of fairly thick wood stock to changes of humidity means that woodworking plants will not need as close regulation of humidity as textile mills, where the fibers are small and respond rapidly to variations in humidity, but the general principle is the same; and since stock is usually stored for some time under cover after leaving the kilns, the storage rooms as well as the factory should be held at practically constant humidity, and all these storage rooms and the factory should be at the same humidity.

Someone has raised the point that in the mill room of a woodworking plant there is so much air blown out through the dust-collecting system that it will be difficult to humidify such rooms. The number of complete air changes will be found to be around eight to twelve per hour, and that kind of problem is not at all unusual in other industries. Of course, such rooms require much more humidifying equipment than rubbing rooms, for example, but there is no inherently impractical condition to be met in any room in woodworking plants. There is no more reason to think a mill room cannot be humidified than to think it cannot be heated. The two problems are identical in principle, and the air changes affect heating just as much as humidifying.

Some woodworking plants use steam jets to produce a certain amount of humidity in the air of the plant. This practice is of course better than no humidifying at all, but with any type of steam jet there is always objectionable drip, and the vapor is of necessity warmer than the room air, which means condensation and eventually leads to rotting timbers and other unsatisfactory results. With a properly designed humidifying equipment, cold or slightly warm water is finely pulverized so as to be easily converted to true vapor, and a free circulation of the room air is produced which really improves working conditions and the general health of employees.

Kenneth Redman.[4] There are three comments on the paper that may be of interest. The first is that, in describing how to compute the moisture content of lumber, why is it always stated to multiply the quotient by 100. If a piece of wood weighs 12 grams, or 12 anything for that matter, and when bone dry it weighs 10, the loss is 2 parts of water. Obviously, 2 divided by 10 is 0.2 or 20 per cent. There is no increasing of any value by 100 times, and the writer believes it would simplify matters considerably for beginners if the Forest Service Laboratory simplified its instructions by omitting the phrase, "multiply by 100." The writer appreciates that the instructions actually provide for multiplying 0.20 by 100, and by adding the words "per cent" the product is thereby immediately divided by 100. But for the sake of brevity why introduce the figure 100 at all?

The majority of furniture manufacturers seem to consider 5 per cent moisture content as the necessary point to dry to, with some not particular if 6 per cent stock enters production. This of course refers to the samples tested. The writer believes these figures have become customary due to past uneven drying, and to prevent 9 to 12 per cent from entering production. Propeller stock during the war was not dried below 7 per cent, and it took 7 to 9 laminations to make a propeller, which must withstand enormous external stresses. Furthermore, tests of furniture several years old reveals a range of a fraction below 8 per cent in the winter to some tests a fraction above 9 per cent in the summer. The usual variation is slight. If the manufacturer took care to eliminate slow-drying pockets by building ample flues in the kiln load, or by mechanical circulation eliminated this hazard, would he not be justified in stopping his drying at, say, 7 per cent? He would not only save kiln time, but his finished product would be nearer to the equilibrium moisture content at which it is to remain during its useful life.

[4] Lumber Seasoning Service, High Point, N. C.

Lastly, many manufacturers carefully dry their stock, then place several protective coats of filler and finish on the exposed portions, and then leave the insides, under sides, and backs practically exposed to climatic changes. At most, one coat of stain or filler is given these portions. If these places were adequately protected against the infiltration of moisture, the annoyance of stuck bureau and desk drawers and immovable file cases, etc., would soon be but a memory.

WDI-54-9

Some Observations on Raised Grain

By ARTHUR KOEHLER,[1] MADISON, WIS.

Woodworkers and finishers are confronted with certain difficulties classed under the category of "raised grain" which, so far, have resisted satisfactory solution. This paper describes some observations on raised grain that may lead to a better understanding of the problems and which may suggest approaches toward overcoming them. Casual investigations made of raised grain suggest some remedial measures, and indicate that there is a large field for research connected with the surfacing of lumber, both as to the cause of the objectionable features encountered and methods of overcoming them. A microscopical study of the way that present-day woodworking tools and machinery cut wood and the development of new equipment which would give more nearly ideal results seem to offer possibilities which would go a long way in improving wood products or reducing their costs.

TWO TYPES of raised grain are commonly recognized and spoken of as such: (1) That in which fibers or parts of fibers project above the surface, and (2) that in which the whole summerwood (or springwood) of the annual rings extends above the surface, giving it a corrugated appearance. A third type in which the tips or edges of annual rings become loose and rise up also occurs. It is more commonly known as "loosened grain," which probably is a better descriptive term, and, in fact, has been accepted as a standard term under American Lumber Standards.[2]

Under the first of these types of raised grain there is one form in which individual fibers, groups of fibers, or even fragments have been loosened at one end, and these ends project like fuzz or minute slivers from the surface after planing or sanding. (Fig. 1.) This phenomenon seems to be a characteristic of certain kinds or types of wood rather than of the method of surfacing them. For example, in some species, such as cottonwood and elm, it occurs commonly, whereas in mahogany, oak, and certain other species of hardwood, it is troublesome in only certain types of lumber. Whether in such cases the fibers are not equally well attached by growth along their full length or whether they are more interlaced, so as to make it difficult for the end which remains fastened to pull out, has not been determined. Possibly in the wood which gives little trouble in this respect the fibers split lengthwise more easily, and, thereby, projecting portions are more easily torn off independent of their attachment to neighboring fibers. A detailed microscopical study of the behavior of the fibers would make an interesting contribution to the subject of raised grain. It has already been found that individual fibers have a natural tendency to twist as they dry. Therefore, any loose ends or fragments of fibers on dry wood would be expected to protrude and assume any position but that which they had in the greenwood. The fact that this kind of raised grain occurs more commonly in some than in other pieces of the same species also raises the question of how the conditions under which a tree grows affect the quality of the wood in it, a subject about which little is known, but one that is important in any kind of timber-growing program.

Another form of raised grain observed is that in which groups of fibers and pore walls overlying the pores are pressed down into the pores in sanding, leaving the surface fairly smooth for the time being, but eventually resulting in the protrusion of these depressed portions, especially if the surface is moistened with any liquid that has a swelling effect on wood, such as water or spirit stains.

Fig. 2*a* shows a surface of mahogany which had been sanded shortly before photographing and Fig. 2*b* shows the same after moistening. The fragments of fibers and pore walls projecting over the pores can readily be seen in Fig. 2*b*. The same is shown even more strikingly for a sample of red oak in Figs. 3*a* and 3*b*. The photographs from which these illustrations were made were taken with oblique light so that all projections cast distinct shadows, thereby making them more conspicuous.

The mahogany and oak specimens were sanded lightly by hand with fine sandpaper, but even under those conditions the "caving in" of the pores could not be prevented. It is obvious that under heavier pressure this condition would be even more serious.

After the microscope had revealed the origin of the raised grain, planing with a sharp hand plane without sanding was tried to see if a smoother surface could be obtained in that way. The results are shown in Figs. 2*c*, 2*d*, 3*c*, and 3*d* for both mahogany and oak. It can be seen that the pores lying at the surface were cut open smoothly without pressing any fibers into them. On moistening the surface there was practically no raising of the grain.

Furthermore, the hand-planed surface of mahogany had a distinctly more brilliant luster than the sanded surface, on which the raised grain had a "frosting" effect. How much of this superior brilliance would be retained after varnish or other transparent finish is applied was not determined. There is a possibility that it might even be enhanced, since transparent finishes usually enhance whatever natural luster wood has.

The second type of raised grain, namely, that in which the summerwood or springwood of the annual rings stands out above the surface after planing, is a common annoyance in the finishing of softwood lumber in particular, although occasionally it also gives trouble with hardwoods. One case in which yellow poplar, which is a wood of exceptional homogeneity, gave trouble in the manufacture of clock cases came to the author's attention. Any irregularity of the surface of finished parts shows up, especially when a glossy coating is applied, on account of the distortion produced in the reflection of light.

Flat-grain lumber in particular gives trouble in this respect, the trouble arising from the planer pounding the harder summerwood into the softer springwood underneath, and both later regaining their former relative positions, thereby raising the sum-

---

[1] In charge of the Section of Silvicultural Relations, Forest Products Laboratory, Forest Service, U. S. Department of Agriculture, maintained in cooperation with the University of Wisconsin. Mr. Koehler has been engaged since 1911 in the study of the cellular structure of wood for identification purposes and to explain the variations in the behavior of wood.

[2] For a description of loosened grain see "Raised Grain: Its Cause and Prevention," by Arthur Koehler, *Southern Lumberman*, Dec. 15, 1929; and *Lumber Trade Journal*, Dec. 15, 1929.

Presented at the Sixth National Wood-Industries Meeting, Winston-Salem, N. C., Oct. 15 and 16, 1931, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

merwood above the plane of the surface. (Fig. 4.) This regain of shape may occur gradually with the lapse of time or rapidly if the surface is moistened. Here, as in the previously mentioned type of raised grain in which the fibers are pressed into the pores, a peculiar characteristic of wood comes into play—namely, that wood if crushed will partly resume its original dimension, particularly so if it is moistened with hot water. It is an old woodworking trick to take dents out of wood by applying a wet cloth and hot flat iron over the dent.

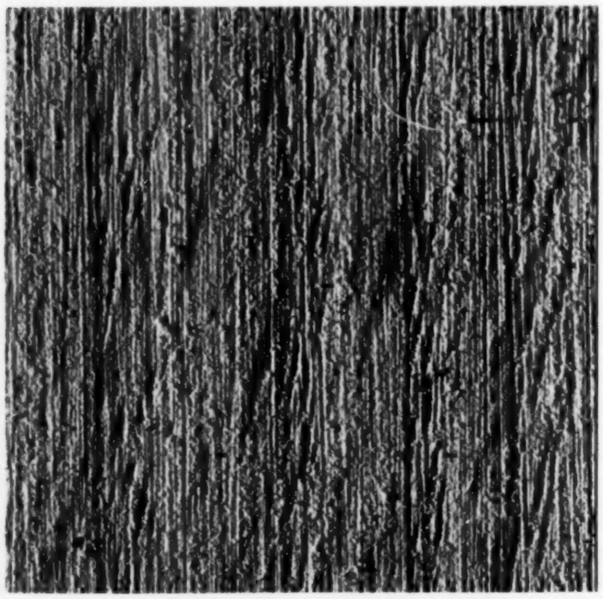

Fig. 1 Raised Grain on Surface of Oak After Sanding but Not Sponged. Magnified 4.1 Times

This type of raised grain occurs principally in lumber that is flat grained or nearly so because the hard summerwood is superimposed over the softer springwood, whereas in edge-grained lumber both springwood and summerwood layers are more or less at right angles to the surface and do not offer opportunity for such deformation in the planer.

In flat-grained softwood lumber it has been found that this type of grain raising is much more pronounced on the pith side than on the bark side of a board. This is due to the fact that on the pith side the outer and harder part of the summerwood immediately overlies the inner and softer part of the springwood underneath. (Fig. 4.) The hard summerwood resists the cutting of the planer most, and therefore is pounded into the immediately underlying springwood. On the bark side of a board the inner and softer portion of the summerwood runs out to a thin edge at the surface. It does not resist cutting so much, and for that reason and because the springwood immediately below the summerwood is a little harder than at the beginning of the annual ring, the summerwood is not pressed into the springwood so readily as on the other side of the board.

A somewhat similar appearance is sometimes produced by dull planer knives that tear away more of the softer springwood, leaving the summerwood projecting above the surface; or in the sanding operation more of the springwood may be taken away if care is not taken. Ordinary wear, such as occurs in unprotected flooring, rustic furniture, drain boards, and lumber exposed to the weathering action of the elements, may also produce a similar effect.

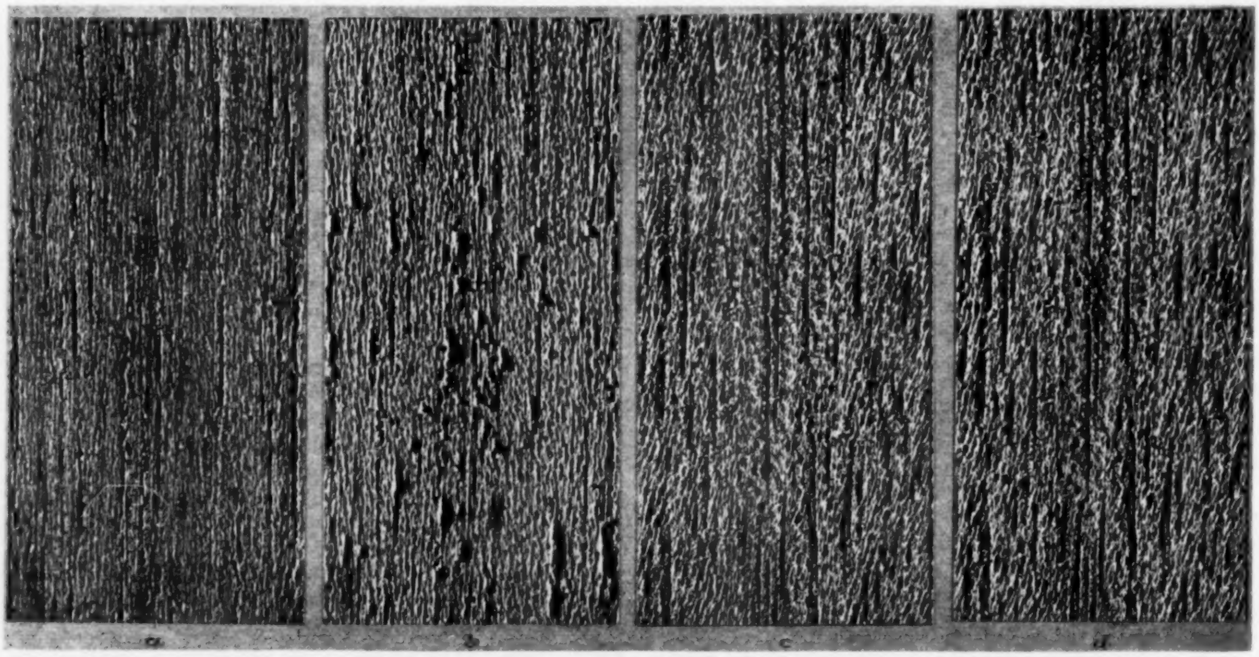

Fig. 2 Plain-Sawed Mahogany. Magnified 4.1 Times
(*a*, Surface sanded but not sponged; *b*, same after sponging; *c*, surface hand planed but not sponged; *d*, same after sponging.)

Another cause of corrugation of lumber is the greater swelling and shrinking of summerwood as compared with springwood. If surfaced lumber dries out considerably after surfacing, the summerwood will become depressed below the springwood, or if it takes on moisture the summerwood will protrude beyond the springwood, in either case leaving the surface corrugated. This condition usually occurs to a more pronounced degree in edge-grained than in flat-grained stock, because in the former the lateral shrinking and swelling of the springwood and summerwood takes place at right angles to the surface and therefore differences are more pronounced.

Occasionally a similar type of raised grain may be produced by uneven pressure on the surface of lumber before it enters the planer. Fig. 5 shows a piece of Western yellow-pine window sash which was very uneven on one surfaced side although smooth on the other. An examination with a magnifying glass showed that the cells in and below the ridges were partly compressed. Evidently they had been compressed even more, but had partly resumed their original shape, thereby rising above the rest of the planed surface. The fact that these ridges were of irregular length and had no relation to the grain of the wood indicates that they were not due to imperfections in the knives or irregularities in the grain, but to uneven pressure on the wood before it reached the knives. Such a condition might arise from sliding the rough lumber over uneven surfaces during handling or on the feeding side of the planer.

A coarser type of corrugation sometimes occurs on the surface of sawed lumber, as illustrated in Fig. 6, which may be mistaken for a type of raised grain. In this case, however, the elevations and depressions have no relation to the grain of the wood. Neither are they the result of shrinking or swelling, since it is evident on close examination that the hollows are actually gouged out. The extreme regularity of these corrugations attests that they are of mechanical origin and undoubtedly are due to vibration of the band saw, the vibrations passing up the saw a little slower or faster than the saw travels downward, thereby making diagonal marks as the saw passes through the log.

REMEDIAL MEASURES

In the foregoing it has been pointed out that there are various types of raised grain and that they are more prevalent in some kinds or cuts of lumber than in others. So far no extensive experiments have been carried on at the Forest Products Laboratory to determine how raising of grain may be prevented or reduced, or how to select wood without this objectionable feature. Observations on the cause of raised grain, however, have automatically suggested some remedial measures.

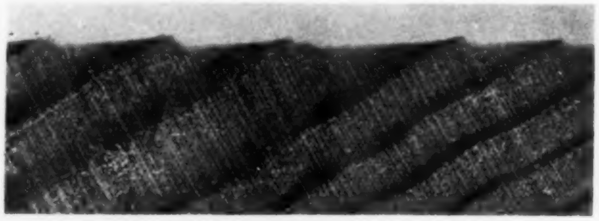

FIG. 4 CROSS-SECTION OF WHITE-FIR PARTITION STOCK, SHOWING RAISED GRAIN DUE TO PROJECTION OF SUMMERWOOD. MAGNIFIED 4.4 TIMES

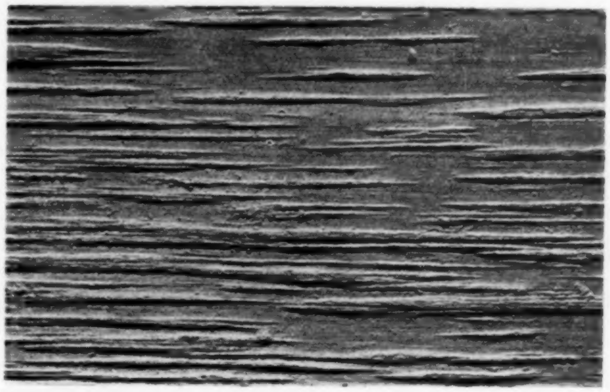

FIG. 5 SURFACE OF SASH RAIL SHOWING RAISED GRAIN DUE TO COMPRESSION OF WOOD BY EXTRANEOUS OBJECTS BEFORE PLANING

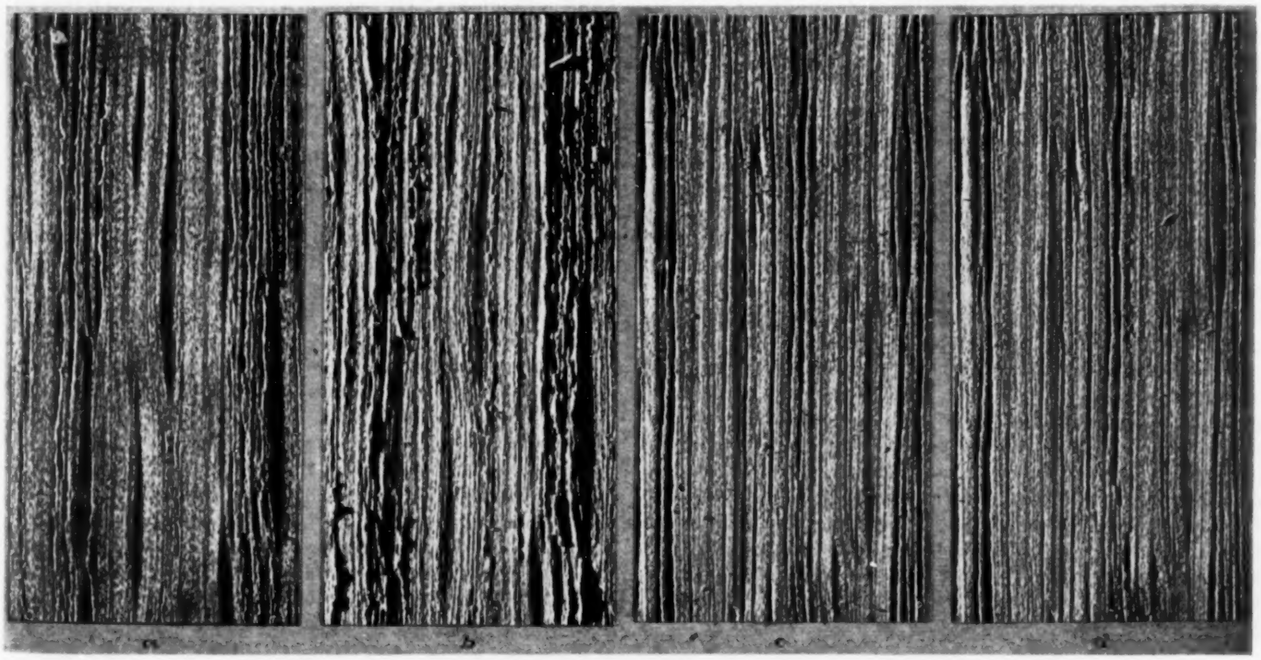

FIG. 3 PLAIN-SAWED OAK. MAGNIFIED 4.1 TIMES

(*a*, Surface sanded but not sponged; *b*, same after sponging; *c*, surface hand planed but not sponged; *d*, same after sponging.)

So far as reducing the projection of fibers or fragments of fibers is concerned, it appears that sanding the surface is not so helpful as planing the wood with a sharp hand plane. In the first place the granules on sandpaper have a tearing action which tends to

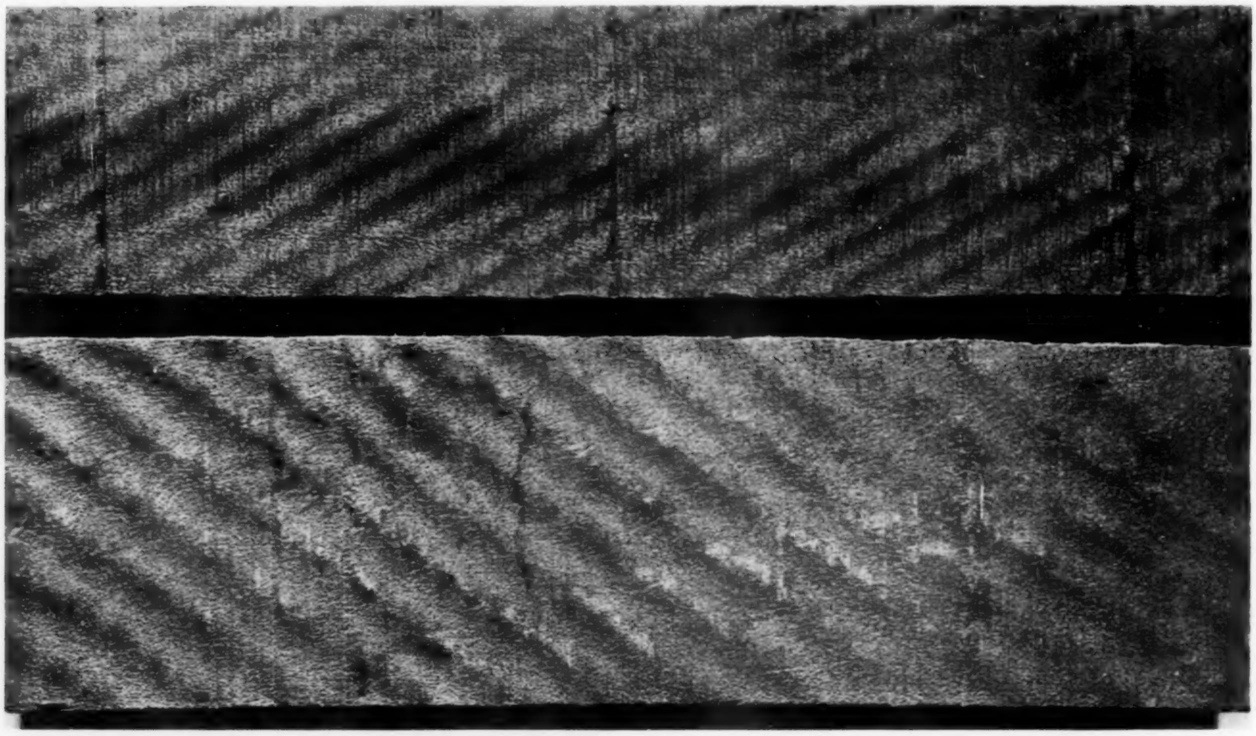

Fig. 6 Corrugated Surfaces of Tupelo Gum at Top and Red Gum at Bottom Due to Vibration of Band Saw

loosen some fiber fragments, and in the second place the pressure which must necessarily be applied in sanding forces fibers and other tissues into the surface pores only to bulge out later, especially if a water stain is applied. Sponging and a second light sanding eliminates a large part of the raised grain, but involves additional expense and is not entirely satisfactory, especially with refractory woods.

Obviously hand planing also is not commercially feasible on account of the expense involved and the difficulty of getting a perfectly smooth finish on flat surfaces. Machines with rotary cutters as designed at present do not solve the problem on account of the "planer marks" which they are apt to leave. Furthermore, such machines could not be used on panels overlaid with thin veneer since it would be impossible to keep the planer from going too deep in places. Possibly a redesign of present machinery or the invention of entirely new methods of wood surfacing are required for the solution of this perplexing problem.

The type of raised grain in which the summerwood projects above the surface also presents a serious problem. As already pointed out it is much more pronounced on the pith side than on the bark side of a board, and edge-grained lumber does not show it so much as flat-grained stock. Lumber therefore can be selected to some extent to avoid excessive grain raising of this type. Undoubtedly the sharpness of the planer and the bevel of the knives also are important factors. Lumber surfaced with a hand plane or sharp rotary planer does not show so much of this type of raised grain as that surfaced with the usual commercial rotary planers.

Discussion

J. C. **Duke.**[3] The author's observation on the non-effectiveness of "sanding" raised the question concerning the care and technique adopted in his sanding practice. Due to the generalness of the statement that "specimens were sanded lightly by hand with fine sandpaper," the question was asked what was meant by "fine sandpaper."

"Sandpaper" is far too broad a description, as it encompasses a field of five distinctly different types of mineral, each with specific properties to meet definite requirements. "Fine sandpaper" includes a vast range of grit sizes, a variety of backing weights, types of mineral coating, and different bond formulas.

It was developed that the author in his term "fine sandpaper" referred to $^1/_0$ and $^2/_0$ flint paper. Flint mineral, by reason of its points of hardness, toughness, and mineral fracture, is one of the least efficient abrasives for woodworking purposes. Due to the relative dullness and lack of hardness of flint mineral, it was thought that some of the observations in the panels described by the author might be accounted for.

There was also the question of how the author's results could compare in measure with those obtained from mechanical sanding procedure in modern woodworking plants. There is a long step from results obtained in surfacing by hand application and by machine. In hand application the abrasive paper passes in the direction of the wood grain and back against the grain, while modern mechanical sanding practice sands or cuts in one direction. It was felt that hand sanding would be analogous with planing where the bit of the plane would cut the surface on the forward stroke with the grain and then reverse the stroke against the grain. Mechanical sanding can be compared with planing where the work is surfaced, the cut being made with the grain. In addition, modern sanding equipment is designed to obtain certain specific results where sanding pressures are controlled and where speed of cut, coupled with selection of type of abrasive grain, delivers the result needed to fit specified requirements.

Studies in the Design of Local Exhaust Hoods

By JOSEPH M. DALLAVALLE[1] and THEODORE HATCH,[2] CAMBRIDGE, MASS.

J. M. Dallavalle

T. Hatch

The failure of many local exhaust systems properly to control industrial dust hazards may be attributed, in part, to the lack of sufficient knowledge of the factors governing the collection efficiency of various types of hoods. The present study was undertaken in an effort to obtain data on the aerodynamic characteristics of simple geometric suction openings which may serve as a basis for future studies of the problem of design of local exhaust systems. Round, square, and rectangular openings were investigated and their aerodynamic characteristics are expressed by means of velocity contours or lines of equal velocity.

Contour lines were found not to be influenced by the total airflow through the hood. They did not differ in their chief characteristics with the geometric shape of the opening, although rectangular openings exhibited a flattening of their contours that varied with the ratio of the sides. An increase in the area was found to cause a displacement of contour lines at right angles to the axis of the opening. Along the axis, however, velocities coincided at distances of 6 in. or more from the face of the hood.

Gross characteristics of suction openings, it was found, could be expressed by means of center-line velocity curves. These curves, which are obtained with less labor than are the velocity contours, may be compared graphically and also mathematically. Simple charts are presented and mathematical equations were obtained for the three types of openings that may be used within the zone of hood influence.

LOCAL exhaust ventilation for the removal of dusts and fumes has been applied with varying degrees of success in almost every industry. Its general application has been recognized by most states, and legal specifications for design have been incorporated in many industrial codes.

Although the use of local exhausts has undoubtedly reduced the health hazards associated with industrial dusts and fumes, recent dust surveys in certain industrial plants have demonstrated that many systems have been badly designed and do not have the required efficiency of dust removal. (1) (2) (3)[3]

The low efficiency of local exhaust systems may be attributed, in most cases, to the improper design and placing of collecting hoods and failure to provide sufficient airflow through them. As a matter of fact, but little fundamental information on the design of hoods is available at the present time. The common basis of design is the rate of airflow through the hood as measured by the negative static pressure at the hood throat. Tables of suction values, based upon experience, have been compiled for various dust-producing processes. (4) The need for wide experience and good judgment in the general use of these factors is stressed, although state codes require rigid adherence to legal specifications. Without attempting to minimize the importance of experience in engineering design, it seems proper to point out that most of the past experience in the design of local exhaust hoods has not been associated with quantitative studies of the actual efficiency of dust removal. Little consideration has been given to the characteristics of different types of hoods or to their relative efficiencies when applied to the various dust-producing processes. This is clearly demonstrated by the fact that the various state codes do not agree one with another. A more complete knowledge of the function and characteristics of various types of suction openings is therefore needed. The final test of efficiency of dust removal should, of course, be based upon actual dust determinations.

The authors have studied the aerodynamic characteristics of a number of simple geometric openings under suction. Results of their investigations are presented herewith, and the data presented should serve as a starting point for more elaborate studies and the collection of detailed information on the design of local exhaust hoods.

In operation, an exhaust hood creates an air velocity at the point of dust generation which counteracts the tendency of the dust to escape into the surrounding space and, if sufficiently great, carries it into the collecting system. The minimum air velocity required for the efficient removal of a particular dust depends upon a number of factors associated with the dust-producing process such as the size and weight of the dust particles and the force with which they are thrown off. The air velocity to be created at the point of dust generation, therefore, constitutes the primary specification upon which the design of exhaust hoods must be based.

The air velocity obtaining at a given point in the zone of influence of a suction opening depends upon a number of factors which must be considered in the design. Chief among these are the shape and size of the opening, the distance from the hood, the position of the hood, and the total airflow through the opening. These factors constitute what may be termed the aerodynamic characteristics of suction openings, and their influence upon the air velocity at the point of dust generation should determine the choice of hoods and minimum airflow requirements.

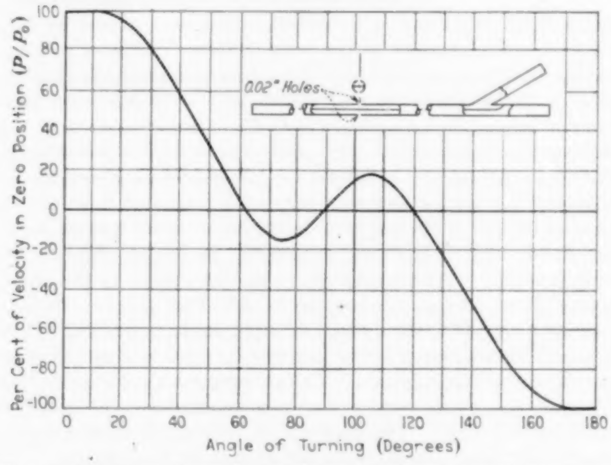

FIG. 1 MODIFIED PITOT-STATIC TUBE AND EFFECT OF TURNING ON VELOCITY-HEAD READING

The value of this method of approach has been demonstrated in a study of the design of exhaust hoods for use with pneumatic granite-cutting tools. (5)

In the present study, the characteristics of round, square, and rectangular openings were investigated. The rectangular hoods were classified according to the ratio of the sides of the openings. These ratios were four in number; viz., $^3/_4$, $^2/_3$, $^1/_2$, and $^1/_3$. The number and sizes of the various openings examined are given in Table 1.

LABORATORY SET-UP

The exhaust system consisted of 40 ft. of 8-in. round duct connected to the intake of a 30-in. steel-plate planing-mill exhauster. Air was discharged from the fan through an outlet chimney which reduced its velocity. Owing to the lowered outlet velocity and the long exhaust duct, the circulation of air in the room caused no disturbance within the zone of influence of the experimental hoods inserted in the open end of the duct. Varying rates of airflow through the hoods up to 2000 cu. ft. per min. were obtained by means of a variable-speed motor, and measurements of airflow through the system were determined by means of a standard 6-in. thin-plate orifice inserted in the exhaust duct. The static-pressure taps of the orifice were located as specified in the report on fluid meters published by The American Society of Mechanical Engineers. (6) During the latter part of the study the orifice was replaced by a venturi meter.

THE MODIFIED PITOT-STATIC TUBE

The instrument used to measure point velocities in the region of hood influence is shown in Fig. 1. It consisted of a straight brass tube 26 in. in length and $^1/_8$ in. in diameter, and was separated into two chambers throughout its length by means of a thin partition. Two holes, 0.02 in. in diameter, were drilled in the mid-section diametrically opposite each other. Each chamber was carefully sealed off from the other and constituted a separate pressure chamber with its own terminus. Because of its small diameter, this instrument probably caused little disturbance of air motion and served to determine the velocity at a given point. In this respect, it was superior to other instruments available.

In operation, the instrument was placed in the air stream with the axis through the pressure openings parallel to the direction of flow. Thus, the total pressure of the air stream was produced in the chamber with its opening facing the stream,[4] whereas the pressure produced in the second chamber was a function of the static pressure of the stream. The modified tube was calibrated against a standard pitot-static tube and it was found that the modified tube gave readings from 1.75 to 2.00 times higher than those obtained with the standard tube; the coefficient was constant at 1.75 for velocities above 950 ft. per min. The calibration curve for the instrument is shown in Fig. 2 for air velocities from 70 to 2000 ft. per. min. Pressure readings are in inches of alcohol and for an air temperature of 80 deg. fahr.

The rotational characteristics of the tube are shown by the graph in Fig. 1. The per cent of maximum pressure (obtained when the openings are parallel to the airflow) is plotted against the angle through which the tube has been rotated. The maximum reading of the tube occurs over a range of ±15 deg., and shows that the instrument is not particularly sensitive to direction in this region. On the other hand, zero pressure readings were recorded at 63 deg., 90 deg., and 117 deg. from the direction of airflow. Therefore, by careful location of any one of these zero positions, the direction of airflow could be determined quickly.

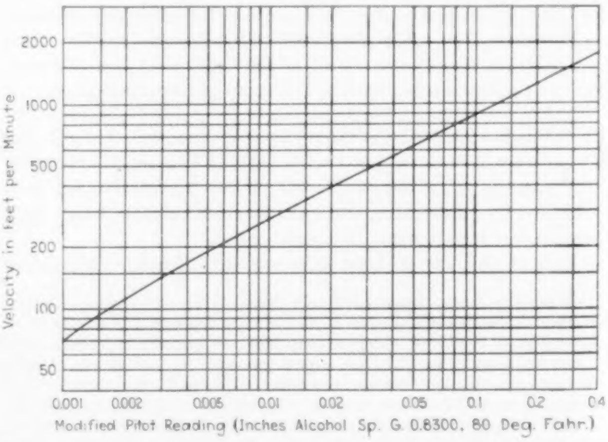

FIG. 2 CALIBRATION CURVE FOR MODIFIED PITOT-STATIC TUBE

Pressure readings were made with a Wahlen gage (7) which was sensitive to 0.001 in. or less of alcohol. Thus, air velocities as low as 100 ft. per min. were determined with considerable accuracy.

VELOCITY DETERMINATIONS

The hood to be studied was connected to the exhaust duct and air was drawn through it at a measured rate. The modified pitot-static tube was then brought to those points within the region of influence where velocity determinations were to be made. Careful location of the tube with reference to the hood was obtained by means of a suitable stand capable of movement in horizontal and vertical directions. Velocity measurements were made at coordinate points in a vertical plane through the axis of symmetry of the hood as indicated in Fig. 3-A. Readings were taken as far out from the face of the hood as possible, the limiting factor being the sensitivity of the Wahlen gage.

---

[4] Since the total pressure of the air stream in space is zero, this chamber was not absolutely essential. Because of fluctuating flow, however, it was felt that the pressure readings would be less subject to errors than with one leg of the manometer directly open to the atmosphere.

Owing to the symmetry of a round opening, velocity measurements in one plane served to determine the characteristics of the opening throughout its sphere of influence. Such was not the case, however, for the square and rectangular openings. In the latter, the velocity conditions were not the same in planes at right angles to each other, and in both cases the corners disturbed the flow considerably. A study of air motion at the corner of a suction opening necessitates the determination of three-dimensional flow and involves a vast amount of labor. The mapping of the whole field of influence of square and rectangular openings was therefore considered impractical. For the square openings, velocity measurements were made in one plane only, through the axis and bisecting one side. For the rectangular openings, studies were made in two center-planes at right angles to each other and bisecting the sides of the opening. Velocity determinations were made at two or more different rates of airflow.

VELOCITY CONTOURS

The velocity measurements were plotted in the manner shown in Fig. 3-B. From the resulting curves velocity contours or lines of equal velocity were obtained. For example, to obtain the contours of velocities equivalent to 20 per cent and 70 per cent of the average velocity at the face of the opening, the values of the abscissas corresponding to the intercepts of these ordinates were obtained for the various velocity curves, as in Fig. 3-B, and plotted as in Fig. 3-C. Velocity contours were prepared in this manner for the several openings investigated.

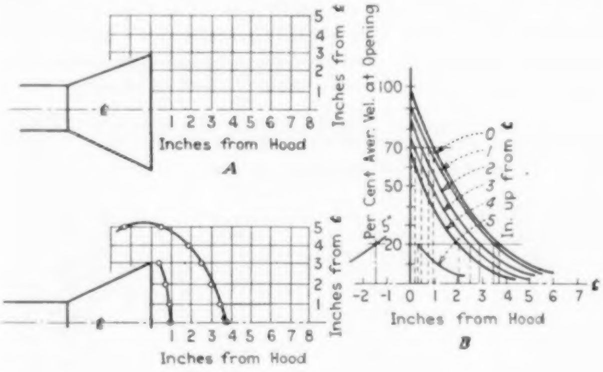

FIG. 3 PROCEDURE IN MAKING VELOCITY SURVEY IN THE ZONE OF INFLUENCE

(A, Coordinate points at which velocities were determined. B, Change in velocity, with distance from hood parallel to axis. C, Velocity contours, plotted from curves in B.)

CENTER-LINE VELOCITIES

It was found, during preliminary studies, that the characteristics of suction openings could be measured grossly by means of the change in air velocity along the axis of the hoods. Center-line velocities were therefore obtained for the various openings studied.

VELOCITY CONTOURS

The aerodynamic characteristics of suction openings, expressed in terms of the velocity contours have been examined with reference to the following factors: (*a*) Volume of airflow through the opening, (*b*) geometric shape of opening, (*c*) area of opening, and (*d*) shape of transition piece.

Effect of Volume of Airflow on Shape of Velocity Contours. An examination of the velocity contours for a given opening shows that they have the same shape regardless of the quantity of flow. This is clearly demonstrated by the fact that the ratio of the velocity at any point to the average velocity across the suction opening remains constant for all flows. Thus, an 8-in. round opening gave approximately constant ratios of point velocity to the average velocity at the hood opening at corresponding points for flows of 1000, 8000, and 450 cu. ft. per min. (Table 2.) This constant ratio was found to hold true for all the openings studied in the present investigation.[5]

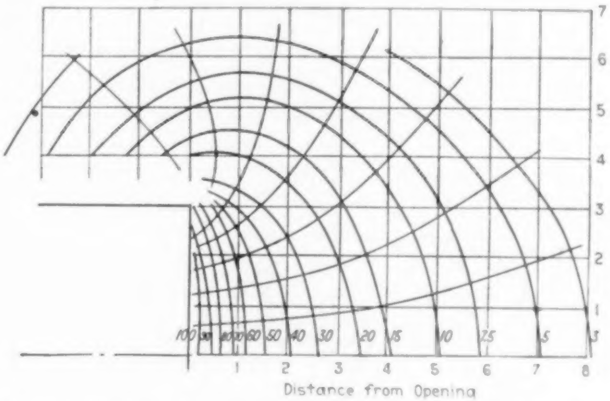

FIG. 4 VELOCITY CONTOURS FOR 6-INCH DIAMETER OPENING. CONTOURS EXPRESSED AS PERCENTAGES OF AVERAGE VELOCITY AT FACE OF OPENING

The average velocity at the face of the hood was calculated from the rate of airflow, measured by the orifice or venturi and the area of the opening. It was observed, however, that the 100-per cent contour did not coincide with the face of the hood, but was located at a distance outward which varied with the size and shape of the opening. This is shown by the velocity contours for a 6-in. diameter opening in Fig. 4. Owing to the disturbance at the edge of the opening, where a sudden change in direction of flow took place, the effective area decreased and hence produced a velocity across the central region higher than the average velocity for the opening. The amount of restriction appears to be a function of the area and perimeter of the hood.

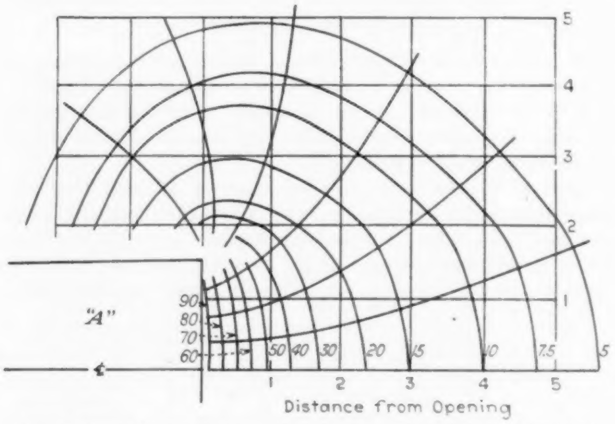
TABLE 2 RELATION BETWEEN VOLUME OF FLOW AND RATIO OF POINT VELOCITY TO AVERAGE VELOCITY FOR 8-INCH DIAMETER DUCT END

Distance from hood, inches	Per cent average velocity Q = 1000 c.f.m.	 Q = 800 c.f.m.	 Q = 450 c.f.m.
1	82.0	83.0	82.2
2	56.6	56.0	56.0
3	35.7	37.6	37.4
4	26.6	26.2	24.8
5	19.4	18.4	17.0
6	12.1	12.9	12.4
7	9.0	10.4	8.4
8	7.99	7.52	7.6
9	6.02	6.55	..
10	4.75	5.35	..

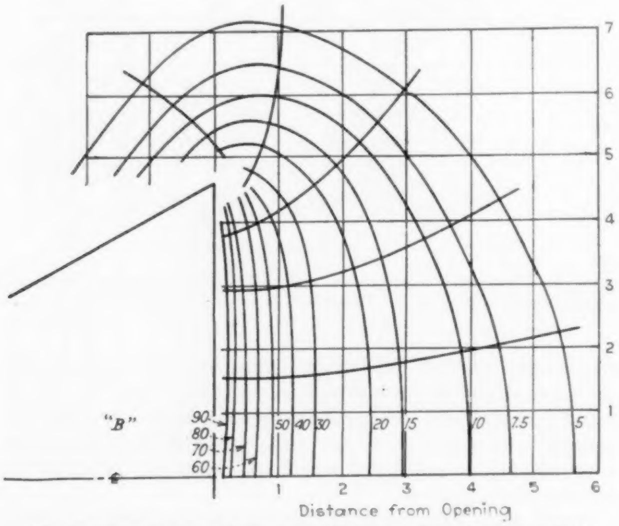
Effect of Geometric Shape of Opening. The velocity contours of all openings studied do not differ greatly in their chief character-

---

[5] This observation is in accordance with the mathematical theory of contour lines. (8)



(*A*, Contours in center-plane, perpendicular to long side of opening.)



(*B*, Contours in center-plane, perpendicular to short side of opening.)

FIG. 5 VELOCITY CONTOURS FOR 3-INCH BY 9-INCH OPENING

istics. The contours are nearly parallel to the face of the hood over the region projected by it, and bending generally takes place in the region corresponding to the edge. As the distance from the opening increases, the bending of the contours becomes more gradual and the velocity lines terminate on the surface of the transition piece behind the opening.

Contours in one center-plane determine the shape of contour surfaces of round openings, owing to their geometric symmetry. In the case of square and rectangular openings, however, the distribution of airflow at the corners differs from the distribution in center-planes. The effect of the corners is to reduce the effective area of the opening which results in a general outward displacement of contour lines as compared with those for round openings of the same area. In the case of rectangular openings, moreover, the flow distribution differs in the two center-planes. The difference is proportional to the ratio of short to long side. There is a flattening of contours along the long side and a corresponding shortening in the plane bisecting the short side. Along the axis there is an inward displacement of contour lines as compared with round openings having the same area. Contour lines for the two sides of a rectangular opening 3 in. by 9 in. in dimension are shown in Fig. 5. They may be compared with the contours of the round opening having approximately the same area shown in Fig. 4.

Effect of Area of Opening. An increase in the area of the opening, with the geometric shape remaining the same, causes an outward displacement of the contour lines at right angles to the axis of the hood. The rate of decrease of velocity along the axis is reduced, but at distances of 6 in. or more from the face the velocities tend to coincide, regardless of the area of the opening. This is shown by the velocity contours for the same flow for 4-in. and 8-in. square openings in Fig. 6. Thus, there is considerable advantage to be gained in using a large opening for the collection of dust at some distance from the hood. Large openings not only give a wider and better contour distribution for the same quantity of flow, but also reduce the loss of energy at the hood entrance.

It should be remembered that in choosing a hood for a particular operation, consideration must be given to the area and distribution of dust generation; i.e., the hood chosen should create maximum flow within the "effective area" of dust generation and minimum flow from areas in which no dust is produced (5, p. 88).

Shape of Transition Piece. The extent to which abruptness of transition enters into the distribution and shape of the velocity contours is of importance since the location of hoods often limits the amount of transition space available. This effect has been examined for three types of 4 in. by 8 in. openings. The transition pieces for the three openings included a simple duct end (no transition), a gradual transition to a 4-in. round duct in a distance of 7.75 in., and an abrupt transition to a 4-in. round duct in a distance of 3.5 in. Point velocities along the center lines of the three hoods are compared in Table 3. The results show no change in velocity with abruptness of the transition piece. Complete velocity surveys were also made for these openings and no change in position of the contour lines was observed. A comparison of contours of a plain 8-in. diameter duct end with a similar opening having a conical transition to a 4-in. duct in a distance of 6 in. also showed that the shape of the transition piece did not materially change the distribution of airflow in the region of influence. Thus it may be said that within the limits of this study the shape of the transition piece has no significant effect upon the distribution of airflow about the suction opening.

TABLE 3 EFFECT OF FLARING ON THE CENTER-LINE VELOCITIES FOR THREE FORMS OF 4-INCH AND 8-INCH HOOD

(Velocities in per cent of average velocity at opening)

Distance from opening, inches	Type of hood		
	Rect. duct end	Gradual opening	Abrupt opening
1	66.0	65.5	65.0
2	37.5	37.5	36.2
3	23.4	23.0	22.6
4	15.1	15.2	14.6
5	10.7	9.20	9.60
6	7.61	6.90	7.00
7	5.50	4.40	4.54
8	3.84	3.72	3.08

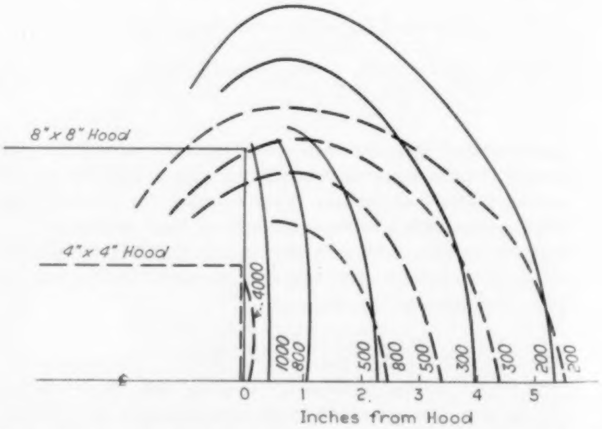


FIG. 6 VELOCITY CONTOURS FOR 4-INCH BY 4-INCH AND FOR 8-INCH BY 8-INCH OPENINGS FOR THE SAME TOTAL FLOW

(Q = 445 cu. ft. per min.)

The transition distance may be decreased until the sides of the hood are perpendicular to the duct to which it is connected. In this case, the hood acts simply as a flange on the duct itself. Under this condition, it has been found that a significant change in velocity distribution takes place. This is a special case, however.

CENTER-LINE VELOCITIES

Representation of aerodynamic characteristics of exhaust hoods by means of velocity contours offers a fairly simple means of comparing graphically various types of hoods. The determination of contour lines, however, involves considerable time and labor. Moreover, the velocity contours do not lend themselves easily to mathematical analysis.

A simpler and more direct means of comparison may be had by the analysis of velocities along the projected axis of the openings. Since exhaust hoods ordinarily draw dust from the area directly in front, the chief factor governing their efficiencies is the distribution of airflow in this region, which may be expressed grossly in terms of center-line velocity curves. They may be compared mathematically as well as graphically. A series of curves for several round openings are shown in Fig. 7. The point velocities are expressed as percentages of the average velocity at the opening.

Graphical Representation of Center-Line Velocity Curves. Center-line velocity curves (Fig. 7) may be presented graphically in the more convenient form shown in Fig. 8, which gives the relation between point-velocity and size of round openings for various distances out along the center-line. By means of the diagonal lines, the velocity at any point may be obtained directly in terms of Q, the total flow through the hood. The logarithmic scale is used for convenience in reading. As an example in the use of the chart: Assume a round opening, 6 in. in diameter, and a total flow through it of 800 cu. ft. per min. The center-line velocity at a distance of 8 in. from the hood is found, and from the chart, the velocity is 4.9 per cent of the average velocity at the face or, from the diagonal lines, 0.25 Q per min. Since $Q = 800$ cu. ft. per min., the actual velocity will be 200 ft. per min. In designing, the limiting factors will ordinarily be the velocity requirement at the point of dust generation and the distance to the hood. Assuming these two factors to be 300 ft. per min. and 7 in. respectively, the chart indicates that a flow of 940 cu. ft. per min. will be necessary through round openings 8 in. in diameter or less. For larger openings, the total flow must be greater, 1250 cu. ft. per min. being required in the case of a 16-in. opening.

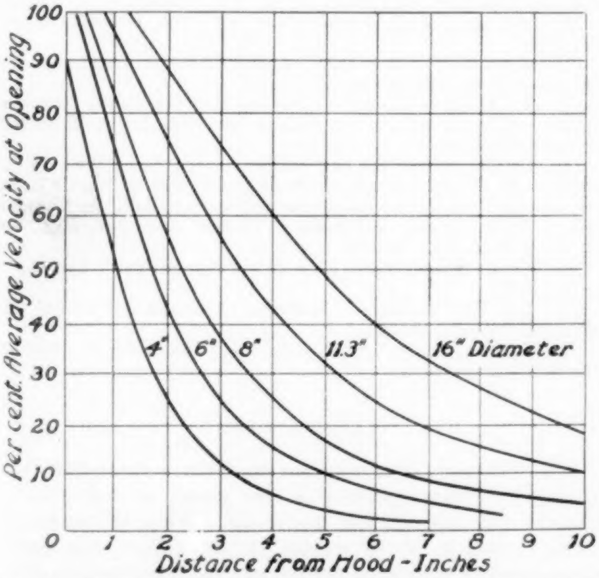

FIG. 7 CENTER-LINE VELOCITY CURVES FOR SEVERAL ROUND OPENINGS—VELOCITIES EXPRESSED AS PERCENTAGES OF AVERAGE VELOCITY AT FACE OF OPENINGS

From the equations presented later similar charts may be prepared for square openings or rectangular shapes having various ratios of sides.

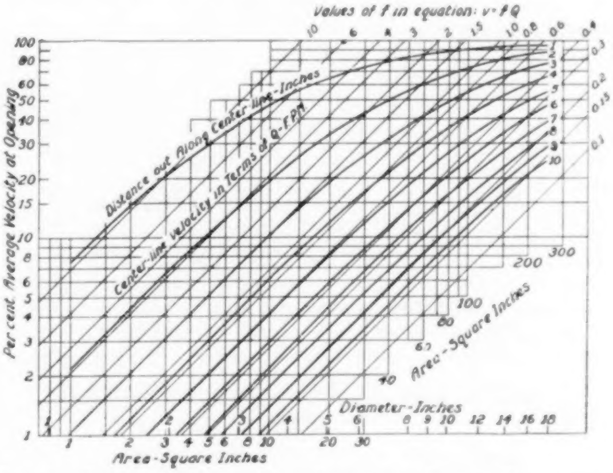

FIG. 8 CENTER-LINE VELOCITY CHART FOR ROUND OPENINGS—VELOCITIES EXPRESSED AS PERCENTAGES OF AVERAGE VELOCITY AT FACE OF OPENING AND ALSO IN TERMS OF Q, THE FLOW THROUGH THE HOOD

Mathematical Analysis of Center-Line Velocity Curves. The center-line velocity curves are limited in one direction and appear to be approximately hyperbolic in shape. An analysis of the data indicates that the curves may be defined by the equation,

$$f(Y) = \frac{m}{x^n} \quad \ldots\ldots\ldots\ldots\ldots\ldots [1]$$

when Y is the point velocity expressed as a percentage of the average velocity at the opening, x the distance from the opening, and m and n constants. When the function $f(Y)$ has the form,

$$f(Y) = \frac{Y}{100 - Y}$$

a linear relationship is given when the equation is written in its logarithmic form, thus:

$$\log \frac{Y}{100 - Y} = \log m - n \log x \quad \ldots\ldots\ldots\ldots [2]$$

Hence, the center-line velocity curves may be rectified to straight lines by plotting the function $\frac{Y}{100 - Y}$ against x on double-logarithmic paper and thus the constants m and n may be obtained.

The center-line velocities for several round openings, plotted in this manner, are shown in Fig. 9. The data follow the straight lines very closely and are representative of the plotted curves obtained for the other openings.[6]

It will be observed that the lines are parallel. The square and rectangular, openings also gave lines parallel to those shown in Fig. 9, thus indicating that the value of n does not change with size or shape of the opening. Its value was found to be —1.91.

---

[6] There was a slight divergence from the straight line at extreme values of x.

The value of m was found to be a function of the area of the opening, according to the relation

$$m = bA^k$$

when b and k are constants. For round openings, the constants had the values 0.0825 and 1.04, respectively. Thus, the final equation for round openings took the form,

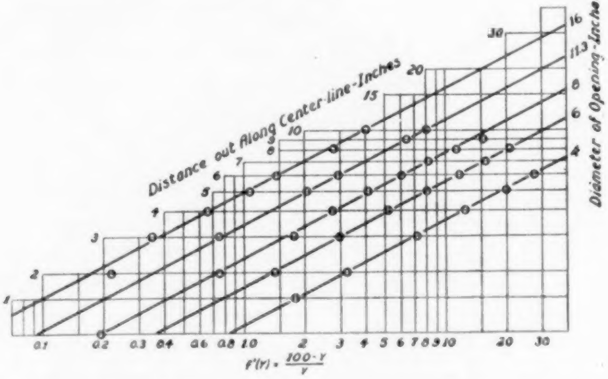

FIG. 9 CENTER-LINE VELOCITY CURVES FOR ROUND OPENINGS RECTIFIED TO STRAIGHT LINES

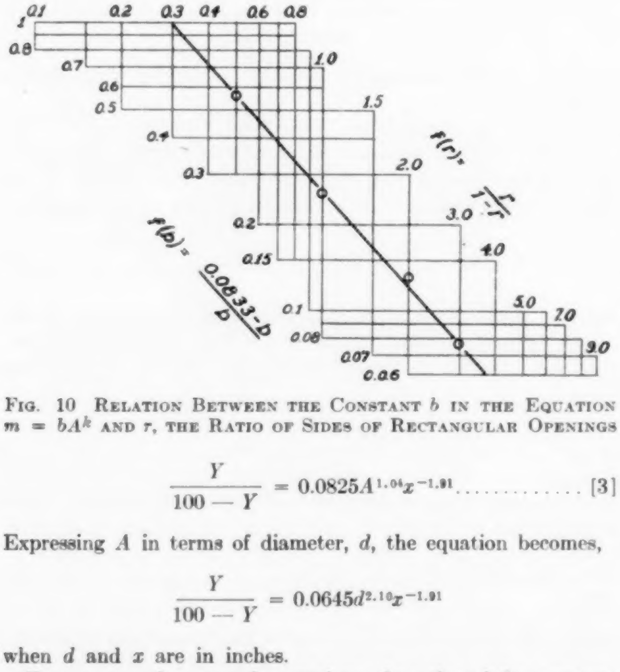

FIG. 10 RELATION BETWEEN THE CONSTANT b IN THE EQUATION $m = bA^k$ AND r, THE RATIO OF SIDES OF RECTANGULAR OPENINGS

$$\frac{Y}{100 - Y} = 0.0825A^{1.04}x^{-1.91} \ldots\ldots\ldots\ldots [3]$$

Expressing A in terms of diameter, d, the equation becomes,

$$\frac{Y}{100 - Y} = 0.0645d^{2.10}x^{-1.91}$$

when d and x are in inches.

For square and rectangular openings, the value of the constant k was found to be the same as for round openings, namely, 1.04. The value of b, however, was found to vary with the ratio of sides, as indicated in Table 4. The relationship is definite and has the form (see Fig. 10),

$$\frac{0.0833 - b}{b} = 0.259\left(\frac{r}{1 - r}\right)^{-1.104}$$

TABLE 4 VALUE OF b IN THE EQUATION, $m = bA^k$, FOR VARIOUS RATIOS OF SIDES OF RECTANGULAR OPENINGS

Ratio of sides	Value of b
1.000	0.0833
0.750	0.0774
0.667	0.0735
0.500	0.0663
0.333	0.0535

Substituting this value of b in the general equation, we obtain finally for square and rectangular openings:

$$\frac{Y}{100 - Y} = 0.0833\left[\frac{1}{1 + 0.259\left(\frac{r}{1 - r}\right)^{-1.104}}\right]A^{1.04}x^{-1.91} \ldots [4]$$

Thus, the center-line velocity curves may be defined completely in terms of the geometric shape and size of the suction openings. The equations may be used to calculate point-velocities along the axis or as a basis for the construction of general charts such as that shown in Fig. 8.

It is interesting to note that the exponents of A and x in the general equations are close to 1 and 2. This suggests that the true form of the general equation may be

$$f(Y) = bAx^{-2} \ldots\ldots\ldots\ldots\ldots\ldots\ldots [5]$$

For, it may be argued that the experimental determinations of the constants are in error or that the function

$$f(Y) = \frac{Y}{100 - Y}$$

is not a correct expression of the conditions. It will be recalled that the 100-per cent contours did not coincide with the face of the openings, thus indicating that the upper limit of Y in the center-line velocity curves is greater than 100 per cent. Whatever the form of the true expression, the inverse-square relationship in Equation [5] may be used for approximate calculations.

Discussion

J. L. ALDEN.[7] It is apparent that the authors have been guided by their experience in the design of dust-collecting systems for stone-cutting equipment. While the statement, "The air velocity to be created at the point of dust generation, therefore, constitutes the primary specification upon which the design of exhaust hoods must be based," is correct for the design of hoods for the collection of dust particles with random trajectories, it does not apply to the case where the dust particles leave their source with predictable trajectories. Some examples of the latter condition are the dusts and chips from woodworking knives and cutters and from abrasive wheels and buffs. In these instances the dust is thrown from the point of generation in a definite direction and with definite velocity. When designing a hood for such a tool it should be so shaped and positioned that the dust is thrown from its source into the point of highest air velocity in the hood and that its direction of motion at that point coincides so far as possible with that of the air stream. When the hood has been so proportioned, it will be found that the required air velocity and hence the suction may be considerably reduced without loss of effectiveness. In other words, contrary to the practice as outlined in the quotation from the author's paper, the hood should first be designed and located to take advantage of the natural velocity and direction of the dust particles, after which the air velocity to keep the dust in suspension may be determined.

[7] Assistant Superintendent of Manufacturing Development of the Western Electric Company, Hawthorne Works, Chicago, Ill. Mem. A.S.M.E.

The charts of this paper effectively demonstrate the futility of attempting to set in motion dust particles which have come to rest several inches from the hood mouth or to change the direction of particles which are already flying away from the hood. As a matter of fact, the principle of hood design stated in the preceding paragraph is a necessary conclusion to be drawn from the information presented by the authors. If this principle is ignored, either the hood will be ineffective or the power cost will be excessive because of the necessity for abnormally high suction. The charts also illustrate the non-directional nature of an exhaust hood as contrasted with the strong directional characteristics of a pressure air nozzle, thereby explaining why the vacuum cleaning of machines except in unusual situations is ineffective.

H. A. COLVIN.[8] If every one, machine designers and owners, will remember one point brought out so clearly, it will prevent a great many mistakes. It is shown that suction will not reach out. It is altogether different from blowing. The suction disappears only a short distance from the opening.

There is another point mentioned that is generally misunderstood; namely, that conveying is done by velocity—of course, velocity and volume, but not by static. A high static or suction reading merely means resistance. Many people think that if they can get strong suction readings, they have a wonderful dust-collecting system; whereas, as a matter of fact, it is the easiest thing in the world to get strong suction readings by adding resistance that actually cuts down the effectiveness of the pipe in handling dust.

Double-End Tenoners and Their Use

By J. H. MANSFIELD,[1] ROCKFORD, ILL.

The paper describes the construction, development, and use of the double-end tenoner from the original belt-driven machine with babbitted bearings, with its limited range of cutting stock to length and making tenons, to the present motorized ball-bearing machine, with its broad range of sizing, tenoning, shaping, dadoing, relishing, notching, and dovetailing all rectangular parts in two passes through the machine, and making certain styles of lock joints. It is by far the nearest to a universal use machine yet developed for a production woodworking plant.

DOUBLE-END TENONERS have been in use for about 75 years. The early machines were belt-driven and usually of the lathe-bed type, similar to Fig. 1. This machine was patented in 1866. A later design of machine, in which the present type of floor base or bed piece was used, is shown in Fig. 2. The method used in driving the copes consisted of a vertical countershaft for each housing, driven by a quarter-turn belt from the main countershaft and driving each of the copes through straight belts over pulleys of sufficient width of face to permit vertical adjustment of the cope spindles. Trouble was experienced in obtaining sufficient power for heavy cope cuts, such as occur in sash and heavy door work, because of the comparatively short, narrow belts. This, together with the inconvenience and danger of the high-speed shaft and belt near the out-feed position of the machine, led to the development of a different method of drive.

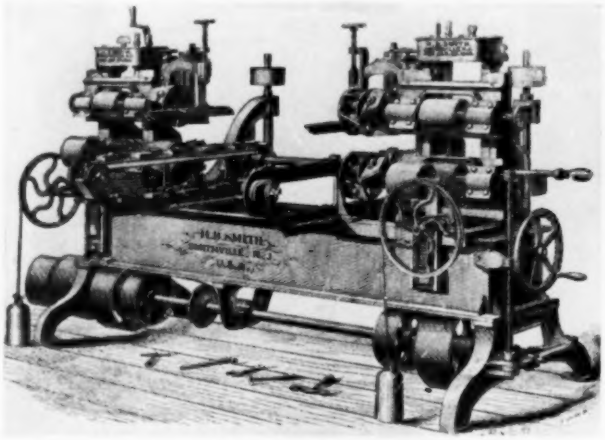

FIG. 1 ORIGINAL DOUBLE-END TENONER, PATENTED 1866

Fig. 3 is about the next step in the development, showing a machine having only lower copes driven by enclosed bevel gears from a secondary countershaft running lengthwise of the machine and gear driven from the main countershaft. The bevel gears consisted of a metal pinion driven by a rawhide gear. This drive delivers much more power to the spindles than the old belted type, takes up less space, and is less dangerous.

These machines were used in sash, door, and furniture work almost entirely and did not have sufficient capacity to handle cuts required on heavy timber framing used in freight-car and passenger-car construction.

Fig. 4 shows a car tenoner suitable for handling timbers up to 12 in. square and 12 ft. long, making single, double, or triple tenons for the heavy sills of cars and locomotive pilots. These were first built in 1898. This machine was sufficiently fast and adjustable to permit handling also the cutting off and grooving of floor boards and other miscellaneous material for freight cars. The characteristics of all these machines are similar in that the right-hand housing is adjustable and in most cases carried the mechanism for controlling the power device for moving the housing. No provision for accurate, quick set-up was provided, such as gages, dials, or graduations on the base, it being necessary for the operator to measure the distance between the various cutters and then check the first pieces for accuracy. The hold-

Fig. 6 Recent Motor-Driven Tenoner, With Right-Hand Housing Carrying Controls

downs were either of a spring or shoe type in one piece or with short sections, such as is shown in Fig. 2. There was no possibility of angle adjustment of any of the heads. In case angle cuts were necessary, they had to be accomplished through the use of special shaped heads.

The next improvements were undoubtedly the adaptation of ball bearings to the spindle housings and the present type of hold-down chains carrying rubber pads. The hold-down chain beams were hinged to swing up and be locked out of the way to save time in making set-ups. In the machine with these improvements the controls for the feed and changing the position of the right-hand housing are at the left-hand end.

Shortly after the introduction of ball bearings in woodworking machinery, direct motor drive to cutter-head spindles came into use. This was accomplished in many cases by users of machines changing over their own tenoners, in some cases putting motor-driven copes only on belt-driven machines, and in others both the motor-driven copes and cut-off saws. With this direct motor drive, angle cuts with the saws and the copes were possible. The drives for the top and bottom tenon heads were not changed, since there was not sufficient space for motors and the belt drive was more satisfactory for them than for either the cope or saws.

An early motor-driven machine was one on which magnetic controls for the motors operated by push buttons were used, with both the push-button and mechanical controls mounted at the left-hand end of the machine. Another development was the addition of the graduated bar or scale over the top of the machine to show the setting for length of stock. These scales were graduated to $^1/_{16}$ in. One of the saws was tilted and the other straight, but it is not known whether the tenon heads and copes were similarly adjusted.

On these earlier machines, attachments such as are now available on all double-end tenoners could not be had, since it was impossible to drive them until direct built-in motors had been developed. The use of the old-style tenoners was thus limited to straight cuts and to such work as cutting off or cutting off and tenoning in straight work. The belt- or gear-driven copes were alleged to be not free enough from vibration to permit their use for shaping.

Fig. 5 shows a late design of motor-driven tenoner which can be had with practically all the various attachments, including jump or stationary dado, relishing attachments, notching attachment, scoring saws, and drop dogs.

In this design the right-hand housing is adjustable and carries push-button motor controls and feed-control levers in a location convenient for the operator. The scale for indicating the length of pieces is carried on the front of the base instead of overhead, and the top of the base is enclosed to keep the dirt out.

Fig. 6 is another recent design of motor-driven tenoner in which the right-hand housing is stationary and carries all of the electrical and mechanical controls. This design permits of the operator standing in one position next to the controls at all times.

Fig. 7 is a double-end tenoner manufactured in Europe. This is of interest because of the novel type of stock hold-downs and the large number of cutter-head motors available. It is claimed that from 8 to 16 motors can be used. The hold-down arrangement appears to be complicated, and sawdust and shavings might cause trouble. No angle adjustment for the top and bottom heads or cut-off saw is indicated, but there are gages indicating the location of the saws.

Present designs of tenoners are capable of handling an almost endless variety of work as now encountered in the woodworking industry. The range varies from ordinary straight or angle cut-offs or tenoning work to sizing large or small panels, table and cabinet tops, shaping and molding edges, and grooving, forming lock joints of various kinds, single or jump multiple dado work in desk or cabinets for shelving, relishing cuts, miters, corner notches, etc.

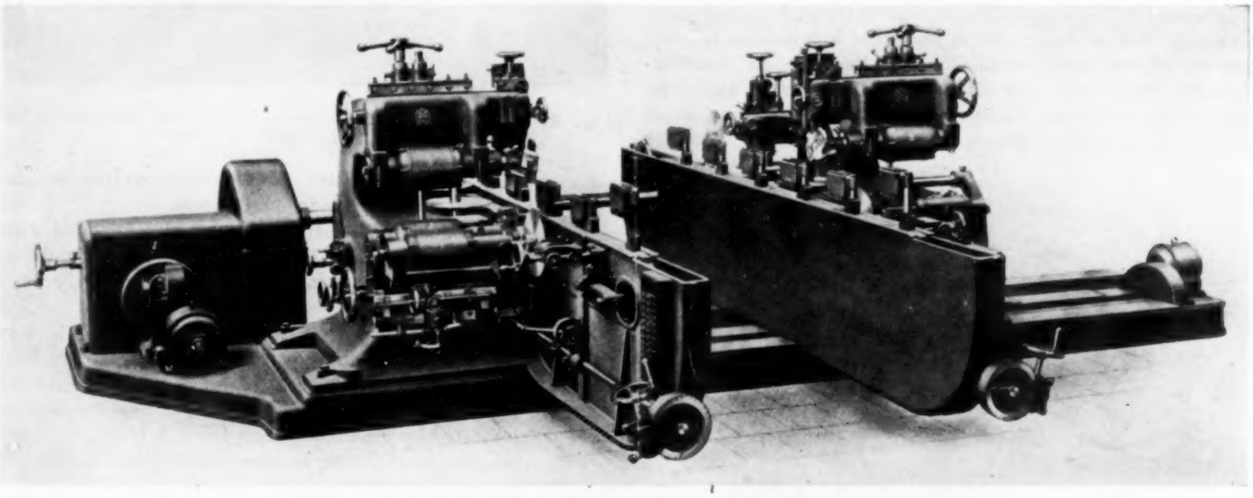

FIG. 7 DOUBLE-END TENONER OF FOREIGN MAKE

As possibilities of the motorized tenoners have been realized, greater accuracy and means for quicker set-ups have been demanded. In woodworking plants, quantities that will keep a double-end tenoner running three or four hours are becoming unusual. Even in automobile-body plants the day's requirements for certain pieces are not sufficient to keep a tenoner running on one piece of work alone, thus making numerous set-ups necessary during the day's run. On the machine shown in Fig. 6 every effort was made while the machine was being designed to facilitate easy set-ups. One of the results of this study is the hinged pressure beam as shown in Fig. 8. To use this to advantage the rate of adjustment of the movable housing had to be faster than had been considered advisable, and it is now possible to open the machine wide from a closed position in a small fraction of the time it used to take. The slow adjustment was quite necessary on early machines as no quick hand adjustment for final setting was provided.

Fig. 9 shows the controls and indicating dials for controlling the movement of the movable housing. The hand lever *A* when pushed either to the right or left controls frictions which move the housing in either direction. As the housing is moved, the dials *B* and *C* are rotated by gears from the adjusting screw and indicate the exact location of the movable housing at all times. Dial *B* is graduated in inches and in feet and inches, and it moves one notch for each inch that the housing travels. Dial *C* has 64 graduations about $^{5}/_{16}$ in. apart, each graduation indicating $^{1}/_{64}$-in. movement of the housing. This is used for the final setting by hand and is accomplished by pushing in handwheel *D* to engage a clutch for rotating the adjusting screw either way. It is thus possible to adjust the movable housing and locate it accurately to within one-quarter of $^{1}/_{64}$ in. without the operator moving from his working position.

This dial arrangement has been used for years on all machine tools such as milling machines, lathes, planers, etc., for measuring closer than mechanics could read direct on their scales. Most of them are graduated to the thousandths of an inch, and on a precision machine manufactured in Switzerland, and used extensively in toolroom work, jigs, dies, etc., the graduations read to 0.0001 in.

In some furniture plants this tenoner is used for cutting parts for sample sets, as the amount of handwork is materially reduced and the various parts are machined in less time and more accurately. One foreign user of this machine has steel go and no-go gages with a 0.003-in. variation for checking the thickness in mahogany and walnut tenons on pieces 18 in. wide. Cabinet makers in that plant have no hand tools whatever and are discharged if found bringing any in, as hand fitting of parts will not be tolerated on radio and phonograph cabinets.

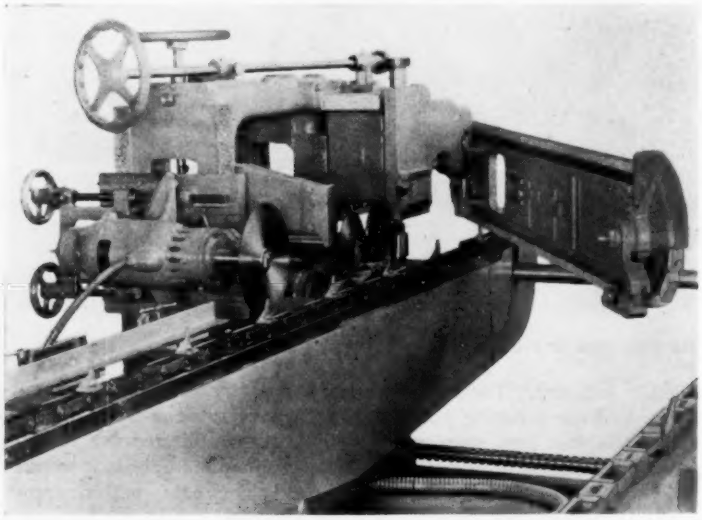

FIG. 8 HINGED PRESSURE BEAM TO FACILITATE EASY SET-UPS

There are domestic concerns also using steel gages to insure interchangeability in manufacturing, a common practice being to send all parts to stock bins before they go to the cabinet department for assembly.

The screws for both vertical and horizontal adjustments of all the cutter heads and saw housings are cut the same pitch and fitted with a graduated collar indicating sixty-fourths of an inch, the graduations being about an inch apart. These graduated collars, in addition to scales, give the exact position of the cut-off saws and tenon and cope heads to within a fraction of $^{1}/_{64}$ in. over the full range of adjustment. The end of each of the screws is fitted with a square for a detachable hand crank for quickly making the larger adjustments.

Locks for each of the screws are provided, so that after being once set, they will hold their position.

For adjusting the top and bottom tenon heads, either with or without scoring saws, the two handwheels mounted on the same center, at *A* in Fig. 6, are fitted with a friction-clamp arrangement, so that when the proper space between the top and bottom heads governing the thickness of the tenon has been reached, the two handwheels can be securely locked together by the hand-clamp wheel *B*, and the raising and lowering can then be done without changing the tenon thickness.

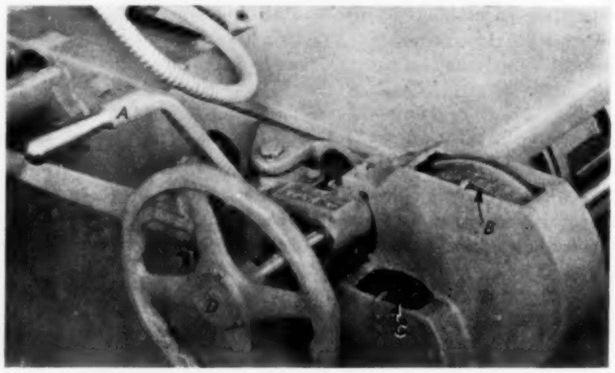

FIG. 9 CONTROLS AND INDICATING DIALS FOR MOVEMENT OF HOUSING

The hold-down chain beams are also provided with scales to show their height above the feed chains, so that this adjustment can be quickly and accurately made without guesswork.

Work that requires parallel angle cuts at both ends can be run on double-end tenoners if it is possible to advance one chain ahead of the other. It is possible to adjust one chain out of square the amount required as indicated by graduations and bring it back to square relative to the other chain accurately and quickly on present-day machines.

With any double-end-tenoner feed chains there are pulsations or variations in the rate of feed for each sprocket tooth in the drive sprocket. When one chain is advanced one-half of the pitch or center distance from chain pin to chain pin, they do not travel together, and the pulsations amount to about $^{5}/_{32}$ in. with an eight-tooth sprocket and 4-in. pitch chains such as are now used. If the angle cut is on short stock, this variation will cause such inaccurate work that it cannot be used; but where the parts are over 2 ft. in length and under 6 in. in width, very satisfactory results can be accomplished. Short angular work can be handled accurately by using special dogs of suitable lengths to give the required angle when the chains are left square. The accuracy of work so far as square cuts are concerned is controlled almost entirely by the feed chains, sprockets, and feed shaft. The length of each of the links must be held within very close limits or the feed will not be uniform. The sprockets must be very accurately cut and of material which will show very little wear over a long period and must be mounted on a shaft of sufficient strength to eliminate any tendency to spring when the machine is set for long stock. Play in bearings for the feed sprocket and shaft also contribute to lack of accuracy, and for that reason ball or roller bearings of hardened steel are used at these points.

Most feed chains are flat on the bottom and guided by gibs on each side. There must be some running clearance between the chain links and gibs, which wear increases, in some cases allowing the stock to shift endwise when passing through the tenon heads and copes on heavy cuts. To eliminate this disadvantage, chain links with a V-bottom running on V-tracks have been developed. This construction insures straight travel of the chains through the machine without any side motion. This straight-line motion is not affected by wear.

Feed dogs are made up of several types—non-adjustable, adjustable, drop dogs, and wood faced for backing up stock when shaping. The author believes firmly in non-adjustable dogs stamped to correspond with the links on which they fit, as this method saves considerable time when changing dogs. A tongue on the dog fits into a slot in the chain link so that the dogs will always go back in the same position and no time is lost squaring up as with adjustable dogs. Greater accuracy in the manufacture of the chains and dogs is required, but the saving in set-up time is well worth the additional cost. Drop dogs are used in some plants where the work varies greatly in width, as the dogs can be left on the machine and work of varying widths put through. When stock wider than the space between two dogs is run, it pushes down one or more dogs below the chain level while the piece passes through the machine, and the dogs are returned by a counterweight or spring when the stock leaves the chains. Drop dogs are more complicated and of weaker construction than the solid ones, and so are naturally less dependable.

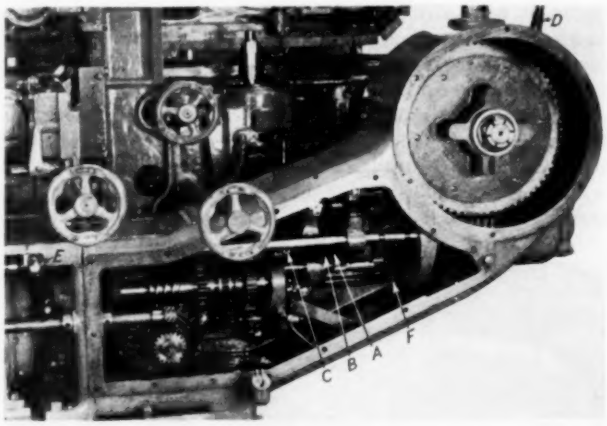

Fig. 10 Feed-Gear Box Showing Drive Mechanism

For large panels and other work, where the cuts are very heavy, the top of the feed chains should be corrugated to hold the stock more securely. Automatic lubricators driven by the feed chains are most essential for insuring lubrication of the tracks. With this method the track and chain receive oil only when the chains are running and do not become flooded, so as to leave oil on the work to cause trouble in the finishing room.

Fig. 10 shows the feed-gear box with both covers removed presenting a clear view of the drive mechanism. The feed motor is geared direct to a shaft having a sliding cluster of three change gears which engage with gears on the worm shaft for changing the rates of feed. Standard feeds are 14, 20, and 27 ft. per min., but these can be increased or decreased for special needs. With a positive drive of this type, it is necessary to build in some form of overload protection, so that in case the stock becomes jammed, something will slip to avoid serious breakages. There are several different methods of accomplishing this, and the one selected as the most suitable consists of a rattle clutch which is used as a safety, and also a start and stop clutch. Part of the clutch is shown at *A* on the side of the large gear of the nest of change gears and is driven by the motor through the three cluster gears. At *B* is the other member of the clutch mounted on the worm shaft and held in contact with the other half *A* by a coil spring *C*, except when disengaged by means of the hand lever *D* or its companion lever at the front of the machine. The tension on the spring *C* can be adjusted to suit requirements and should be just a little more than enough to feed the machine when running on the heaviest work. In case of a jam, the half *B* moves endwise on the worm shaft, permitting its teeth to ride over the top of the teeth on the half *A*. The feed is thus instantly stopped and the noise caused by the clutch teeth sliding over each other attracts the operator's attention, so the operator will shift the feed lever to entirely disengage the feed and locate the trouble.

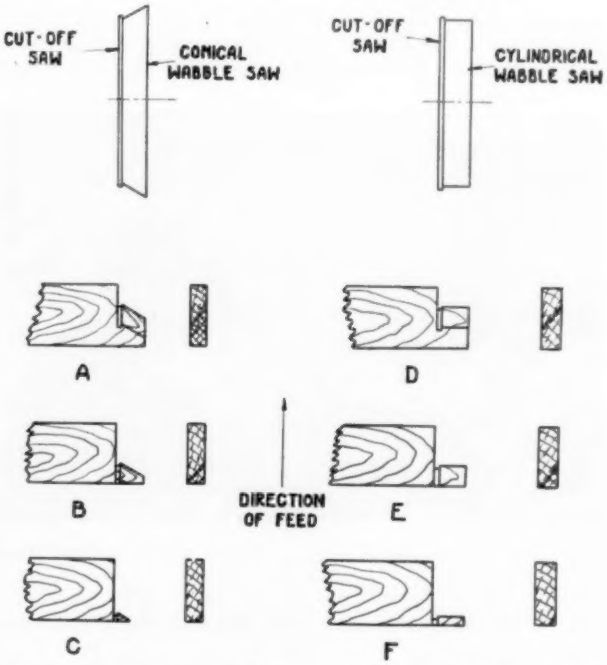

Fig. 11 Cuts Nearing Completion, With Both Conical and Cylindrical Wabble Saw and Cut-Off Saw

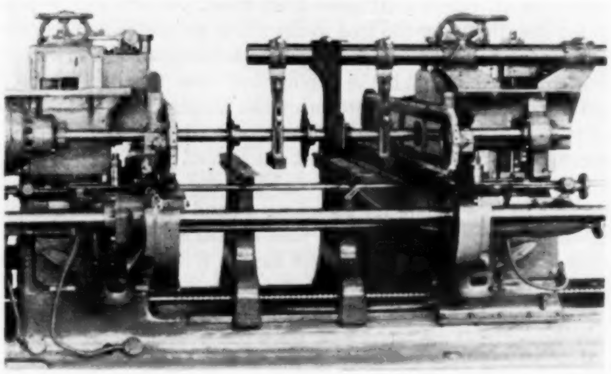

Fig. 12 Rear View of Tenoner Equipped With Jump Dado

In this design the leverage of the clutch over the feed chain is constant regardless of the rate of feed being used.

Other methods of overload protection have been tried with varying degrees of success, among them the use of a belt with spring-loaded or weighted idler, friction clutches, and electrical protection for the motor. Friction clutches and belts depend upon friction for their driving power, and with most surfaces a variation in temperature, atmospheric conditions, or a little oil will affect the power transmitted. With an electrical overload protection for the feed motor an adjustment is necessary for each change of feed, as the ratio between the r.p.m. of the motor and the speed of the feed chains varies with the rate of feed. The pull on the chain delivered by the motor at 27 ft. per min. is about three-fifths of that at 15 ft. Most electrical devices depend either upon a magnetic circuit or heating elements for their operation, and in case of the latter too much time is required for its operation to make it effective as an overload protection on any feed mechanism. The magnetic type can be adjusted to very close ranges, but must be set for change of feed, which the average operator will not do.

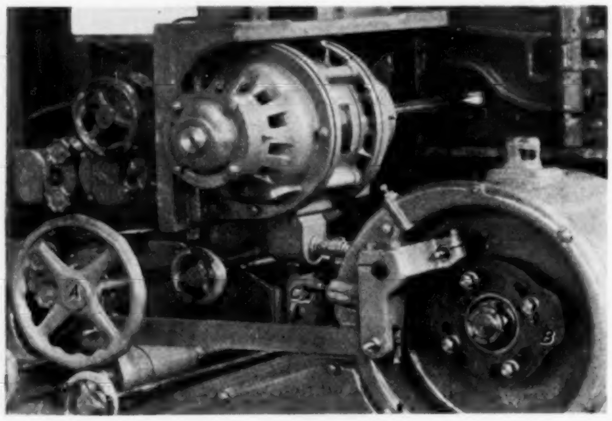

Fig. 13 End View Showing Cam, Motor, and Adjusting Hand Wheels

In the feed box shown a gear-type lubricating pump positively driven by gearing from the motor delivers oil to an indicator at the top of the housing, from where it is carried through suitable piping to all points that need lubrication. A reservoir is provided directly under the feed worm which maintains oil at a constant level, so that the worm is partly submerged. After the oil has circulated through the piping and over the bearings and gears it returns to the bottom of the housing and is then recirculated. All of the gearing is of hardened steel, and the bearings are anti-friction type, either ball or roller.

The worm shaft projects through the end of the housing and terminates in a square for attaching a hand crank to be used in making set-ups. The rate of feed is changed by moving the cluster gears *F* by means of the handle *E* which indicates the desired feed.

Veneered stock, especially when built up with casein glue and face veneer of $^1/_{28}$ in. thickness, tears badly while being tenoned unless scoring saws are used or the direction of rotation of the tenon head is reversed to cut with the feed instead of against it. Of the two methods the scoring saw is much more satisfactory. These saws are motor driven, and the housings are mounted in some machines on ways in front of those for the top and bottom tenon heads and adjusted in a similar manner. On one of the latest machines they are mounted on the housings of each of the top and bottom tenon-head motors and provided with vertical and horizontal adjustment so that after once being set to cut with their tenon head, they require no further adjustment as they move with the tenon head unit whenever the set-up is changed. With either type of scoring saw, motors can be shut off and the saws adjusted clear of the stock when not needed.

Refuse cutters for hogging up the off-fall have been used with varying success to eliminate the blocks falling on the floor when cutting off narrow pieces and in the more difficult job of handling edgings when sizing panels and case-goods tops. The usual type is a cylindrical wabble saw mounted next to a cut-off saw of slightly larger diameter. This cuts up the scrap in line with the cut-off saw so that as the cut-off saw progresses in the work the scrap is disposed of by the refuse cutter. The difficulty is that the pressure of the wabble saw against the work is sufficient to cause not only tearing up of the stock at the end of the cut, but also splintering back into the stock as the cut is completed. One type of hogging attachment, consisting of a conical wabble saw and cut-off saw combination, has been developed that eliminates this condition. Fig. 11, at *A*, *B*, *C*, *D*, *E*, and *F*, indicates the condition with both types as the cuts near completion. Referring to view *C* a very small portion of scrap is left in the shape of a triangle with its base next to the stock. As the cut progresses this triangle decreases in area faster than the amount of stock connecting it to the board. This reduces the pressure and leverage brought to bear by the wabble saw and avoids breaking off. Highly satisfactory results have been experienced with this on a large variety of work. Desk tops of built-up veneered up to 2 in. thick have been handled. The off-fall is chewed up and carried away by the exhaust system instead of falling on the floor as edgings. With a successful hogging attachment, both edging and shaping can be accomplished on tops which are of greater length than the distance between the cut-off saws and the cope spindles, as there are no edgings carried through to the cope cutters.

Figs. 12 and 13 show the rear view of the machine equipped with a jump dado and an end view of the same machine showing the cam, motor, and adjusting hand wheels. The dado shaft is mounted in a ball bearing at the adjustable end of the machine, and this bearing is housed in a slide carried on ways on the vertical housing. At the stationary end of the machine the shaft is supported in a sleeve that carries the rotor of the motor and is mounted on ball bearings. The whole motor assembly travels on a slide gibbed to ways on the vertical housing. On long machines over-arms carrying stock hold-downs and steady bearings for the dado shaft may be mounted on either end of the machine. When not in use, the arm can be removed or slid back through its supporting bearings out of the way.

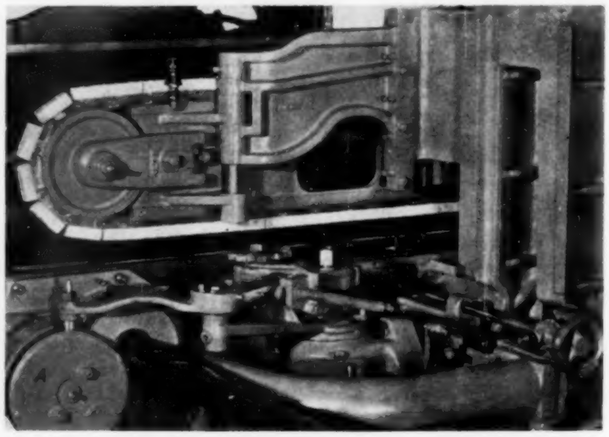

Fig. 14 Relishing Attachment Driven by Cope Motor

The slides carrying the end bearing and motor are vertically adjustable by means of a handwheel, at *A* in Fig. 13, connected to the vertical adjusting screws by means of worm and worm gears in each housing. This vertical adjustment is used either with the jump or stationary dado shaft. The jump movement is controlled by the cams *B*, which can be furnished with either single or double lobes for a jump every 16 or 32 in. of travel of the feed chains. Two cams are used, one outside the other, so that the duration or length of jump can be adjusted to suit requirements. The amount of raise is set by the adjusting screw *C* varying the movement from zero to $^3/_4$ in. The cams *B* are mounted on an extension of the hub of the feed-worm gear, insuring a very steady positive movement. Cuts as wide as 14 in., such as are used in lock boards for automobile doors, down to slotting desk-pigeonhole stock, are handled with great savings in time.

Fig. 14 shows a relishing attachment mounted on and driven by one of the cope motors and controlled by a cam *A*, gear driven from the main feed shaft. The cam *A* is made in two pieces, similar to the one for controlling the jump dado, to permit adjustment, instead of making up a special cam for each job. The cutter is driven by the cope motor through enclosed hardened-steel gearing and is held into the cut by heavy coil springs which are positively pulled out at the right time by the cams. In case of an accident, such as forgetting to start the cutters, the unit will be pushed back by the stock compressing the spring. Cams can be furnished for relishing one or both ends of a tenon.

A single-notching attachment, mounted on the horizontal ways for the cope-spindle housing, is used for notching the tops of telephone stands and similar novelty furniture. It is controlled by a cam geared to the main feed shaft. Another type is for notching the front and rear edges of the stock as it passes through the machine so that at one pass all four corners are notched out for legs.

Fig. 15 Unusual Pieces of Work

The standard double-end tenoner used to consist of cut-off saws, top and bottom tenon heads, and cope spindles with a feed mechanism. On modern electrified machines, various modifications or attachments have become almost as standard in certain lines of work as the saws and tenon heads were on the old belt-driven machines.

Other features, such as sanding attachments, dovetailing attachments, serpentine dovetailing attachments for seats and tops of school furniture, corner-rounding attachments, and transfer tables, have been developed.

The amount of stock cut at one setting determines to a large degree the economic success or failure of complicated set-ups on any machine, whether for metal or woodwork. In woodworking plants this is especially true, as the rates of feed are very high.

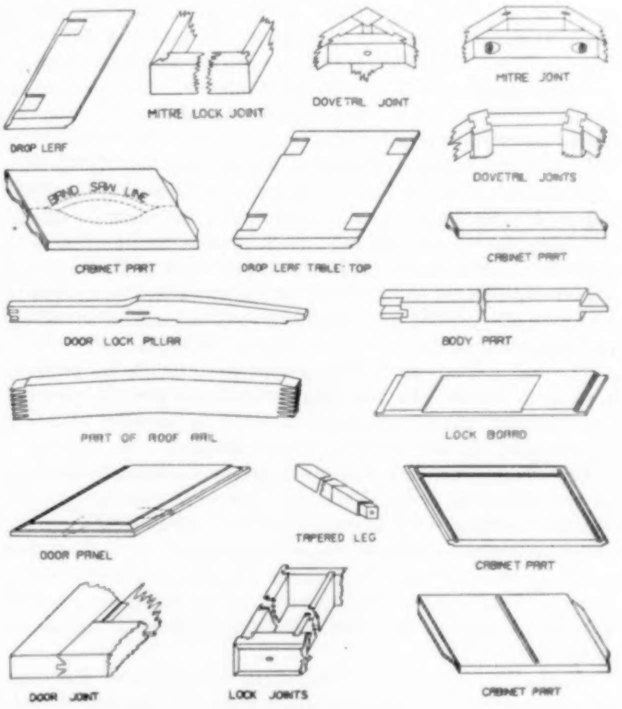

Fig. 16 Range of Standard Work Handled on Tenoner

Reports of as many as 46,000 pieces being put through a double-end tenoner in eight hours are on record, whereas in metal work, other than punched parts, 200 to 300 a day is reasonable output.

A great many attachments for a tenoner which are mechanically feasible are not successful because the difficulty of quick and accurate setting for different jobs makes it desirable to break up the operations and run them on simpler hand-fed machines at lower costs.

The double-end tenoner can be equipped with the exhaust piping and hoods assembled on the machine. Formerly the piping and hoods were made up by local tinners or blowpipe companies especially for each machine to the purchaser's order. This was objectionable because the piping might not work satisfactorily.

Maximum production of a double-end tenoner is determined by the spacing of the dogs, the rate of feed, and the number of pieces between the dogs. With the dogs located on 8-in. centers on alternate links, the numbers passing through the machine per minute are, for 15 ft., $22\,^1/_2$ dogs, for 20 ft., 30 dogs, and for 27 ft., $40^1/_2$ dogs. How well the space between dogs is filled depends on the operator's ability to pick up several pieces quickly. The way stock is piled on trucks has considerable influence on the feeder's ability to pick up a large number of small parts. Piling successive layers in alternate directions or sticking them similar to lumber in a kiln is a great help. Two men can advantageously feed small stock, although in most cases one man can keep the chains filled up.

Set-up time varies according to the number of heads that have to be changed and the skill of the set-up man. Some plants allow 25 minutes for each set-up, considering that it is an average for all cases. Where jump dado, relishing, and other attachments are used, the time for setting-up will be much greater.

A canvass of users of the most modern tenoners shows that work is changed at intervals of from 30 minutes to 2 hours and that average runs are less than an hour, thus showing that set-up time has a marked effect on production. There are cases where 24 distinct set-ups are made on one machine, with a total output of 10,000 pieces for an average day's run. In another case, a machine running continuously tapered and tenoned 23,000 desk legs, requiring two passes through the machine, making a total of 46,000 pieces handled in 8 hours and 3 minutes. For production as high as this it is evident that the operator kept the space on the chains between the dogs full of legs.

Further examples of production are the running of 300 desk tops through the machine twice, sizing and shaping the front edge and both ends in 1 hour and 20 minutes, including the set-up, and 250 radio-cabinet banded tops being sized and shaped in 45 minutes. The time for these operations when performed on a shaper was 9 hours, and the work produced on the tenoner was of higher quality, owing to the steady feed, more secure holding, and the perfect straight-line travel due to the V-tracks.

The ease of set-up and a large production is further indicated at a plant in which, after running a double-end tenoner for some time, it was found that 118 jobs could be handled at a decided saving that were formerly run on shapers.

The extreme accuracy of an up-to-date tenoner is demonstrated in the following work. Veneered tops were run through the machine, putting a $^1/_4$-in. groove in the front and both ends to receive solid bands and mitered corners glued in place. The tops are then brought back for shaping the edges to meet the top veneer. This requires that the first job of sizing must be absolutely perfect and the stock accurately located for the second run.

Another concern has similar work on executive-desk tops which range from $1^3/_4$ to $2^1/_4$ in. thick and up to 10 and 12 ft. long. The shaping lines match perfectly on the sides and corners. It is claimed that ability to maintain this accuracy is due entirely to V-chains and V-tracks.

Multiple operations such as cutting and grooving desk-drawer fronts can be handled by placing the panel in a form supported on the feed chains, making the first cuts with the trim saws and the center cuts and grooves with saws and grooving cutters on the stationary dado shaft. The forms can be returned to the in-feed side of the machine, either by truck or a chute between the chain ways.

Curved English passenger-coach pillars are successfully handled in forms, clamping several pieces at a time. This particular work is performed in teak, which is extremely difficult to cut because of the large amount of silica or sand embedded in the wood. It is necessary to regrind the knives after 2 to $2^1/_2$ hours, and they then have to be whetted up three or four times between grinds.

Fig. 15 shows a few rather unusual pieces of work, especially the English passenger-coach pillar and the four drawer fronts cut from one piece of stock. Both of these are handled in special forms. The English passenger-coach post is a good example of combined tenon and dado work.

Fig. 16 shows some of the standard work in furniture, sash and door, and auto-body plants and gives a good idea of the variety and range that can be economically handled on up-to-date tenoners.

Discussion

Peter J. Schloemer.[2] The author has devoted the major part of the paper to the construction and detail of only one particular make of tenoner, rather than conveying the many features available and methods of operation possible on various modern-type tenoners.

It is true that great developments have been made since the introduction of direct motor-driven tenoners, but the writer does not agree with the author when he states that the use of the old-style or belt-driven tenoner was limited to only such work as cutting off and tenoning straight work and that attachments such as are now available could not be had.

It is a fact that attachments such as automatic jump dado arbor, automatic jump relishers, combination groover and trim saw cuts, scoring saws, and many other features were all used with great success on belt-driven tenoners long before the direct motor-driven tenoner was first brought out. Shaping of edges with cope heads was also accomplished successfully through gear-driven cope spindles, as many tenoners of this type are still in successful operation today.

The author calls special attention to the hinged pressure beam shown in Fig. 8, but does not explain what particular benefit is derived from this feature in relation to the use of or the production possible on the tenoner.

In the writer's opinion, the methods of adjustment of the pressure beams as used on other makes of tenoners have a decided advantage, because with those methods the operator is enabled to do certain grooving operations directly over the feed chains by moving the pressure beams forward or just outside the feed chains.

It is true that accuracy in production operations on any tenoner depends entirely on the accuracy of the feed chains and driving sprockets, as these are the most vital and important features on the machine.

The writer does not agree with the statements relative to the feed chains, as the author endeavors to convey that perfect and accurate work can be done only on tenoners equipped with V-chains running on V-tracks. Work of the finest nature and accuracy has been accomplished on tenoners equipped with flat chains many years before the V-chains were introduced.

Referring to Fig. 10, the paper goes into detail relative to the construction of the feed-gear box, but here again the author does not state what benefit this feature has in relation to the use of or the production possible on the tenoner. Neither does the author state whether it is possible to make quick changes of feed rates with this type of feed-gear mechanism.

The writer would like to add to the author's reference to the feed drive as used on modern direct motor-driven tenoners the method used on a tenoner of a different make than the one illustrated in the paper. On this tenoner a four-speed feed motor is used and operates through a drum control. With this method the operator can instantly increase or decrease the feed rates without stopping the feed chains or without loss of time in the production of the tenoner. Further, the operator is enabled to instantly increase or decrease the rate of travel of the movable base when changing from a long to short distance between shoulder lengths or reverse, without stopping the feed motor. In addition, he can also reverse the direction of travel of the feed chains in case of necessity. As the production of any tenoner is based to a great extent on the feed rates, it is readily seen where this method has a decided advantage.

With reference to the work that can be accomplished on a tenoner, there is no limit, as new and additional uses for it are being found constantly. In addition to the many varieties illustrated in this paper, the writer wishes to add the following:

Grooving operations are done with the scoring saws in conjunction with the trim saw, tenon, and cope operations.

Drawer-front panels can now be glued up in one piece, enabling the better matching of figured or fine face veneers properly and with a saving of core stock material. These can then be ripped to proper widths on the tenoner in one pass through the machine.

---

[2] Wilkin-Challoner Company, Oshkosh, Wis.

Door fronts with matched veneers are built up in one panel, then trimmed to width, edges jointed or shaped, and ripped through center in one pass through the machine.

Milled-to-pattern cutter heads are now used on the dado arbor to cut special shapes and grooves across grain and through the finest of face veneers without any sign of tearing out at the edges of cuts.

End panels of kitchen cabinets can now be trimmed to length with a shelf groove cut with groover saw on same spindle with trim saw, tenoned on one or both ends, three jump dado grooves across center, one or both ends rounded with cope cutters, and either one, two, three, or all four corners notched complete in one pass through the machine.

Many other operations of equally interesting nature are now being done regularly, and there is no limit to which the modern tenoner can be adapted and to the savings that it can bring about in the production of almost any plant.

Special saws and cutters are now available, enabling one to work the hardest kinds of materials successfully.

Perfect work is being done today in many plants on old-type tenoners with capable and intelligent operators, but it would be amazing to many plant managers could they realize how much greater production with less cost these same operators could produce on a modern double-end tenoner.

Arthur D. Smith, Jr.[3] The paper has brought out the history and evolution of the double-end tenoner. However, the type of cuts that can be made on the double-end tenoner is important enough to bear further stressing.

We have line drawings covering the equipment and cuts that we can make. Blueprints have been made of these for the draftsmen (or detailers) and the machine operators. The draftsmen have a clear understanding of our equipment and the type of cut possible, also the capacity of the machine as to length, width, thickness, depth of cuts, etc., and they make their detail drawings accordingly.

The author did not mention the saw, head, and knife equipment required and it might be interesting if the writer describes the drawings. Starting at the infeed end of the machine, the cut-off saws bring the piece to the desired overall length or width. This 14-in. or 16-in. combination saw is filed to give a smooth cut when ripping or cutting. The 14-in. saw will cut off in multiple lengths stock up to 12 in. wide. By removing the stationary dogs and using drop dogs, stock of unlimited width may be fed, because as soon as the material is engaged between the chain and traveling rubber hold-downs, the stock will be pulled through without the assistance of the dogs.

The cutting saw arbor may be tipped 45 deg. from horizontal in a clockwise or an anti-clockwise direction. There is a notation that when cutting fireproof material or plywood glued with an abrasive casein glue, the operator is to use a $^3/_{16}$-in. Carboloy-tipped saw, as also on plywood covered with linoleum, rubber, bakelite, or Formica.

The lower half of our drawing shows a hogging head, which is a standard Huther Bros. dado set, made up with $^1/_8$-in. spur saws at the outside and two-point cutters in between with a total thickness of $1^1/_2$ in. Whereas a single saw will leave a waste strip with is apt to cause trouble at the tenon or cope heads, the hogging heads reduce the off-fall to shavings, which are taken up by the exhaust hood. By changing the arrangement of the hogging head, the rabbeting may be done at the cut-off saw, provided it is not convenient to do these operations with tenon heads or copes.

Another drawing shows the scoring-saw mandrels with standard equipment—the $^1/_{16}$-in. scoring saws used to score down through face veneer and crossband, preliminary to tenoning. The scoring saws may be tilted to 45 deg. in either direction. The maximum and minimum length between shoulders and the maximum and minimum thickness of stock are given.

Grooving saws mounted over a special head may replace the scoring saws. This machine is equipped with these groovers for both $^3/_{16}$-in. and $^1/_4$-in. grooving. When grooving fireproof wood or other abrasive materials, the operator is instructed to use a groover with Carboloy teeth. This rule is standard, but is shown on each drawing for emphasis.

The scoring-saw mandrels may also be equipped with a small dado set. This is mounted on the same type of head as are the grooving saws. Each dado set consists of two $^1/_8$-in. spur saws, two $^1/_4$-in., one $^1/_8$-in., and one $^1/_{16}$-in. two-point cutters. This enables cutting a dado varying in width from $^1/_4$ to $^{15}/_{16}$-in. The depth of cut depends mainly upon the power of the scoring-saw motors. As delivered, these motors could not drive a $^{15}/_{16}$-in. cut deep into hardwood. Accordingly they have been changed for operation from a frequency changer, speeding them up to 6000 r.p.m., and practically doubling the horsepower. At this higher speed, there is no difficulty in pulling any cut desired.

The scoring-saw mandrels may also be equipped with special dovetail cutters for making a long male dovetail on the end of the stock, as used in store-fixture and cabinet work, on drawer sides, divisions, etc.

On the tenon heads, with the usual arrangement of both heads cutting a tenon spaced in the center of the piece, the maximum width of tenon is 3 in., but by double-passing through the machine, a 6-in. tenon could be cut.

The top tenon head can also cut a rabbet from the top face of the stock. Similarly, the bottom head could be used to cut a rabbet from the bottom face.

The cope arbors are the most versatile of all the arbors of the standard double-end tenoner. This arbor may be tilted 45 deg. in one direction and 10 deg. in the other. The maximum and minimum length of stock and the maximum and minimum thickness of stock are shown. These arbors are equipped with 3-in. joining heads. This is a solid steel four-knife round head, used for jointing or facing the edge of the stock where a smoother cut than given by the trim saws is required.

The cope arbor may also be equipped with a grooving saw. The machine is provided with $^3/_{16}$-in., $^3/_4$-in., and $^3/_8$-in. groovers, each 9 in. diameter. The operator is instructed to use Carboloy groovers when cutting fireproof wood or other abrasive materials.

The cope arbor is equipped with a panel raiser for scooping out backs of panels. This is a two-point steel cutter, especially ground. The equipment is placed on the cope arbor and secured with collars and lock nut on top of shaft. This reduces to a minimum the set-up time for these operations.

By employing the standard Wilkin-Challoner cope heads, but with a cutter ground with 45 deg. face, one is able to make both male and female members of the lock miter. Other cuts necessary to the lock miter have been made by the tenon or scoring-saw mandrels previous to the material reaching the cope head.

Another type of cope head used is the shaper disk. High-speed steel knives are inserted in grooves and held with bolts which go through the disks and firmly lock the knives. Most any type of molding can be ground in the face of the knife, which enables the double-end tenoner to do all types of shaping.

The cope spindle may also be equipped with a dado set. This machine is equipped with dado sets both 9 in. and 10 in. in diameter, each set consisting of two $^1/_8$-in. spur saws, eight $^1/_4$-in., two $^1/_8$-in., and one $^1/_{16}$-in. two-point cutters. The operator can assemble a dado set to give any desired width from $^1/_4$ to $2^7/_{16}$ in. He can cut to a depth of 3 in. with the 9-in.-diameter sets and $3^1/_2$ in. with the 10-in.-diameter sets.

---

[3] President, George W. Smith Woodworking Company, Philadelphia, Pa. Assoc-Mem. A.S.M.E.

It is easily seen that a great variety of work can be done on a standard double-end tenoner. If special equipment, such as fixed and jump dado arbors and relishing and notching attachment, be added to the standard machine, the breadth of work which can be done on a double-end tenoner is greatly increased.

It has been asked why we do not run the grooving saws on the tenon arbor instead of using the scoring-saw arbor. Because of the importance of reducing the set-up time to a minimum, we never disturb the tenon heads. It is much more simple to use the scoring-saw arbors, as we can get at them more readily.

Author's Closure

In Mr. Schloemer's discussion he asks the particular benefits of the hinged pressure beam as shown on Fig. 8. The design of beam was worked out for the purpose of making the space around the top and bottom tenon heads more accessible by swinging open like a gate. It is supported by a vertical hinge on a bracket at the outfeed end, fits in between finished surfaces at the infeed end of the bracket, and is further supported by a clamp on a bracket just at the rear of the cut-off saws when in use. Savings of 5 to 10 minutes are made with this type of pressure beam over others each time either the top or bottom tenon head has to be removed.

The objection raised, lack of adjustability of the pressure bar relative to the feed chains, is not serious, as the question has never been raised by the users of these machines. There is space between the hinged support bracket and the pressure bar for grooving cutters.

Many will argue the merits of V-chains and tracks as against flat chains and tracks. A study of machine tools for producing accurate work, such as grinders, planers, boring machines, and lathes, indicates the wide use of V-guides where extreme close work is demanded. In the woodworking field the saws known as the straight-line rippers have chain feeds using V-tracks.

In connection with feed-chain drives on tenoners or any other machine, either single-speed or multi-speed motors may be used. With either, the same reduction from the motor to the feed sprockets or rolls must be made, requiring about the same number of gears, pulleys, or sprockets. With a single-speed motor in addition to the reducing drive, it is necessary to provide some means of speed changing such as a cone pulley or change gears. In the machine described, sliding gears similar to those used in automobile transmissions are used, and they are controlled by a lever conveniently located, providing a feed-changing method which is quick and can be accomplished without stopping the feed or its motor.

The electrical control for the single-speed motor may be of the simplest type.

With the four-speed motor the only saving in the mechanical hook-up possible is the gears or pulleys for speed changes. The electrical control must be more complicated and usually calls for a drum controller in connection with some type of overload protection.

It is almost impossible to provide a simple and effective electrical overload protection device for a multi-speed motor without going to great expense. Overload protection in case of jams is very necessary on machines having positive feeds by means of chains and dogs where there is no chance for the work to slip as with feed rolls.

Another objection to four-speed motors is that the range of speeds available is in a ratio of 600, 900, 1200, 1800, having a range of 3 to 1 from high to low, or in a ratio of 900, 1200, 1800, 3600 having a range of 4 to 1 from high to low. Either of these ratios is greater than is required in average tenoner work.

Production on a double-end tenoner is not controlled by the ability to change from one rate of feed to another quickly, but by utilizing the highest rate of feed possible and keeping the chains full of work. With either type of feed, higher rates of feed than standard can be provided and are used in plants on small work that can be handled with hopper feeds.

Mr. A. D. Smith brings out clearly the savings that can be made in tenoner operations through close coordination of the engineering and production departments and indicates that a great deal of study has been given this phase of work in his plant.

WDI-54-12

Developing a New Wood Product Through Research

By THOMAS D. PERRY,[1] NEW ALBANY, IND.

Many appeals have been made before the Wood Industries Division for research, and several papers have been presented, particularly that of Dr. J. W. Lawrie, in October, 1930. The development of a new prefinished plywood flooring is covered in detail, beginning with the product selection and discussing competitive products of both solid wood and non-wood. Considerable attention is given to the principles of market analysis, although it is admitted that the present depression renders such investigation of less than usual value. Detailed consideration is given to product analysis, emphasizing the limitations and shortcomings of available wood floorings. This analysis is followed by the respective and corresponding steps required to overcome these shortcomings. Practical or applied research is the basis for all the solutions. Emphasis is placed on the strength and rigidity qualities of plywood as well as on the manifest advantages of prefinishing. Several unanticipated advantages appeared from time to time among the research steps. In conclusion it is pointed out that the development of this plywood flooring, from its inception to its acceptance by the market, has been accomplished in an unusually short time, and therefore offers encouragement to other woodworkers to do likewise in their field.

IT IS a well-established manufacturing axiom that new products almost invariably come as the result of aggressive research methods. To many woodworkers, however, research is a relatively unknown term, with somewhat vague possibilities. Wood products have probably benefited less by research than other major branches of manufacturing, while electrical manufacturing, communication engineering, mechanical refrigeration, the radio, the auto, and many modern conveniences could not have come without research. Hence, a brief outline of an actual problem and answer in the wood-industries field may offer information and inspiration to other woodworkers.

Research is recognized as of two distinct varieties, i.e., fundamental and applied. Fundamental, or pure, research is the searching out of scientific facts with regard to the nature of raw materials, as well as the principles controlling their conversion into useful products, but seldom concerns itself with the gainful character or individual application of these facts. Applied research, on the other hand, is that type of research that converts fundamental facts into profitable industrial applications. The former requires a scientific, investigative turn of mind that can concentrate on the search after truth wherever it may lead. The latter type of research requires an entirely different type of mind—one that can concentrate on a definite practical objective, that can sense and grasp the dollar value, that can sell the idea to industrial leaders, and that can explore and select the necessary immediate steps between the fundamental idea and its profitable development into a practicable product.

In the woodworking field fundamental research is well exemplified by the activities of the Forest Products Laboratory at Madison, Wis., as well as by such schools as the New York State College of Forestry at Syracuse and the Forestry Department of the University of Washington at Seattle. Outstanding examples of applied research in this field are "Balsam Wool," an insulating blanket, developed by the Weyerhauser Lumber interests, "Plymetl," a laminated wood-and-metal product originated by the Haskelite Company, and "Masonite," a composite board or sheet of disrupted wood fiber.

The new product "Uplyco" prefinished flooring, the development of which is outlined in this paper, was distinctly an applied-research program. Laboratory activity had a relatively small part in the program, unless the building construction industry be termed a widely extended field laboratory. The practical research work was about evenly divided between field investigation, as well as intensive customer demonstration, to determine consumer requirements, and factory experimentation, to develop economic and efficient manufacturing processes.

Excess Capacity From Consolidation

Upon the completion of the legal steps in the consolidation of this corporation in July, 1930, we found ourselves with three plywood-manufacturing units admirably located and adequately equipped, but serving an industry that was suffering acutely from excess productive capacity. To close down one or more of the plants was easy, but to preserve and increase industrial profits in a period of depression was a challenging task. The first step, obviously, was to concentrate all the available general plywood business into the one plant best equipped for this purpose, and thus reasonably insure its profitability. The next step was to foresee so far as possible the probable trend of industry and select known or develop new products to keep the other plants both busy and profitable. One of the difficulties encountered in making this choice was the tendency of former factory users of plywood to make their own plywood rather than to purchase it. While this trend was evident during busy years, it was most conspicuous during such lean years as the present. Not even the most optimistic executive could visualize a return of the normal demand for plywood that had existed in past years. This definitely barred the path against any known plywood product, since excess capacity of two kinds already existed. This background made imperative the selection of a new product that would inevitably

---

[1] Chief Engineer, United Plywood Corporation. Mem. A.S.M.E. The author has devoted many years to engineering in the wood-industries field and has served as vice-president and manager of the Grand Rapids Veneer Works and as consulting engineer for Bigelow, Kent, Willard & Co., Boston, Mass. He is chairman of the Wood Industries Division of the A.S.M.E., and is the author of many articles dealing with lumber-handling equipment, woodworking, and engineering practice with veneer, plywood, and solid wood.

Presented at the Sixth Annual Wood-Industries Meeting, Winston-Salem, N. C., Oct. 15 to 16, 1931, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

require research, development, and promotion in order to preserve and enhance corporation profits.

PRODUCT SELECTION

There are two principal reasons influencing the selection of a new product: First, that of having the manufacturing facilities, and, second, that of possessing the necessary distributing organization. It is a well-established fact that it is economically sound, if possible, to select new products that can be marketed advantageously through the existing distributing organization rather than to choose a product that may be suited to manufacturing facilities. Manufacturing problems are more concentrated and tangible, permitting easier readjustment, than are the marketing problems, where the organization has a broad geographical spread and many intangibles such as manufacturing reputation, recognized publicity, salability, etc. In the case in question, however, the distributing organization had not been extensive, since the previous output had been sold as a semi-raw material (plywood) to a relatively few large manufacturing organizations that would complete the processing and convert the purchased plywood into furniture, radios, doors, interior equipment, showcases, and the like. Plywood, therefore, was in a somewhat difficult situation, since its value and even its very existence were seldom recognized by the general buying public that bought a wood product, not because it was plywood, but because its ultimate form was either useful or attractive. Since the existing distribution facilities were not extensive or elaborate, it seemed justifiable to select and develop a product more in keeping with existing manufacturing facilities even though it might require the creation of a new and intensive distribution organization.

The plywood factory chosen for the development of the new product had already done some experimenting, in previous lean seasons, with a unit or sheet flooring that would appeal to the public because it could be purchased and laid in larger sections than the conventional strip flooring. The experimenting on this floor had extended over a period of several years, but at no time had it been regarded as a serious problem nor had it ever been considered as an outlet that promised large volume.

While many other products were considered, hardwood flooring was ultimately selected as the most promising of the various suggested products that were reasonably available. The reason for this decision was partly the substantial experimental work that had been done, partly its adaptability to manufacturing facilities, but chiefly that the home-building program of the United States promises greater volume in the next few years than any other field in which plywood might be used. Not only is the country behind in its home-building program, but the lure of the roads created by the automobile is yielding quite definitely to the attractiveness of the home with its radio. The automobile caused people to go away from home for their pleasure, but the radio has brought them back and has emphasized the need and desire for comfort and luxury in the home. Consequently, not only is there a shortage of existing homes, but we are facing the renovating and remodeling of a multitude of existing homes to make them more comfortable, more pleasing, and more livable.

Flooring, in the main, was found to have been selected chiefly for utility and low price; as a decorative factor it had been given relatively little thought or attention. Hence, surrounding conditions appeared clearly to justify the development of a new and better hardwood floor, and plywood construction seemed to offer unusual opportunities for improvement over present solid-wood products.

COMPETITIVE PRODUCTS

While no ardent proponent of a new product will admit it has any actual competition, it is absolutely necessary to recognize that there are many allied competitive products that must be carefully considered in their relation to a proposed new product. Hardwood flooring had been used for generations, and a wide variety of types and species was available. The wood flooring in the United States was divided into four principal groups, as follows:

Strip, laid in relatively narrow units ($1^1/_2$ to $2^1/_4$ in.), tongued and grooved, blind nailed, reasonable in cost, and adapted to a wide variety of uses for homes, offices, factories, public buildings, and the like. This had wearing qualities, but a minimum of artistic value.

Parquetry, consisting of various symmetrical and artistic unit blocks and assembled patterns, used principally where cost was not a consideration and where the appearance was all-important. Combinations of strip and parquetry were seldom utilized.

Plank, or colonial flooring, used in random widths and lengths to reproduce the intrinsic charm and historic background of the colonial periods of home building.

Factory, in the main built for sturdiness to resist hard service, but without regard to appearance. Some types were unusually thick, with either edge or flat grain exposed, and in some instances with end-grain wearing surface (these grades of factory flooring were not considered in the development program).

In addition to the competitive wood floorings enumerated, there was found to be a wide range of other materials which might be termed substitutes for wood flooring, such as concrete, stone, tile, terrazo, rubber, fiber, composition, and linoleum. It was found that many of these products had been aggressively promoted, and their success had been due partly to intrinsic merit, but more especially to promotional zeal and merchandising skill. In other words, a large amount of substitute materials had been installed where general wood flooring would have been better had it been merchandised with equal skill and vision. It was therefore necessary to develop a promotional and distribution program that was at least the equivalent of such substitute flooring.

It is not intended to convey the impression that wood flooring is always suitable for every location. It is well recognized that non-wood flooring materials have a legitimate place, but the investigation led to the conclusion that in many instances skilful merchandising had extended some of these products beyond their normal field of application.

MARKET ANALYSIS

Market analysis is a broad term that has been used to cover a wide variety of surveys to determine the past and potential marketability of a new product. In the judgment of the author, its scope should be limited to these four principal functions:

(1) Volume of similar products sold during the five years preceding, together with a prediction of reasonable future sales volume.

(2) Effective sales channels for the new product.

(3) Probable customer demand, or the proportion of the available business that may be anticipated for a new product.

(4) Pricing problems, including standard costs and operating budgets.

The peculiar current business conditions made this market analysis particularly difficult and compelled the use of methods that would ordinarily be considered too inexact.

(1) *Volume of Flooring.* Complete market statistics of manufacture and sales for the whole flooring industry were nowhere available, since some trade organizations in the field were found to be demoralized and hardwood flooring also had been made by many small non-reporting manufacturing units. It was possible, however, to obtain partial statistics from two trade organizations representing the principal manufacturers of oak and

maple flooring, as given in Table 1 and 2. It was also possible to ascertain with accuracy the floor area of school buildings erected year by year, since this branch of public service is thoroughly covered by reporting agencies; this is shown in Table 3.

It did not seem wise to extend the period of investigation further than five years, since the trend of industrial events would make earlier statistics of relatively little current value.

The slump in volume during the years 1929 and 1930 rendered these statistics of relatively little actual value and precluded any reasonable estimates of probable volume for 1931 and 1932. The investigation of trade volume is, however, an essential step in market analysis and would have been of marked importance in any period except that of a world-wide depression.

(2) *Effective Sales Channels.* The selection of the most advantageous sales channel was found to be a decidedly complex problem, although not seriously affected by the current business situation. If hardwood flooring was to be distributed, was it best to adopt a policy of selling direct to the consumer, endeavoring to contact a multitude of prospects, either by mail or commission men, or of selling through the wholesaler or jobber, who had a large number of products and could not well concentrate on a few, or of going direct from the factory to the retail dealer, who might be willing to undertake a campaign on a speciality, but who would require from the manufacturer an extensive demonstration and sales organization? A careful study was made of the methods adopted by other specialty manufacturers, such as of rock-faced shingles, fiber boards, insulating and acoustic panels, plaster materials, builders' hardware, and other construction specialties. The result of this investigation was to conclude that a direct customer distribution was not advisable, since this would alienate all the recognized and existing distribution channels. Where a jobber gave evidence of merchandising ability, it was more advantageous to work through such a jobber than to approach his trade direct. There were also found many locations where jobber distribution was inefficient and undesirable. Price differentials were therefore set up to provide for a reasonable pricing of product direct from the factory to the retail local dealer or from the factory through the jobber to the retail local dealer. Experience has demonstrated the wisdom of this course.

(3) *Probable Customer Demand.* An intensive investigation into local market conditions in various vicinities should yield reasonably definite data as to local absorptive capacity, especially in the case of a well-established product. In the case of a new and relatively unknown product, the data would be much less satisfactory and dependable.

The current flooring demand was found to be characterized by distinct style and period trends, with particular emphasis on colonial types and on styles harmonizing with the novel and somewhat startling modernistic tendencies.

A new product, with individual characteristics of its own, could not afford to ignore these contemporaneous conditions, and therefore should partly meet them. At the same time it should not entirely subordinate its own outstanding qualities and ignore opportunities that only required concentrated development.

Depressed business conditions also complicated the determination of a volume objective. It was therefore decided to start the sales campaign rather modestly in a zone around the factory extending some 200 miles in each direction. With the information as to customer requirement and absorptive capacity in this area, it then became practicable to enlarge this zone and gradually cover more and more states. Such a field demonstration may be slow, but its results are reasonably certain, and it is much less costly than unintelligently covering too much territory. The prompt response of the consuming public in the first zone permitted a more rapid expansion than had been anticipated.

(4) *Pricing Standards.* A large mass of evidence was collected showing purchase price and installation cost of the various available solid-wood floorings, as well as substitute floorings. Cost comparisons vary widely in different communities, according to size, social status, labor costs, and many other circumstances. While such comparative costs have a definite bearing on the price set-up of a new product and on the manufacturing-cost allocations that can be made, yet they are likely to vary too much to be conclusive. It should be kept in mind that any new product will have its own inherent advantages that influence comparisons of competitive cost. The final determination of logical and obtainable prices was made only after several extensive field demonstrations in selected localities, as outlined.

Much study was given to price schedules, standard factory costs, and budgetary control, not omitting a sincere application of the "trial and error" methods to some problems that might appear otherwise unsolvable.

The reproduction of actual tabulations is inadvisable, partly because accounting problems are too extensive for engineering discussion, but more especially since it is difficult to illustrate principles without divulging facts that might be wrongly used.

PRODUCT ANALYSIS

In order to create and develop a new product that would deserve and win consumer attention, it was necessary to examine with care the advantageous qualities and definite limitations, in various directions, of the existing styles and grades of flooring. It would have been unwise to go directly into a competitive field with only a normal type of product and to enter a difficult competitive situation that promised little profit and recklessly increased productive capacity in an already overproduced field. It was therefore the aim to overcome, so far as was feasible, the principal shortcomings of existing types of flooring. The principal limitations and shortcomings were found to be as follows:

(*A*) The shrink, swell, warp, and twist of ordinary solid lumber flooring required that it be laid in relatively narrow strips to avoid unpleasant curling of the individual board and insanitary cracks between the boards when atmospheric conditions varied, as in a dry heated home in the winter and in a damp unheated room in the summer.

(*B*) The tendency of solid wood flooring to split around nails either when damaged in laying or when strained to hold the flooring down. These splits usually developed in the tongues and grooves and were found to be the principal cause of loose and squeaky floors.

(*C*) The unreasonable cost of laying narrow strip flooring in random lengths with excessive amount of nailing. Not only did the cost element enter, but also the time required to complete the job.

(*D*) Parquet floors, in both wood and other materials, were found to be nearly prohibitive in price, because of the manufacturing cost of small units and the abnormally high installation cost when each piece had to be individually laid in place and fastened by the various available methods. It was found that practically all parquet was so manufactured and laid, and that consequently its use was greatly restricted.

(*E*) The high cost of scraping, sanding, and applying finish materials as well as the poor quality of finish on floors installed under modern construction conditions with unfavorable temperature and humidity and unavoidable dust and damage.

(*F*) The entire absence of eye appeal, characteristic of all unfinished wood products. The feminine buyer, and she is in the big majority, is particularly susceptible to color and harmony values that can be developed in prefinished flooring.

(*G*) The lack of protective packaging and standard sized units for convenient and efficient warehousing and delivery.

(*H*) The laying of wood floors in reinforced concrete (fireproof) buildings was done in two ways; either over a subfloor placed on strips or screeds anchored to the concrete slab, sacrificing some 3 to 4 in. per story height, or laid direct on concrete with an adhesive mixture or mastic, producing a bond of uncertain strength and problematical life.

PRODUCT DEVELOPMENT

The overcoming of these various limitations of solid wood flooring became a series of more or less overlapping research problems. Each answer was a combination of past experience, field demonstration, economical factory processing, and customer acceptance. While in no instance was a complete solution reached, it was extremely stimulating to find that intensive and correlated research eventually led to reasonably complete results. Using the same designations as in the foregoing list of limitations, an outline of these results is as follows:

(*A*) *Constant Dimensions of Plywood.* The shrink, swell, and twist of solid lumber have long been successfully overcome in the making of furniture, cabinets, desks, phonographs, pianos, doors, and the like through the use of plywood construction, and plywood manufacturers had conclusive experience in that direction. The hard usage and wear to which all floors are normally subjected put standard plywood with its thin veneer faces out of the question, but the fundamental principle of plywood cross-laminations had been adequately demonstrated to neutralize the normal shrink and swell of wood, or at least to reduce these variations to a practicably neglible minimum.

Government laboratories have repeatedly demonstrated that, pound for pound, well-designed plywood is stronger than steel. It was necessary, therefore, to develop a type of flooring in plywood that would have a thick enough face to withstand hard wear, as well as cross-plies of sufficient stiffness to prevent side warping, and still have adequate lengthwise strength in the face and back.

The result of extensive experimenting and rigorous tests under all conditions proved that a segmental sawn lumber face, made of narrow strips and frequent butted ends, would destroy the stresses and strains of long, wide boards and thus eliminate the twisting tendency from the face, as well as utilize the face lumber economically; that the single or duplex cross-plies must have a thickness of not less than an aggregate of $^1/_4$ in., with equally thick longitudinal members in one or two units; and that the face must approach $^1/_4$ in. thickness to provide adequate wearing surface. This resulted in a balanced five-ply construction with three lengthwise members, the normal direction of lumber strength, and two crosswise members to neutralize shrink and swell, all firmly glued together, to prevent changing widths and to keep the boards from warping sidewise.

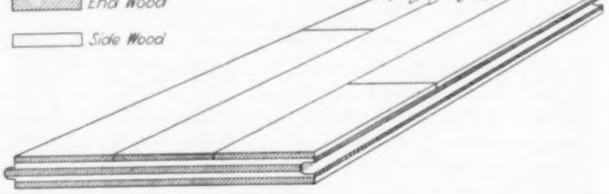

FIG. 1 PLYWOOD FLOORING, FIVE-PLY $^5/_8$-IN. BY 6-IN. BY 6-FT. 8-IN. STANDARD STRIP

(Showing balancing effect of alternating crosswise layers. The laminations in tongue and groove prevent splitting.)

Thus five-ply laminated flooring, with faces of close-textured dense oak or maple and backs and cores of chestnut or poplar (with their well-known inert properties and gluing qualities) resulted in a plywood construction of sufficient strength and adequate balance.

A water-resistant glue, like casein (designated by the U. S. Government for airplane plywood), produced an adhesive joint stronger than the natural bond of the wood fibers that will tear apart in the wood rather than separate at the glue joint. The machining operations will slightly reduce the thickness of face and back, but still leave a sturdy strip of five-ply flooring $^5/_8$ in. thick. This type of plywood floor fabrication and the resulting floorboards are shown in Fig. 1.

(*B*) *Non-Splitting Quality of Plywood.* Reference to Fig. 1 will show that the tongue in plywood floor is actually three-ply and that the upper and lower grooves are both two-ply. It is well known that plywood cannot be split across a glue joint. Tests proved that when lifting plywood flooring from a pine subfloor each sloping nail held up to 75 lb. direct pull and the nail was drawn out with the floor; when nailed to a hardwood plug in concrete, the individual nail power was 150 lb. In no instance did either tongue or groove show any sign of splitting. A challenging test of the non-splitting quality of plywood floor is shown in Fig. 2, in which 40d spikes were driven into 2 in. lengths of floor without predrilling of holes, resulting in neither splitting of wood nor breaking of glue joint.

It is evident that this non-splitting quality permits the use of larger-bodied nails. Most floor nails were discovered to have been so slender (to prevent splitting) that they bent easily, resulting in bruised floors and installation delays.

A special large-bodied ($12^{1}/_{2}$-gage), high-carbon steel, coated fivepenny ($1^{3}/_{4}$ in.) nail was an accessory product, developed and sold with the plywood flooring.

(*C*) *Reducing Nailing Expense.* In order to overcome the excessive laying and nailing cost, it was demonstrated by a series of tests that plywood flooring, as described, could be made up to 6 in. wide and blind-nailed through the tongue, thereby reducing the actual laying cost to less than half that of the normal $2^{1}/_{4}$ in. wide strip flooring and to approximately a quarter that of the $1^{1}/_{2}$ in. width. The relative widths are shown in Fig. 3.

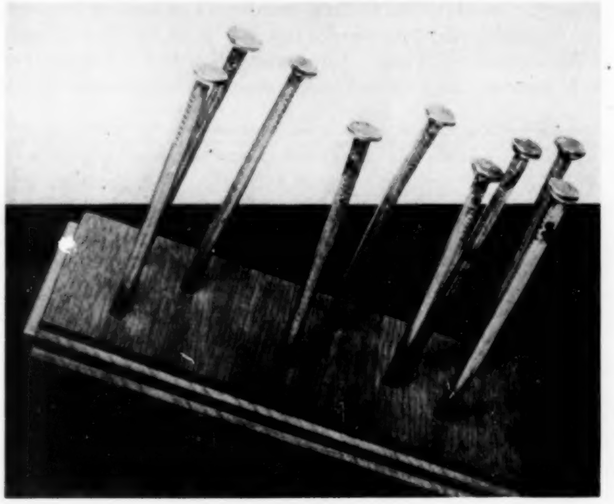

FIG. 2 NON-SPLITTING QUALITY OF PLYWOOD
(These 40d spikes were driven in a section of plywood floor 2 in. long, without predrilling holes for nails.)

Solid flooring was necessarily laid in $2^{1}/_{4}$, 2, and $1^{1}/_{2}$ in. widths to minimize (and not with entire success) the shrink, swell, and warp of untreated solid wood. Treated or impregnated wood changed dimension less than untreated, but did not allow any great increase in practicable width of flooring strips. The "come and go" of untreated wood is between 5 and 10 per cent, which in a room 20 ft. wide means a minimum aggregate of 12 in. if concentrated at one point, but also results in a minimum average of 0.1 in. between 2-in. strips in the same area. Plywood variations are less than one-half of 1 per cent, and consequently negligible.

The 6-in. plywood floor boards, blind-nailed every 16 in. ($1^{1}/_{2}$ nails per sq. ft.) with specially designed nails, as previously described, provided adequate floor attachment, and the more frequent nailing of narrow solid boards (6 to 10 nails per square foot) was found to be excessive in time, labor, and material costs.

(*D*) *Popularzing Parquet by Reducing Its Cost.* The problem of reducing the cost of parquetry flooring to promote its use and develop its popularity required another series of demonstrations to develop an application of plywood construction principles that would give a similar stability and laying economy to this more attractive type of flooring. Parquetry is especially designed to add beauty to the decorative scheme, either to increase the appeal of unoccupied rooms or to supplement the attractiveness of furnished quarters. The rectangular parquetry faces of artistic and colorful woods were non-continuous and required balancing cross-bands for the crosswise as well as the lengthwise square faces. The answer proved to be a three-ply balanced foundation with a superimposed parquetry face, thus providing the necessary counterbalancing for the transverse face squares and still preserving the stiffness of the cross-core used in the strip flooring already described. This four-ply construction is shown in Fig. 4 and obviously brings an even greater advantage to parquetry flooring than does plywood construction to the strip flooring. Parquetry flooring, which can be inexpensively laid in long boards, is a far-reaching improvement that opens the entire field of moderate-priced homes to parquetry floors.

(*E*) *Prefinishing Flooring at the Factory.* The type and quality of floor finish achieved under normal construction and contracting procedure left much to be desired. The scraping and sanding was laborious, much of it inefficient, and neither the finishing materials nor the mode of application were on a par with modern knowledge and mechanical application equipment.

This emphasized the importance of prefinishing the floor at the factory before laying. Furniture has long been so prefinished before sale and installation, and why not flooring? Plywood flooring, made in standard widths and lengths as described, tongued and grooved on edges and ends, could be laid with practically no cutting except at the walls of each room. The only nailing required was the blind-nailing through the plywood tongue, and that in the hands of skilful workmen, with "unbendable" nails, need not harm the finished surface. Hence the problem of prefinishing became one of determining the best finishing materials under a series of standard tests and of devising a progressive chain conveyor in the factory to carry flooring boards past the various mechanical application stations and through a series of controlled and regulated driers to the final rubbing and waxing station.

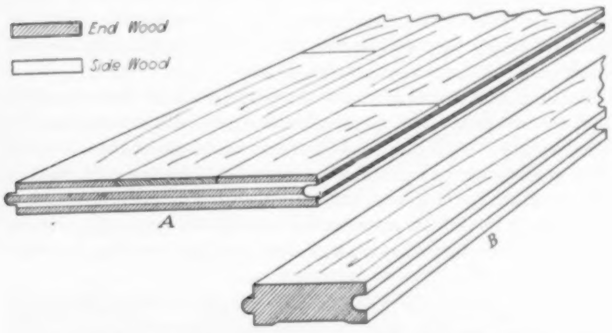

FIG. 3 GRAPHIC WIDTH AND THICKNESS COMPARISON
(*A*, standard plywood flooring, 6 in. wide by $^{5}/_{8}$ in. thick. *B*, standard solid flooring, $2^{1}/_{4}$ in. wide by $^{13}/_{16}$ in. thick. The $^{5}/_{8}$-in. plywood exceeds the $^{13}/_{16}$-in. solid flooring in aggregate strength.)

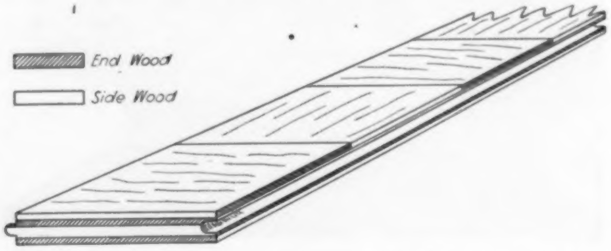

FIG. 4 PARQUET PLYWOOD FLOORING FOUR-PLY, $^{5}/_{8}$-IN. BY 4-IN. BY 6-FT. STANDARD BOARD
(Showing balanced three-ply base, on which is superimposed the non-continuous parquetry face.)

Prefinishing, however, is not a necessary feature of plywood flooring, but it is a distinct step in advance over the customary hand methods and is equally applicable to solid types of wood floorings and to other flooring materials, if the floor is manufactured with sufficient care and precision.

(*F*) *Expressing Beauty in Wood.* Rough lumber, as well as planed but unfinished lumber "in the white," arouses only a minimum amount of artistic vision and imagination, having a very low "eye appeal" value, and consequently has little real attractiveness to the homemaker, especially in this day of strong color contrasts and of brilliantly hued linoleum and tile floorings. Parquetry squares of oak, maple, walnut, mahogany, and other species, in various combinations, artistically stained and prefinished, were found to add greatly to customer appreciation and to facilitate sales approach as well as to insure buying interest.

Woodworkers in general, as well as retail distributors of lumber, were found to be singularly backward in intelligently developing this color value of their raw material.

The value of beautiful wood had long been recognized by makers of sheet-metal products, who had consistently imitated the beauty of wood in steel passenger vehicles, sheet-metal furniture, and metal office partitions.

(*G*) *Standard Packaging.* It is only within a comparatively short time that producers of wood products have given any serious thought to the manifest advantages of efficient packaging. The day of unpackaged distribution, except in the case of bulky low-grade products, is rapidly passing, and successful industries are discovering that convenient, protective, and attractive containers are a distinct merchandising aid.

In the case of flooring, an investigation revealed that no manufacturer had progressed beyond the open bundling, strapping, or wiring stage. Random lengths were one fundamental reason, thus confirming our program of standard lengths and widths. Open-bundle flooring was found to absorb a harmful amount of moisture in transit, in warehouses, and on construction. Hence, a complete corrugated container was adopted (see Fig. 5), overlapping at sides and ends, with steel strapping, affording adequate protection from rough handling, reasonable protection to normal moisture content, and convenient size for one-man handling and piling.

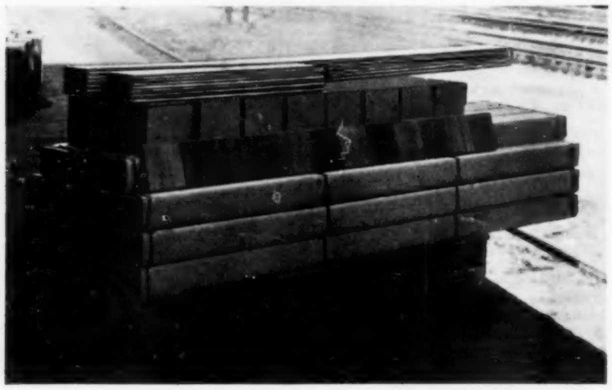

Fig. 5 Standard Carton
(Plywood flooring in standard packages, both for adequate protection and convenient handling.)

(*H*) *Attaching Wood Floors to Concrete.* Whenever reinforced-concrete construction depends on T-section calculations for its strength, it prevents bedding wood strips or screeds in the slab and requires that they be laid on top of the slab and grouted. This, with its accompanying sub-floor, sacrifices some 3 to 4 in. per story height, or nearly 3 per cent of building height.

Hot or cold mastic adhesives have rather serious objections, since slight variations in temperature or humidity may seriously weaken the bond. If a mastic floor once "lets go," there is no remedy but entire replacement. The ultimate holding life of mastics is not yet known. At best, these mastics are untidy and likely to deface finished floors.

Careful study and experimenting resulted in an innovation in anchoring hardwood floors to concrete, as indicated in Fig. 6. This process is a distinct improvement over laying in mastic, since it is cleaner and makes a stronger mechanical attachment. Holes are drilled in seasoned concrete with a 1-in. electric star drill, and these holes are plugged with $^{15}/_{16}$ in. square walnut plugs driven down flush. The concrete and plugs are then thoroughly coated with a waterproof asphaltum paint or are covered with an inexpensive roofing on which the plug locations are clearly marked. Of course the concrete sub-floor is laid out accurately in 6-in. zones (the width of the flooring boards) before drilling for plugs. The flooring is then blind-nailed into the plugs with a nail angle of approximately 45 deg. Actual tests show that a pull of 1000 lb. is necessary to withdraw these plugs, and approximately 200 lb. to withdraw a flooring nail driven at the 45-deg. angle into the plug. This strength greatly exceeds nailing into a pine sub-floor.

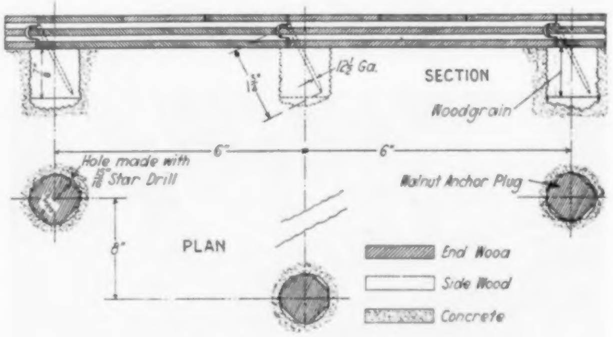

Fig. 6 Anchor Plugs in Concrete
(Mechanical method of attaching plywood flooring to a concrete sub-floor more dependable than mastic adhesive.)

General Problems

Space will not permit more than passing mention of the difficulties involved in remodeling and equipping a factory for straight-line plywood-flooring production, particularly when it is realized that straight-line production was a novelty to a woodworker. The problems encountered in promoting, marketing, and distributing the product were not only challenging, but withal decidedly encouraging. The objections to be met in persuading floor layers and customers to abandon obsolete customs and careless procedure, as well as to provide level and substantial sub-floors, involved a distinct change in standard specifications and education toward a better flooring consciousness for an improved type of floor.

These and many other problems added zest and interest to the task. It became increasingly evident that the consuming public was in a distinctly receptive mood for the new type of prefinished plywood flooring.

Pattern Parquetry

Many distinct advantages made their unexpected appearance from stage to stage of the development, adding many intermediate incentives to the research problem. One of these was the wide range of combination parquetry and strip pattern panels that can be developed from short lengths with artistic and pleasing results. An actual installation in colorful walnut and oak is shown in Fig. 7.

Overlaying Old Floors

Overlaying existing floors in occupied edifices opened a tremendous field not formerly available to wood flooring of any type.

While this overlaying was first undertaken with standard $^5/_8$-in. flooring, it was soon discovered that for such purposes a $^3/_8$-in. three-ply (see Fig. 8) was adequate, more reasonable in cost, and required less change in floor levels. The original worn floor was usually left in place, thus affording unusually sturdy support for the $^3/_8$-in. overlay.

PATENT PROTECTION

The development of adequate patent protection was another phase of the major problem. The ease of obtaining patents in this country, with no assurance of their probable legal validation in court, complicated the drawing of the patent specifications. Time only can prove the wisdom and ability expressed in the group of patents as actually filed. No new product should be developed without careful patent coverage.

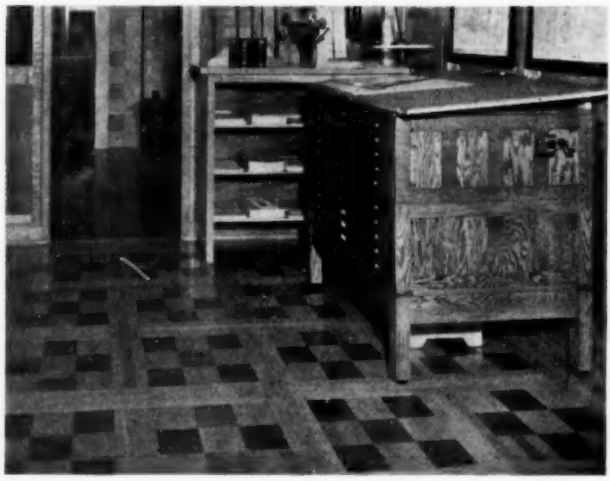

FIG. 7 PATTERN PARQUETRY
(Photograph of floor in author's office.)

PLYWOOD SUB-FLOORS

The advantages of a smooth, level sub-floor were undeniable, since ordinary sub-floors were found to be laid usually from almost any grade of rough or planed lumber, and in many instances from lumber previously used for concrete forms. Obviously no top floor could be expected to overcome the faults of a defective sub-floor. Investigation revealed that a five-ply $^5/_8$-in. subfloor, of fir or pine in 4-ft. by 8-ft. sheets, cost little if any more than the inferior sub-floors, added much to the bracing of the building, and also provided a level and continuous surface for any type of pattern parquetry.

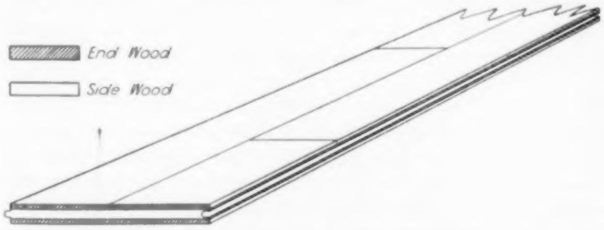

FIG. 8 OVERLAY PLYWOOD FLOORING
(Made in $^3/_8$-in. by 4-in. by 6-ft. 8-in. standard strip, three ply, with plywood grooves and solid tongue prevented from splitting by adjacent plies, above and below.)

CONCLUSION

The actual experimenting extended over a period of some five years, although the intensive research work was limited to less than a year. Mr. Charles F. Kettering, of the General Motors Research Laboratories, states that research projects take an average of seven years for fruition and that only a few out of many projects prove to be worth while. Not only has the past year of constructive development seen the product brought to successful marketability, but during this time the factory has been tooled up and a promotion and distribution organization has been created. The trade—wholesale, retail, architectural, and consumer—has enthusiastically accepted the product as the most outstanding flooring improvement of a decade.

Research does not always bring results so quickly nor does every idea prove so fertile. A consistent and persistent research program, however, will always reward men of vision and initiative who drive ahead vigorously and judiciously along the highway of progress.

Discussion

CARLE M. BIGELOW.[2] This paper could well be used as a standard-practice instruction by a great many manufacturers of woodworking products in developing new products. There is probably hardly an industry that has accomplished less research along the lines of product development than the woodworking industry. Furthermore, whenever they have approached this problem they usually considered it solely from the manufacturing rather than the distribution angle.

As the author brings out, it is more important with most products that satisfactory distribution is assured than it is that they can be manufactured readily. Almost any product can today be manufactured rather readily. We have an immense technique of manufacturing knowledge. On the other hand, we are woefully ignorant as to how to distribute products.

For several decades the fundamental theory of most manufacturers has been to give their principal consideration to the manufacture of a product and secondary consideration to its disposal. Under present conditions and the conditions which will probably be met for several decades to come, it is essential that we must first determine as to whether we can distribute a product, where it can be distributed, in what amounts, and at what expense, and then proceed to build up manufacturing facilities to meet the selling conditions, rather than expecting that selling conditions will meet manufacturing conditions.

The development of prefinishing and proper packaging and application also is of particular interest. Too often, wooden products which are to be used in subsequent fabrication or construction application are turned out in bulk amounts and the methods of application and finish left to the user. Very often, wood-fabricated materials are criticized for failure which really has been caused by method of application or finish.

The author has covered these points thoroughly in his development. For the short period of time in which this development has been accomplished he and his organization deserve great credit.

ARTHUR KOEHLER.[3] This is a good example of the possibilities of research in the development of wood-using industries. Unfortunately wood use does not have as much of this kind of work to its credit as would be desirable from the standpoint of the manufacturer and user of wooden products, and even from the standpoint of the owner of timber land. New and better uses of wood have not developed like those for steel, rubber, petroleum, and coal-tar products. There are several good and, to a large extent, hitherto unavoidable reasons why such has been the case, but the time has come when the wood-using industries must pay as much attention to making new and better products as they have in the past to reducing production costs, if they are to stay in the picture of national industries and if we are to find a ready market for all the wood that can and should be grown on millions of acres fit for nothing but growing timber.

Aluminum Oxide Versus Garnet as a Wood Abrasive

By J. F. Traendly,[1] St. Paul, Minn.

A comparison is made of aluminum oxide and garnet as surface-coated abrasives in woodworking. Garnet as found in the native state breaks into wedge-shaped pieces that when cemented to a surface of paper or cloth continue to fracture so as to produce further sharp edges. Aluminum oxide is a manufactured product, made in the electrochemical furnace by fusing bauxite and adding coke and iron. The hardness, toughness, and fracture of the two abrasive materials are compared. A table is given that covers time-study tests of belts used in a woodworking plant, with the labor and material costs.

Though the subject under discussion is a comparison of aluminum oxide with garnet as a wood abrasive, a more complete understanding of the properties of these two abrasives will be gained by knowing the early history of surface-coated abrasives, commonly but incorrectly known as "sandpaper." The idea of the present form of surface abrasives was gained probably from the twelfth century through their use of dried sharkskin and splintered whalebone for scouring purposes. In the next century, the Chinese attached crushed seashells to parchment with natural tree gum. Later, Swiss artizans used ground glass coated on a parchment or hide. The gumming of abrasive grains to flexible backings appears to have been started on a commercial scale in this country during the year 1828 by the Baeder Adamson Company.[2] The manufacturing process was the hand coating of individual sheets, but after a few years it was made in long strips, power being provided by dog-driven treadmills.

Of further interest is the reference to a leaf found in tropical seacoast areas that exudes a resinous gum, upon which the windstorms had deposited small particles of beach sand. When the gum dried and hardened, the result afforded nature's first conception of a surface-coated abrasive product.

Confining the discussion to commercially made products, one of the earliest and most common abrasives used was "silica," which occurs in nature as quartz, flint, and chalk flint. Crushed or ground glass was an accepted abradant in earlier days for sandpaper manufacture, and is still in use in England and continental Europe. Natural aluminum oxide, known as "corundum," has been used, but not to any great extent because its properties vary.

Garnet was introduced in 1880, but was then used more extensively in the shoe-manufacturing industry for polishing soles and heels. The introduction of garnet represented the first constructive step in the improvement of woodworking abrasives.

Aluminum-oxide grain, while generally and favorably known for many years as a metal-cutting abrasive, was not introduced to the woodworking industry for machine sanding until about 1923. Prior to that time its principal function as a wood abrasive was in mechanical floor sanding and surfacing.

Garnet

Garnet is as old as time. It was formed in the cooling and hardening of the earth's crust. It is found in many sections of the United States and in Canada, as well as in Spain. There are six well-defined species, of which one alone has proved of value as a wood abrasive, and this is almandite.

Almandite, so valuable as a wood abrasive, is obtained in the northern section of New York State. The deposits center largely in Warren County in the Adirondack mountain range.

Extraction of garnet is from quarries, which consist of a series of open pits that are developed into regular benches. Holes are drilled 10 ft deep, and these are shot with either 40 per cent or 60 per cent gelatin. Boulders are block-holed with small charges of dynamite. The broken ore is loaded into 3-ton cars with a steam shovel and hauled to the mill. The garnet-bearing ore passes through a milling operation which liberates the garnet from the surrounding rock by crushing. The separation of garnet from the crushed rock is accomplished by wet jigging. The garnet, being heavier, separates from the crushed rock under the influence of the motion and water. The yield is approximately 8 per cent, meaning that $12^1/_2$ tons of rock must be handled to secure 1 ton of garnet concentrate. The production o abrasive garnet in the United States in 1924 was 8290 short tons. In all likelihood this figure represents the maximum yearly output because during that year aluminum-oxide abrasive grain was beginning to receive attention as a woodworking abrasive having unusual value in certain operations.

The physical characteristics of almandite garnet which make it a desirable abrasive to use in the manufacture of garnet paper and cloth and combinations are its properties of hardness, toughness, and fracture.

Hardness. This is a property not easily defined. In the Mohs scale of hardness, wherein the diamond, the hardest known mineral, rates as 10 and talc rates as 1, garnet ranges from 6.5 to 7.5. Hardness in an abrasive mineral is the factor that determines which materials the point of the abrasive can penetrate. Obviously, if the mineral cannot penetrate the surface of the object being abraded, the only effect will be frictional attrition. Garnet has therefore not been used successfully as a metal-cutting abrasive.

Toughness. This property is important, since the penetration of a mineral into an object is only part of the problem. The mineral must have sufficient resistance to shear to prevent a point breaking off prematurely, instead of performing like a cutting tool. The toughness of minerals is not known. It cannot yet be accurately measured by scientific methods. All data are relative. According to some tests, garnet is about 65 per cent as tough as aluminum oxide, and to others 30 per cent.

Fracture. Garnet naturally breaks into ideal shape for coated-abrasive use. Its shape is a wedge having a triangular cross-section whose base varies from 0.3 to 0.7 the length of its sides. There are some particles whose cross-section is a parallelogram. It is important to note that these predominant shapes have edges caused by the intersection of sides at less than right angles, and

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

it is the length and nature of these edges that make garnet an effective wood abrasive. The sides of garnet particles are often conchoidal (dish shaped like a shell, or having a hollow-ground effect). This is of secondary importance to the nature and extent of edges. As the grains are broken in use, further sharp edges are produced, as garnet appears to have just sufficient brittleness to break under the strain of ordinary use rather than to polish down to a smooth surface.

ALUMINUM OXIDE

Aluminum-oxide abrasive grain differs from garnet in many ways. Garnet is a mineral, used about as found in nature. Aluminum-oxide is manufactured, being a product of the electrochemical furnace. It is made by fusing bauxite under carefully controlled conditions, adding coke and iron. The heat melts the ore, and a slag containing impurities comes to the top. The iron combines with the silica and forms a metallic button on the bottom. The molten aluminum-oxide liquid is permitted to cool slowly to allow proper crystalline structure. The best mineral has a good distribution of the remaining impurities, and has a consistently large and tough crystalline structure. Extremely high heats are used in the formation of crystalline aluminum oxide, exceeding 3600 deg fahr. It takes several days to cool a pig of grain. The desirable properties that make this type of mineral acceptable for woodworking grain are hardness, toughness, and fracture.

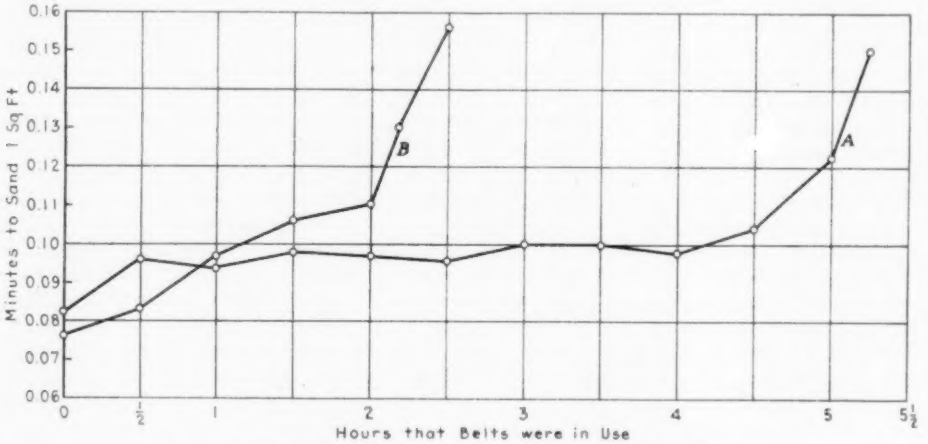

FIG. 1 TIME-STUDY TESTS OF BELTS USED IN SANDING WALNUT
(Curve *A*, grade 3/0 aluminum-oxide paper; curve *B*, grade 3/0 garnet paper.)

COMPARATIVE COSTS OF ALUMINUM OXIDE (*A*) AND GARNET (*B*), IN DOLLARS

	Cost of belt	Sq ft sanded	Time of sanding, min	Labor cost of sq ft sanded	Labor costs per min	Labor costs per sq ft	Sandpaper cost per sq ft	Added costs of belt changes	Total costs per sq ft	Total costs per M sq ft
A........	0.62	1277	130.91	1.4182	0.01833	0.001111	0.000485	....	0.001596	1.60
B........	0.49	435	51.95	0.5628	0.01833	0.001290	0.001130	0.000340	0.002760	2.76

Hardness. In the Mohs scale of hardness it has a rating of 9.5 as compared with garnet's 6.5 to 7.5. This hardness is ample to abrade any surface except that of a diamond.

Toughness. As indicated under the heading of garnet, toughness is a most important factor. It is this property, as well as hardness, that makes aluminum oxide preeminent in the field of wood abrasives, especially for machine sanding. The resistance to shear or premature rupture is the property that adds to its longevity as a wood abrasive. In addition, this toughness permits the retention of a cutting edge longer than is possible with the more friable, relatively brittle garnet.

Fracture. Initially, crystalline aluminum oxide for woodworking-abrasive purposes had a poorer fracture than garnet. Its toughness made it difficult to break the crystals to produce edges. The normal shape was the crystal just as it developed while cooling in the pig, and crushing tended to preserve this shape except where small particles were broken off, giving a faceted appearance. Considerable improvement has been made in the crushing of this type of grain, and the trend has been in the direction of producing a close approximation to the garnet shape. The grain manufacturer today classes aluminum oxide in three broad steps, starting with the cube-like structure, which is converted into the manufacture of grinding wheels, and extending to the more wedge-like crystals, which are selected for use in surface-coated abrasives. The objective is a grain having the garnet shape, combined with all the physical properties of hardness and toughness that may be found in aluminum oxide.

Comparison of these two minerals is not complete without a careful study of relative performance in coated-abrasive form under conditions as alike as it is possible to obtain in a woodworking plant. From the viewpoint of the manufacturer of coated abrasives, it was necessary to make an early determination of the practical utility of aluminum-oxide grain in coated form as a wood abrasive so as to avoid needless duplication of manufacture in a line as varied as sandpaper proves to be.

For the purpose of illustration, the Department of Commerce, cooperating with the surface-coated abrasive manufacturers, and functioning through the Bureau of Standards, to determine recommendations for simplified practice on the elimination of waste, reduced the number of these items, without reducing the number of minerals or the backings, down to a point where they now are as follows:

1 Five distinctly different types of abrasive mineral in which there are 17 different grits ranging from fine to coarse.
2 Two kinds of coating, both open and closed, with the exception of two types of mineral
3 Five different weights of paper backing
4 Three weights of cloth backing multiplied by three distinctly different colors of cloth backing
5 Two weights of combination backing
6 Twelve to 15 standard widths of roll material, with a tremendous variety of products cut to special and standard sizes and shapes.

The variety of manufacture resultant under these conditions gives a range of products totaling many thousands of individual items. Accordingly, the question of adding a new line to be manufactured as well as stocked in many parts of the country was a problem of no insignificant proportions, especially if the economic justification was not well established.

Before aluminum-oxide grain in coated form was offered to the woodworking industry it was tried in a preliminary way in the company's testing laboratories on belts, disks, and drum sanders. The immediate indication was that this new application of aluminum-oxide grain had very decided possibilities. This was followed by field work in the plants of many large users of coated abrasives, and finally the finished result was turned over to a limited number of users for actual test under average operating conditions. Plants were selected that would give a wide variety of experience from the angle of different types of wood and veneers commonly in use. The graph (shown in Fig. 1) depicts the comparative results obtained by the time-study department of one large user, and is representative of the data recorded in other plants under a wide variety of operating conditions.

The use of aluminum-oxide grain, particularly in the field of abrasive-belt sanding, opened some interesting studies as to the advantage of increasing belt speeds by reason of the greater relative toughness and hardness of aluminum-oxide grain as compared with garnet. Some plants advanced their belt speed from between 2000 and 3000 ft per min to between 4000 and 5000 ft per min. Under this advance of speed, garnet, because of its relatively more brittle nature, would shatter and lose its cutting edge in a relatively short time.

Finish was a question that was given considerable attention, with some quite controversial angles from the start. This was settled conclusively by making a careful comparison of panels surfaced, under like conditions, by both types of coated-abrasive belts, with results in favor of aluminum-oxide grain.

In addition to the utilization of higher sanding speeds, due to the greater toughness of aluminum oxide, which permitted retention of the cutting edges longer than garnet, it also developed that the inherently greater hardness of aluminum oxide enabled the use of lighter sanding contact pressures, particularly for belt sanders, than was possible with garnet except in the initial stages of its use. Cutting-efficiency curves showing the relative performances of the two types of belts generally started with a rate of cut initially higher with garnet, but when the first "bite" was diminished through early fracture of the needlelike cutting points of garnet, the relatively higher rate of cut diminished, and gradual dulling took place, requiring increased pressure to maintain an economical cutting rate.

In the field of drum and disk sanding, a similarity of problems existed. The desirable properties of aluminum oxide, in greater hardness and toughness, are called into use to equally great advantage except in the instance of excessively gummy and pitchy woods.

In conclusion it may be said that aluminum oxide has found a definite place in the woodworking industry. Garnet continues to find favor in operations where it is not possible to use it to the maximum capacity potentially available in aluminum-oxide grain.

A.S.M.E. Record and Index, 1932

THIS section of the Transactions contains a record of the activities of The American Society of Mechanical Engineers for the year 1932, together with an index of its publications. It is issued in pamphlet form to every member of the Society who requests it and when bound with the technical papers of the Professional Divisions for the use of libraries and official depositories throughout the world, it completes the permanent record of the Society's activities.

The Record and Index Section of Transactions includes all the reference material likely to be of permanent value and of interest to future searchers. As an index it provides a means of locating the technical information in the Society's publications. It includes the separate indexes of the Transactions and *Mechanical Engineering,* together with a miscellaneous index to reports or other technical publications of the Society that have appeared during the year and a list of papers issued in mimeographed or similar form for meetings in 1932, but not published.

A considerable portion of the Record and Index is devoted to memorial notices of members who have died during the year. Special care has been given to the preparation of these brief biographies with the idea in mind that fitting attention should be given to significant events in the lives of deceased members, even though they may fall outside the immediate field of mechanical engineering.

CONRAD NEWTON LAUER

President of The American Society of Mechanical Engineers
1931–1932

Conrad Newton Lauer

CONRAD NEWTON LAUER, president of The American Society of Mechanical Engineers for the term 1931–1932, was born on November 25, 1869, at Three Tuns, Montgomery County, Pennsylvania. He received his education in public and private schools in Montgomery County and through special instructors. From 1893 to 1902 Mr. Lauer was with the Link-Belt Company, serving in various capacities ranging from time clerk to acting superintendent of the plant. During this time he was sent to the Bethlehem Steel Company to secure data, and later assisted in introducing scientific management methods in the Link-Belt plant.

In 1903 Mr. Lauer became associated with Dodge & Day, engineers, and he remained with their successors, Day & Zimmermann, Inc. During the first ten years of his service he dealt with a large variety of problems incidental to the selection of industrial equipment, the layout of equipment, routing of materials, and the determination of types of building structure best suited to house such equipment and processes. His work also embraced investigations for banking interests. During the World War he was in charge of large construction projects under Government contracts. In the latter years of his connection with the Day & Zimmermann organization he was its vice-president and director. Since 1929 he has been president of the Philadelphia Gas Works.

In 1923 Mr. Lauer was the Cyrus Fogg Brackett lecturer before Princeton University. He is the author of "Engineering in American Industry," and is a contributor to the technical press. He has also been a special lecturer before the University of Pennsylvania and is a trustee of the Corporation of Worcester Polytechnic Institute. He received the honorary degree of Mechanical Engineer from Stevens Institute of Technology in 1929.

Mr. Lauer became an associate of the A.S.M.E. in 1903, and a member in 1923. He was a member of the Committee on Meetings and Program of the Society from 1922 to 1926, serving as its chairman in 1926. He was a manager during the next three years and vice-president from 1929 until he became president of the Society. In 1919 he was chairman of the Philadelphia Local Section. He is also a member of the Committee on Revenues of the Society appointed December 5, 1927, and of the Committee on Economic Status of the Engineer on which he served as chairman from May 14, 1928, to January, 1932.

In 1929, Mr. Lauer, desiring to commemorate the civic and humanitarian achievements of engineers, established a trust fund of $15,000 for the institution of a gold medal, named, with Mr. Hoover's consent, the Hoover Gold Medal. The first award was made to Herbert Hoover in April, 1930, on the occasion of the Fiftieth Anniversary of the A.S.M.E., and other awards will be made from time to time for distinguished public service. The trust fund is held by the A.S.M.E. and administered by a Board of Award consisting of representatives of the four national engineering societies.

Mr. Lauer is active in numerous engineering and civic undertakings and a member and director of many social and professional clubs. He is vice-president and a member of the executive committee of both the Philadelphia Chamber of Commerce and the Regional Planning Federation of the Philadelphia Tri-State District. He is an honorary member of the Princeton Engineering Association of New York, past-president of the Philadelphia Engineers' Club, and a member of the New York Engineers' Club, the Taylor Society, the Newcomen Society of London, The Franklin Institute, the Executive Board of the American Gas Association, and the Pennsylvania Gas Association.

Unifying the Engineering Profession

By CONRAD N. LAUER

MY ILLUSTRIOUS predecessor, Robert Henry Thurston, first President of The American Society of Mechanical Engineers, delivered an address before this Society in November, 1880, in which he set up for all who were to follow him in this office an obligation to deliver a presidential address and a standard of excellence for that address that it is difficult to attain. Those who, in recent years, have read Dr. Thurston's words express amazement at his wide knowledge of contemporary engineering, his prophetic vision of future developments, and his clear understanding of the relations of engineers to their profession and of their profession to questions of public interest.

The concluding section of Dr. Thurston's address is entitled "The Ethics of Cooperation." He had affirmed that in the work of the engineering society there was a need for men of the world and men of science, "observers, discoverers, and inventors, explorers in all fields of research, students of nature's facts, and codifiers of nature's laws and teachers of all applied sciences, as well as workers in field, in workshop, and in office." He added, "We shall find that the promotion of mutual welfare is consistent with the most perfect system of mutual cooperation and mutual aid in all the truest and highest aims of life." Tonight I wish to direct your attention to some cooperative efforts that affect not only our professional welfare but the public interest, and to indicate the desirability of finding a simple and effective way of coordinating them.

Obviously an effective profession must be a united one, and for this reason this Society may well concern itself with the organization of the engineering profession as a whole. To that end let me review briefly the steps that have been taken over a period of years by which united action by the profession has been secured, and let me offer some suggestions as to future steps for the unification of society organization.

These projects illustrate convincingly the benefits of cooperation in accordance with the unwritten principles which have always actuated this Society in such relationships: First, unselfish cooperation with other related societies; second, planning actively for the future so that development may not be haphazard; third, giving the most effective service to members of the engineering profession; and fourth, inspiring the engineering profession to render the most valuable service that it can to the public.

The Development of the Spirit of Cooperation in Engineering Societies

The earliest engineering societies were formed, as was our own, by groups of individuals as agencies for the self-improvement of members through the presentation and publication of papers, the development of the professional spirit, and the pooling of individual library resources. In addition these societies provided certain standards of attainment in engineering as expressed in the qualifications set up for various grades of membership. These were worthy objectives in days when the engineering profession was young and its members were poorly organized. They will always remain the essential objectives of such organizations. They satisfied our needs as specialists in engineering and absorbed practically all of the activities of engineering societies until the turn of the century, when the impact of engineering was making itself felt in the social and economic changes in civilization. At that time engineers were becoming conscious of their growing importance in the changing life of the world, and sought by working together with other men practising in the same fields to give direction and effectiveness to their professional work. Engineering had emerged as an important cultural factor that transcends the narrow limits within which its numerous branches are traditionally confined. An insistent urge for a united profession as a means of increasing the effectiveness and prestige of the individual engineer in private practice and of professional bodies in the public service, with the same recognition of the profession by the public generally that is accorded to older professions, had made itself known in various movements looking toward greater unity of objectives and actions. This seemed in many ways to be counteracting the centrifugal forces that had been at work for some time and had resulted in a galaxy of individual societies of specialists, and to lead logically to the coalescence of these numerous groups into a single national engineering society. Before discussing the desirability of such a coalescence, let me review briefly some of the major activities that have been the result of cooperation for the common good.

Some Examples of Engineering-Society Cooperation

An early evidence of this desire for team work was the foundation, in 1902, of the John Fritz Medal for the recognition of leaders in engineering. Later, Andrew Carnegie, a man of rare and far-seeing vision, provided an exceptional opportunity for cooperation by his gift of the Engineering Societies Building in New York, the present home of many of the major professional engineering organizations, where the library facilities of the four Founder Societies are consolidated in one of the best and most widely used engineering libraries in the entire world. This building, dedicated in 1907, brought the engineering profession together on an intimate working basis, and for that reason has been of incalculable value in advancing the common objectives of all branches of the profession. Its affairs and those of the library are administered by the United Engineering Trustees, Inc., and the Engineering Societies Library Board, respectively.

In 1914, actuated by a desire to promote engineering knowledge, our own Past-President, Ambrose Swasey, established The Engineering Foundation as an instrument of several engineering societies to aid in the research activities of these bodies. His proposal was accompanied by substantial gifts that have reached a total of $750,000. With characteristic modesty and vision Mr. Swasey declined to have his name attached to the Foundation. In all his statements in connection with the Foundation he has expressed the hope that others will assist the progress of research by adding to the funds he has provided. I am happy to state that Mr. Henry R. Towne, another past-president, and Mr. Edward D. Adams have been inspired by Mr. Swasey's example to make substantial additions to the Foundation's endowment. The Engineering Foundation is now carrying on its work of aiding research in science and engineering, and of advancing in many other ways the profession of engineering and the welfare of mankind.

Cooperation for the Public Welfare

Turning now to the relations of engineering societies with the public, it will be recalled that the World War provided a multitude of opportunities for engineers to serve the Government and

---

Presidential Address delivered at the Annual Meeting, New York, N.Y., December 5 to 9, 1932, of The American Society of Mechanical Engineers.

the public without regard to their professional society affiliations on questions which required the competent advice of technically trained men. In order to make the services of individual experts of the engineering profession available and to provide an organization of authority and professional standing, the four Founder Societies formed the Engineers' Council in 1917. The services rendered by this Council proved to be valuable and effective, and demonstrated that in peacetime, as well as in war, there is a need by government bureaus, legislative and administrative departments, and other national bodies for unbiased and informed opinion on the engineering factors involved in questions of public interest. In 1920, therefore, the Council was reorganized as the Federated American Engineering Societies, subsequently renamed the American Engineering Council.

The formation of this body represented a significant change in the attitude of the profession toward the public. It calls together periodically in Washington representatives of many national and local engineering societies for the purpose of focusing the thinking of engineers for group service on national problems in which engineering principles and interests are involved. The American Engineering Council has been a powerful factor in developing a spirit of cooperation in the engineering profession. Its committees and representatives are highly respected by legislative and administrative agencies in Washington because they provide competent and disinterested advice on matters of public interest. It has sponsored a series of important studies on the relationship of engineering to industrial operations, such as those on waste in industry, the relation of safety to production, and the twelve-hour shift in industry. A committee of the Council is now preparing the groundwork for a study of the balancing of the forces of production, consumption, and distribution, a significant contribution to economic and sociological thinking.

State councils to perform locally services similar to those that the American Engineering Council renders to the nation at large have been formed in a few states, such as Minnesota, Colorado, and Utah, and offer further examples of the effectiveness of cooperation by engineering organizations.

Cooperation for Industry and the Engineering Profession

The effectiveness of the cooperation of engineering societies with industry is demonstrated by developments in industrial and engineering standardization. Up to 1918 many bodies were engaged in the formulation of such standards. In 1918 the American Engineering Standards Committee, now known as the American Standards Association, was formed through the joint efforts of five engineering societies, and ever since has grown in membership and in influence. Forty-five national organizations are now affiliated as member-bodies, and the Association is the official channel for international cooperation with similar national standardizing bodies in each of twenty foreign countries; it acts also as a clearing house for the distribution of information about standardization in the United States and elsewhere.

The registration and licensing of engineers, touching as they do the legality of the engineer's right to practice, are also questions of common interest. While one state, California, had enacted a law in 1891 requiring registration and while there were altogether eleven states with licensing laws on their books in 1920, most of the discussion and interest in these questions on the part of engineers has developed since 1920. Fifteen states have put on their statute books some form of requirement for legal recognition of the engineering profession. Now, under the leadership of the American Society of Civil Engineers, a model law is being developed. There are at present twenty-six states with licensing and registration laws, and a body, known as the National Council of State Boards of Engineering Examiners, has been organized to provide a working arrangement for the coordination of procedure in the administration of these laws in the various states. This is an activity of increasing importance and interest.

The study of engineering education, undertaken in 1923 by the Society for the Promotion of Engineering Education, brought about the cooperation of engineering societies, industry, governmental agencies, and individuals throughout the entire range of the field of study. The elaborate report issued by that organization in 1930 gave a clear picture of the conditions in the schools and of the relationship between the education and training of engineers and the requirements of professional, industrial, and economic phases of modern life. It has provided the basis for sound advances in engineering education and in the profession itself, and demonstrated once again the value of cooperation.

In addition to the John Fritz Medal, already mentioned, other awards are made by several societies acting jointly so as to represent more completely the engineering profession of the United States in doing honor to men of attainment. The most recently established of these is the Herbert Hoover Medal, founded, in 1930, to signalize the public service of men who have gone outside of their strictly professional work to interest themselves in civic and human affairs. The medal is awarded by a joint board of the Founder Societies, and was first bestowed, in 1930, on the engineer-statesman whose name it bears.

A Recent Outstanding Example of Cooperation

During the past two months seven engineering bodies, acting jointly, have formed the Engineers' Council for Professional Development. The purposes of the Council are to coordinate and promote efforts and aspirations directed toward higher professional standards in engineering education and practice, to enhance the prestige and solidarity of the engineering profession, and to secure greater effectiveness in dealing with technical, social, and economic problems. It will immediately concern itself with the development of a scheme whereby the progress of the young engineer toward professional standing can be recognized by the public, by the profession, and by the individual himself through the development of technical and other qualifications which will enable him to meet high professional standards. This is a conspicuous example of what extensive and comprehensive objectives may be set up by engineering societies working together in harmony and with intelligence.

The American Society of Mechanical Engineers is proud of the fact that the formation of this new body resulted from the work of its Committee on the Economic Status of the Engineer. But without the enthusiastic cooperation of the American Society of Civil Engineers, the American Institute of Mining and Metallurgical Engineers, the American Institute of Electrical Engineers, the American Institute of Chemical Engineers, the Society for the Promotion of Engineering Education, and the National Council of State Boards of Engineering Examiners, who joined with the A.S.M.E. in forming the Council, it could never have been hoped that this would become the truly representative and authoritative body that it now is.

The Problem of Unification

These examples of engineers working together toward common objectives are concrete expressions of some of the ideals that are held for the advancement of the engineering profession. The objectives are worthy of the efforts expended for their attainment, and these latter have been organized with the idea of bringing about certain results useful either to the profession itself, to industry, which it serves, or to the public. However, it has been noted that many of these cooperative enterprises have necessitated the formation of organizations to carry out their projects. These organizations have grown both in number and in size. They have set up for themselves, or have been asked to set up.

additional objectives. Their functions are not always clearly understood, with the result that there is danger of overlapping and a lack of clearly defined relationships among themselves and the engineering societies that have created them. The conclusion seems inescapable that the engineering profession is tending toward overorganization. It would seem that one of two alternatives must be chosen as a way out of our perplexing position. If we are to assume that these cooperative activities are more important than the numerous specific objectives for which individual engineering societies were formed, then the profession and the public would be well served by the consolidation of all engineering societies and related organizations into a single body that could act and speak for the engineering profession. If these joint activities are merely those in which all engineering bodies can work most effectively through cooperation, then, by proper organization their usefulness can be assured and their procedure and relationship clarified and simplified without losing the undoubted benefits of the existence of long-established and vigorous societies, held together by common professional interests, whose very strength and progressiveness have given rise to these related bodies engaged in tasks of mutual concern and profit.

It is my opinion that the time is not ripe, and indeed it may never be ripe, to advocate the first of these alternatives, that is, the formation of a single engineering society to serve a profession which, in spite of its many common objectives, has so many specialized interests. The effectiveness of the existing major national engineering societies in dealing with the problems, practices, and procedures in the fields they represent is unquestioned, and the vigorous individual development of these societies must continue. Their joint activities must also continue and expand, as the individual societies collectively represent the profession and because common interests and objectives do exist. In general, the common objectives are:

1 The development of the individual engineer by selection, education, guidance, and recognition of his attainments
2 The focusing of the intelligence and knowledge that engineers possess on problems of public interest
3 The aiding of research and standardization in engineering and industry.

Joint agencies, therefore, may be in need of coordination and simplification, but not of consolidation. A committee representing the four Founder Societies is engaged in a study of this question. I believe that if the members of the engineering profession will support this committee, its findings may lead to such coordination and simplification. I do not believe that there exists a sentiment in favor of a single engineering society replacing not only the numerous organizations created by the present engineering societies, but those societies themselves as well. Rather I believe that sentiment is in favor of some form of my second alternative.

CONCLUSION

The numerous examples of successful cooperative endeavor which I have quoted demonstrate the practicability of achieving noteworthy results without destroying the autonomy of existing societies or diverting them from the purposes for which they were formed. It is an impressive indication of the vigor and progressiveness of these bodies that in a period of economic distress they have been able to bring about the formation of such a potentially useful and comprehensive organization as the Engineers' Council for Professional Development. This great accomplishment, which marks the beginning of an important epoch in the history of engineering, was made possible by the desire and ability of organized groups representing professional, educational, and governmental points of view to work together constructively and harmoniously in matters of common concern. No single engineering society embracing the entire profession could do more, and might, because of the inertia of its ponderous machinery, do even less.

Today engineers may look with renewed hope and enthusiasm to the unfolding of this new epoch. Every member of the profession, through the society to which he belongs because of his personal interests, has an active concern in a program of professional development that starts with the secondary school and carries on through the engineering college and apprenticeship in the profession to a final recognition of competency and attainment. Never has so comprehensive a program been laid before engineers with the machinery for its accomplishment ready for operation and the combined energies of long-established professional societies guaranteeing effective action. In attaining the objectives of this program, each engineering society will develop greater strength and prestige, and realize the fruits of former cooperative endeavors. All will find, I feel sure, as Dr. Thurston affirmed more than fifty years ago, that "the promotion of mutual welfare is consistent with the most perfect system of mutual cooperation and mutual aid in all the truest and highest aims of life."

The American Society of Mechanical Engineers

THE personnel records and other information presented in this first section of the Record and Index refer, except where otherwise noted, as in the case of Local Section and Student Branch chairmen, to the official year beginning in December, 1931. Such information is purely of historical nature and is included here as a permanent record. Further information may be secured from the Headquarters of the Society.

Officers and Council[1]

Dates in parentheses denote expiration of terms

PRESIDENT

Conrad N. Lauer

PAST-PRESIDENTS

Terms expire in December

William L. Abbott (1932)
Alex Dow (1934)
Charles M. Schwab (1933)
Charles Piez (1935)
Roy V. Wright (1936)

VICE-PRESIDENTS

Terms expire December, 1932

Harvey N. Davis
William A. Hanley
Thomas R. Weymouth

Terms expire December, 1933

Robert M. Gates
William B. Gregory
Frederick H. Dorner
Charles M. Allen

MANAGERS

Terms expire December, 1932

Harold V. Coes
James D. Cunningham
C. F. Hirshfeld

Terms expire December, 1933

William L. Batt
Harold L. Doolittle
Herbert L. Whittemore

Terms expire December, 1934

Eugene W. O'Brien
Harry R. Westcott
Alexander J. Dickie

TREASURER

Erik Oberg

SECRETARY

Calvin W. Rice

EXECUTIVE COMMITTEE OF COUNCIL

Conrad N. Lauer, *Chairman*
Harvey N. Davis, *Vice-Chairman*
Calvin W. Rice, *Secretary*
Robert M. Gates
Harold V. Coes
Harry R. Westcott

Advisory Members: Chairmen of the Finance Committee, the Local Sections Committee, and the Professional Divisions Committee.

CHAIRMEN OF STANDING COMMITTEES

Representatives on Council but without vote

Finance, David Lofts, *Chairman*
K. L. Martin, *Vice-Chairman*
Meetings and Program, F. M. Feiker
Publications, W. H. Winterrowd
Membership, H. W. Butler
Professional Divisions, W. F. Dixon
Local Sections, J. M. Todd
Constitution and By-Laws, T. C. McBride
Awards, A. M. Greene, Jr.
Relations With Colleges, M. C. Maxwell
Education and Training for Industries, R. L. Sackett
Library, A. S. Miller
Standardization, L. K. Sillcox
Research, W. H. Fulweiler
Power Test Codes, F. R. Low
Safety, H. W. Mowery
Professional Conduct, A. G. Christie

EXECUTIVE SECRETARY

C. E. Davies

EDITOR

G. A. Stetson

ASSISTANT SECRETARIES

Ernest Hartford
C. B. LePage

Standing Committees

Past Presidents[12]

Alexander Lyman Holley, *Chairman of the Preliminary Meeting for Organization of The American Society of Mechanical Engineers* (1882)[13]

1880–1882	Robert Henry Thurston (1903)
1883	Erasmus Darwin Leavitt (1916)
1884	John Edson Sweet (1916)
1885	Josephus Flavius Holloway (1896)
1886	Coleman Sellers (1907)
1887	George H. Babcock (1893)
1888	Horace See (1909)
1889	Henry Robinson Towne (1924)
1890	Oberlin Smith (1926)
1891	Robert Woolston Hunt (1923)
1892	Charles Harding Loring (1907)
1893–1894	Eckley Brixton Coxe (1895)
1895	Edward F. C. Davis (1895)
1895	Charles Ethan Billings (1920)
1896	John Fritz (1913)
1897	Worcester Reed Warner (1929)
1898	Charles Wallace Hunt (1911)
1899	George Wallace Melville (1912)
1900	Charles Hill Morgan (1911)
1901	Samuel T. Wellman (1919)
1902	Edwin Reynolds (1909)
1903	James Mapes Dodge (1915)
1904	Ambrose Swasey
1905	John Ripley Freeman (1932)
1906	Frederick Winslow Taylor (1915)
1907	Frederick Remsen Hutton (1918)
1908	Minard Lafever Holman (1925)
1909	Jesse Merrick Smith (1927)
1910	George Westinghouse (1914)
1911	Edward Daniel Meier (1914)
1912	Alexander Crombie Humphreys (1927)
1913	William Freeman Myrick Goss (1928)
1914	James Hartness
1915	John Alfred Brashear (1920)
1916	David Schenck Jacobus
1917	Ira Nelson Hollis (1930)
1918	Charles Thomas Main
1919	Mortimer Elwyn Cooley
1920	Fred J. Miller
1921	Edwin S. Carman
1922	Dexter Simpson Kimball

---

[10] A.S.M.E. representative from Board of United Engineering Trustees, Inc.

[11] Deceased December 10, 1932.

[12] A list of past vice-presidents, managers, treasurers, and secretaries will be found in the 1930 Record and Index, pages 10–12.

[13] Dates in parentheses denote year of death.

1923	John Lyle Harrington
1924	Frederick Rollins Low
1925	William Frederick Durand
1926	William Lamont Abbott

Report of the Council

THE close of the fiscal year 1931–1932 finds the Society in a strong position. Notable advances have been made and the work of the Society has been highly fruitful despite the curtailment of expenditures made necessary by the reduction of income from dues and advertising.

Mechanical engineers have suffered from the lack of industrial and engineering activity. The Employment Service has striven to meet a situation which was beyond its control. Members have contributed time and money through local agencies which have been organized to provide emergency aid, in some cases solely for engineers. The Council, in sympathy with the times, when requested has made possible quarterly payments on dues. The first payment assures the sending of *Mechanical Engineering* and the *A.S.M.E. News* throughout the year. Further, rather than having a member withdraw from the Society, the Council has also provided for members in arrears to retain membership status without receiving publications and to be exempt from payment of dues until further notice during the period of the business depression.

MEMBERSHIP CHANGES—OCTOBER 1, 1931, TO SEPTEMBER 30, 1932

	Membership		Losses				Additions			Totals

The Council trusts that as a result of this liberal policy all members may keep their connection with the Society until such time as they can meet their obligations.

The opportunity offered to individual members for participation in the activities of the Society has been large. Two meetings of the Society, eight national meetings and six special meetings of Professional Divisions, including the First National Process Meeting, and 434 Local Section gatherings indicate that this opportunity was not materially less than that offered in the previous year.

Because of the exigencies of the times, the Council held only two meetings during the year and placed upon the Executive Committee the responsibility of carrying on between Council meetings. That Committee formulated a definite program of Society activity and met monthly to forward it and to transact routine business. The results of this program and of the Standing Committee activities are summarized in the following paragraphs.

The success of the new Student Branch plan in the 15 schools in the South was demonstrated at the First Southern Student Branch Conference at Chattanooga in April. The Council authorized the installation of the plan in three additional areas during 1932–1933.

The recommendation of the Committee on the Economic Status of the Engineer resulted in the establishment of the Engineers' Council for Professional Development, a joint organization whose general objective is the enhancement of the professional status of the engineer. The American Society of Civil Engineers, American Institute of Mining and Metallurgical Engineers, The American Society of Mechanical Engineers, American Institute of Electrical Engineers, American Institute of Chemical Engineers, Society for the Promotion of Engineering Education, and National Council of State Boards of Engineering Examiners are participating in this program.

As further steps in the broad program of improving the status of the engineer, the Council approved the general principle of State Councils of Engineers, and authorized the Committee on Registration of Engineers to represent the Society on all joint agencies dealing with registration.

Mechanical Engineering was developed into a magazine which touches more broadly the work and interest of every member. The publication of articles on economics and social problems and on biography and history has met with a cordial response and has demonstrated the engineer's interest in these subjects.

The balancing of income and expenditures has been of continuous concern during the year. The income from dues and advertising decreased more rapidly than expenditures could be decreased, and a draft upon reserve of $67,998.38 was necessary. Fortunately, the Society is in a sound position financially, and with a balanced budget in 1932–1933, will be able to carry on its activities without embarrassment.

The Administrative Office has been reorganized by direction of the Council on the basis of a report of an outside firm engaged for that purpose, with a resultant smaller personnel. This reduction, with lowered salary rates and vacations without pay, decreased the payroll expenditure by 22 per cent. The Council providéd an unemployment relief fund available on a made-work basis for members of the staff who have been released from service.

The reports of the Standing Committees of Council follow.

CALVIN W. RICE, *Secretary*

FINANCE

Vigorous efforts were made during the past year, 1931–1932, to reduce the expenditures of the Society to meet the greatly curtailed income. Through the splendid cooperation of standing committees, the appropriations under their supervision were reduced by 17 per cent. Printing economies and the reduced number of advertising pages made possible a reduction of 32 per cent in the cost of printing and distributing publications. Drastic economies in the Secretary's Office, accomplished by reorganizing the Office, by reducing the staff, and by salary reductions, resulted in a decrease of 19 per cent in the administrative expense. A reduction of 23 per cent in the expenses of the Engineering Index was brought about largely by a change in the method of printing the cards. These reductions have been achieved without affecting to any great extent the usual activities of the Society or its service to members.

The income for the past year, excluding that received from initiation fees, which is not used for operating purposes, was 32 per cent less than the income for 1930–1931. This is largely accounted for by the decreased revenue from advertising and the sale of publications and from a probable loss in dues. Gross income from advertising this year was 48 per cent less than that in 1930–1931; gross income from the sale of publications was 31 per cent less than in the previous year.

Dues in arrears on September 30, 1932, amounted to $110,876.36. In the belief that a considerable part of this amount will not be paid, a reserve of $55,000.00 was set aside to cover a probable loss, thereby reducing the dues receivable to $55,876.36, amounting to a 17 per cent reduction in dues income for the fiscal year.

TOTAL EXPENDITURES

For control purposes, the expenditures of the Society are segregated into four classes: first, Committee Expenditures, that is, monies spent directly by Committees or Council; second, Printing and Distribution Expenses of Publications (Editorial and Advertising Expenses appear under the heading of Administrative Expense); third, the Administrative Expenses, including all salaries and office operating expenses under the supervision of the Secretary and in addition the Editorial Department and Advertising Department expenses; fourth, Engineering Index Expense, including all salaries and other expenses of preparation, printing, selling, and distribution.

A comparison of the total expenditures for the fiscal years 1930–1931 and 1931–1932 is given in the following table:

	1931–1932	1930–1931
Committee Expense	$ 96,523.86	$116,073.62
Publications Expense (Printing and Distribution Only)	156,606.36	230,932.77
Administrative Office Expense	306,905.89	380,295.57
Engineering Index Expense	84,552.41	113,379.71
	$644,588.52	$840,681.67
Relief Fund	2,978.75	
	$647,567.27	

The use to which these expenditures is put in carrying on the work of the Society is shown in the following tabulation:

	1931–1932	1930–1931
General	$ 35,493.33	$ 44,630.18
Society Activities	150,769.97	175,241.50
Technical Committees	55,356.48	64,883.97
Text Publications (Printing, Editorial, and Distribution)	142,573.54	179,390.56
Advertising and Sales (Printing, Soliciting, and Distribution)	175,842.79	263,155.75
Engineering Index (Printing, Editorial, Soliciting, and Distribution)	84,552.41	113,379.71
	$644,588.52	$840,681.67

General Expenses include those for Council, the Library, American Engineering Council, the Nominating Committee, and Awards. The decrease of $9863.15 in General Expenses was due in part to the discontinuation of assessments for the study of the Economic Status of the Engineer; and to reductions in appropriations of 31 per cent to Council, of 11 per cent to American Engineering Council, and 15 per cent to the Nominating Committee. Assessments for the Library and for Awards were slightly increased.

Expenses for Society Activities include those for Meetings, Local Sections, Professional Divisions, Student Branches, Employment Service, and for the staff expense of handling these activities and the routine procedure for the Membership Committee. These expenses were decreased by $24,471.53, a reduction of 14 per cent.

Technical Committee expenses include the direct appropriation to the American Standards Association ($1500.00), grants in aid of research ($300.00), and staff expenses to support the Boiler Code, Research, Standardization, Power Test Codes, and Safety Committees. The decrease of $9527.49, or 15 per cent, was brought about by discontinuing the appropriation to the International Electrotechnical Commission ($1320 in 1930–1931) and by savings made in the staff expenses.

Text Publications Expense include the expense of printing, distributing, and editing Transactions, the *A.S.M.E. News*, and the text pages of *Mechanical Engineering*. The decrease of $36,817.02, or 20 per cent, was due to suspending publication of the membership list, to a reduction in the number of pages in *Mechanical Engineering*, to the adoption of a less expensive method of printing advance papers, to a reduction in the number of papers included in Transactions, and to savings made in the expenses for the editorial staff.

Expenses of Advertising and Sales include (1) printing and distributing the Mechanical Catalog and the advertising pages of *Mechanical Engineering*, (2) cost of securing advertising income, (3) printing and distributing publications sold, and (4) the expenses of the publication sales department. The decrease of $87,312.96, or 33 per cent, in this item is due to the reduced number of advertising pages sold and printed.

TOTAL INCOME

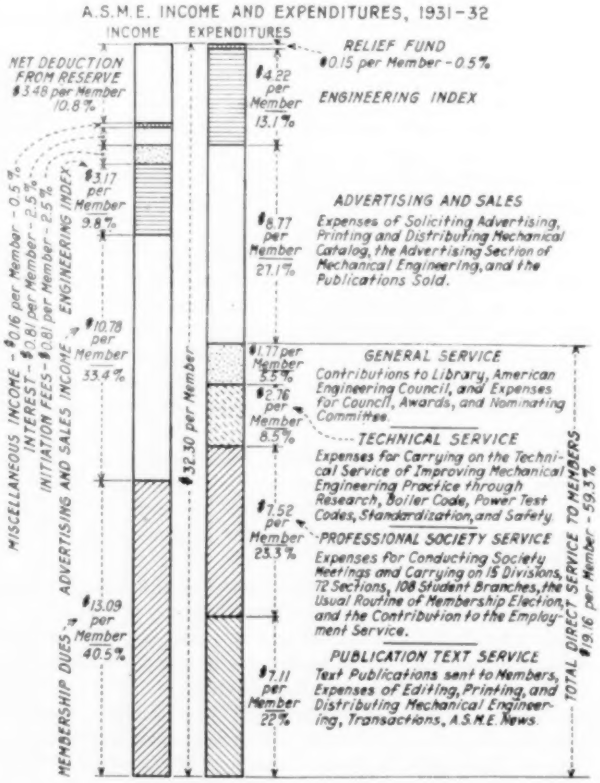
A comparison of income for the past two years is given in the following tabulation:

	1931–1932	1930–1931
Initiation Fees	$ 16,288.33	$ 25,863.27
Student Fees	$1,158.00	....
Membership Dues (Including Dues Receivable)	316,137.28	$314,828.31
Interest and Discount	16,168.57	22,080.10
Mechanical Engineering Advertising	103,757.32	213,771.23
Mechanical Catalog Advertising	60,807.47	102,262.77
A.S.M.E. News	802.00	889.00
Publication Sales	53,134.03	61,768.71
Engineering Index	63,552.17	108,508.64
Miscellaneous Sales	2,212.07	3,364.35
	$617,728.91	$827,473.11
Less: Bad Debts	2,427.10	1,558.99
	$615,301.81	$825,914.12
Less: Probable Loss of Dues Receivable	55,000.00	
	$560,301.81	
Unexpended Commitments, 1930–1931	1,030.50	
	$561,332.31	
From Reserve	86,234.96	
	$647,567.27	

The net income available for operating purposes, after deducting the $55,000.00 reserve for probable loss of dues, was $560,301.81, or $84,286.71 less than the total expenditures of $644,588.52, excluding the relief fund expenditure from reserve. The Council authorized that this amount be taken from the accumulated surplus. Inasmuch as $16,288.33 received from initiation fees was placed in the initiation fee reserve fund, the net deduction from surplus was $67,998.38, of which $55,000.00 was the reserve for probable loss of dues and $12,998.38 was a net operating loss.

INCOME AND EXPENSES PER MEMBER

An analysis of the income and expenditures for 1931–1932 on a per-member basis is shown in the accompanying chart.



NOTE: The average membership during 1931–1932 was 20,053.

BALANCE SHEET

A statement of the assets and liabilities of the Society is given in the accompanying balance sheet in the simplified form adopted by the Council.

The accounting procedure for the Engineering Index has been a matter of continuous discussion by the Council and the Finance Committee. The Index was carried as a separate project and advances to it were recorded as assets. The Index operation has faced serious financial difficulties during the past year. The Council, believing that carrying this item as an asset was unwise, voted to write it off and to combine the Index accounting with the accounts of the Society.

Because of the reduced income, the Council decided not to make a deduction this year from the deferred charges for the Fiftieth Anniversary, nor to set aside the usual $5,000.00 reserve for retirement allowance. The Council made an appropriation from working surplus of $7,000.00, or as much thereof as might be necessary to provide aid on a make-work basis to members of the staff released from service. Expenditures this year amounted to $2,978.75, leaving an unexpended balance of $4,021.25.

In order to continue its reputation for the prompt payment of its obligations, the Society's borrowing requirements amounted to $185,000.00 at the end of the fiscal year. Substantial reductions from this amount will be made in the first part of next year by the receipt of dues and by collections for Mechanical Catalog advertising.

Wm. J. Struss & Co., certified public accountants, give the results of their examination of the books of the Society for the fiscal year ended September 30, 1932, in the accompanying statement of assets and liabilities.

Respectfully submitted,

David Lofts, *Chairman* **E. A. Muller**
Kingsley L. Martin, *Vice-Chairman* **Walter Rautenstrauch**
John H. Lawrence
R. V. Wright } *Council Representatives.*

[1] Working Surplus consists of the following three items:

Initiation Fee Reserve	$211,440.38
Previous Surplus Investment	70,005.89
Other Working Surplus	78,595.01
	$360,041.28

MEETINGS AND PROGRAM

During the fiscal year, October 1, 1931, through September 30, 1932, two meetings of the Society were held, the Annual Meeting in New York, November 30 to December 4, 1931, and the Semi-Annual Meeting at Bigwin Inn, Lake of Bays, Ontario, Canada, June 27 to July 1, 1932. The program for the former meeting appears in the Record and Index section of the Transactions for 1931 (see pages 45–47) and the latter program will be found in the 1932 Record and Index.

ANNUAL MEETING

Planning the Annual Meeting program consists of (1) selecting a series of events of broad interest and of inspiring forward-looking nature, (2) coordinating the programs of the Professional Divisions, and (3) planning the entertainment and excursion events.

In the Annual Meeting program for 1931 the broad-interest program events were generally excellent: The Towne Lecture by Dean Wallace B. Donham on "The Temporary Emergency and Twenty-Year Planning," the Thurston Lecture by Dr. E. L. Thorndike on "Psychology and Engineering," the address by Commissioner Frances Perkins on "State Labor Departments and Professional Engineers—Cooperation Essential to Progress in Accident Prevention," the Presidential Address of Dr. Roy V. Wright on "The Engineer Militant," and the award of Honorary Membership with suitable exercises to Dr. Calvin W. Rice, Secretary of the Society for twenty-five years, and to Dr. Palmer C. Ricketts.

In addition, a Public Speaking Contest was initiated as a means of interesting individual engineers in the importance of a better manner of presenting engineering material before audiences, the series of lectures by Dr. S. Marion Tucker on "Talking With an Audience" were continued before enthusiastic audiences, and the Second Art Exhibit showed work of engineers during 1931.

The number of papers presented was equal to that at the previous Annual Meeting but the attendance was about ten per cent smaller.

BIGWIN MEETING

The Bigwin Meeting presented an international program arranged with the cooperation of the Engineering Institute of Canada and individual members of the Institution of Mechanical Engineers of Great Britain. This program of excellent papers, combined with the fine entertainments arranged by the Ontario Section and the beautiful setting for the meeting, made the gathering a most successful one.

IMPROVEMENT OF ENGLISH

The Meetings and Program Committee thoroughly supports efforts to improve spoken and written English. Following the address at the June, 1931, meeting of the Society for the Promotion of Engineering Education by J. W. Parker on "The Need for Speech Training by Engineers" the Committee cooperated in the plans for the 1932 Summer Session for teachers of English to engineers, and two members of the Committee, J. W. Parker and R. I. Rees, delivered lectures at the Session.

Respectfully submitted,

F. M. Feiker, *Chairman*
J. W. Parker, *Vice-Chairman* **R. I. Rees**
C. P. Bliss **E. C. Hutchinson.**

PUBLICATIONS

The effects of a reduced income were seriously felt by the Publications Committee in carrying out its function of supervising the Society's publications, but the emergency was met and was not without beneficial compensations. Transactions for the calendar year

1931 appeared in a single volume instead of the two which have been necessary since the new method of publishing was adopted in 1926. The original plan of quarterly publications for every division has been so modified, except for the Aeronautical Division, that semi-monthly issues, making a total of 24 (including the Record and Index) divided among all of the remaining divisions, are now published. Definite publication dates have been set by the requirements of the Post Office Department and have greatly facilitated the work of the staff.

Among the benefits resulting from hard times has been the necessity of scrutinizing every paper with more than usual care to appraise its value in printed form. The Committee on Meetings and Program, the Divisions, and other paper-procuring agencies have aided wholeheartedly in this effort to reduce the volume of papers in Transactions. In cooperation with the Committee on Meetings and Program, the Committee on Professional Divisions, and the Research Committee, a procedure looking toward the improvement of the quality of papers has been worked out and approved by the Council.

The problem of better and cheaper publication of papers not destined for Transactions has been worked out with the result that all preprints and reports, not to be set in type, are reproduced by the photo-offset process in accordance with a standard style. Such papers are generally available for meetings and for distribution on request. Synopses of them, with request blank, appear in *Mechanical Engineering*, and copies are preserved, bound together, and filed with the Engineering Societies Library. There they are appropriately cataloged. They are also indexed for the Society's Record and Index. Their availability is thus assured.

The printing of the Membership List was omitted this year as an economy measure.

The *A.S.M.E. News* appeared regularly twice monthly, but in much abbreviated form, set in very small type to conserve space, and lacking its usual illustrations. Only most pressing matters could be treated, and then inadequately. Such a situation obviously cannot be justified except in view of the low state of Society finances. A comprehensive study of the *News* is in progress by the Committee.

Mechanical Engineering, while reduced in size, showed a healthy development in reader interest, by a more attractive make-up and articles of broader scope and more general nature. Comment has been favorable and encouraging.

The Mechanical Catalog reflected the general lack of business throughout the country with its reduced number of pages and entries.

One of the encouraging aspects of the publication situation is to be found in the reduced costs of publication. A careful check-up of costs was made and bids on the printing of Transactions and *Mechanical Engineering* were solicited from a number of printing houses. In view of the reductions granted by the Society's printer it was found impossible to save money by making a change. The committee was satisfied that its printing costs are as low as can be obtained anywhere for such quality and volume as exist. Other economies in printing have greatly reduced costs of Transactions papers. The newly adopted photo-offset process should result in further savings.

A major portion of the Committee's attention was directed to a review, made at the request of President Lauer, of the Society's publications and of the policy under which they are administered. This review includes a thorough analysis of the advertising problem and resulted in recommendations that the policy of accepting advertising in *Mechanical Engineering* and other Society publications be continued, and that all of the present publications of the Society be continued. A proviso with respect to the *News*, still under study, made the report subject to further recommendations on this publication.

At the 1931 Annual Meeting the Publications Committee attempted to interest the delegates to the Local Sections Conference in publication matters, particularly in *Mechanical Engineering*. Such efforts must be continued, and with a magazine that touches more broadly the work and interest of every member, attractively put together, the Committee feels that its enthusiasm for this publication and the part it plays in the profession of engineering is justified. It is significant that the publication of articles on economic and social problems, and on biography and history, have met with a cordial response and have demonstrated the engineer's interest in these subjects. New writers have been discovered and readers who too long have been silent are writing their comments to the editor. There is ample evidence that *Mechanical Engineering* is becoming more widely read and discussed as every month goes by.

The Engineering Index entered its fourth year of operation by the Society. Rigorous economies in the operation of the Index were effective in reducing the expenses by $29,000.00. Unfortunately the income dropped $45,000.00 and the Engineering Index is compelled to report a deficit. Further economies have been put into effect to balance the budget during 1932–1933.

The report of the Finance Committee shows figures from income of publications. The Committee on Publications attempted to bring the expenses for the printing and distributing of publications in line with this decreased income. The following figures show the amount spent for printing and distributing Society publications during the past fiscal year in comparison with the preceding year.

Publications Income

	1931–1932	1930–1931
Mechanical Engineering Advertising	$103,757.32	$213,771.23
Mechanical Catalog Advertising	60,807.47	102,262.77
A.S.M.E. News	802.00	889.00
Publication Sales	53,134.03	61,768.71
	$218,500.82	$378,691.71
Less: Bad Debts	2,427.10	1,558.99
	$216,073.72	$377,132.72

Publications Expense
(Printing and Distribution)

Mechanical Engineering Text Pages	$ 31,676.16	$ 36,566.61
A.S.M.E. News	9,133.48	10,543.39
Transactions	45,591.20	59,026.34
Membership List	197.63	7,127.35

PROFESSIONAL DIVISIONS

During the past year Professional Division activities have been slightly curtailed, chiefly in respect to national meetings, several Divisions feeling that the time was not opportune for such meetings. Efforts were concentrated in fields where favorable conditions prevailed, so that some of the Divisions have had very successful national meetings. Probably the most outstanding of these from the point of attendance and interest was the national meeting of the Printing Industries Division, held in New York, March 14 and 15. This meeting had a total attendance of nearly 1,000 and surpassed any previous meeting held by the Division. The Aeronautic Division sponsored a special Pacific Coast Aeronautic Meeting at Berkeley, Calif., in June, in addition to its national meeting in Buffalo.

The Process Industries Committee held the first national Process Meeting of the Society at Buffalo in June, assisted by the Petroleum Refining Committee of the Petroleum Division.

In planning the activities of the Divisions, an effort was made to combine meetings, and at the same time to present all the valuable material in the way of papers that was offered; so that, in spite of the depression, the Divisions were able to provide almost the usual amount of technical material, which was made available in either printed or mimeographed form.

During the last year the other activities of the Divisions have progressed. The Divisions have continued their excellent work in arranging sessions at the Society's Annual and Semi-Annual Meetings, and have assisted Local Sections in meetings. They have prepared their annual progress reports covering developments in their fields. In research and standardization work they have been active either through their own subcommittees or in initiating committees under the A.S.M.E. Standing Committees on Research, Standardization, and Safety.

All activities of the Divisions for the year can be summarized as follows:

8 National Meetings: Printing, Management, Materials Handling, Aeronautic, Oil and Gas Power, Process, Applied Mechanics, and Wood Industries
7 Special Meetings (larger than local): Pacific Aeronautic, Buffalo Machine Shop, Fuels, two Tulsa Petroleum, and two Textile
25 Local Section Meetings aided
44 Special Division subcommittees working
1 New research project suggested
34 Sessions arranged at Annual and Semi-Annual Meetings
15 Progress reports prepared.

As to additional activities for the coming year there seems to be an opportunity for the Divisions to assist the Society in improving the status of the engineer. Some years ago this work was really started by the Railroad Division's analysis of earnings and opportunities of engineers in the railroad industry. The Machine Shop Practice Division later conducted a similar survey. The splendid work which the Society is now doing in cooperation with other societies in the matters of certification and registration seems to point the way for the Professional Divisions to give active assistance in their own fields in advising and assisting especially the younger engineer in improving his status in accordance with whatever plans are developed by the main societies. It was recently pointed out by one of the Divisions that the Society was doing very little to assist the young engineer after he leaves college, as most of the material that was published in the way of technical papers was for the more advanced engineer. It was suggested that something might be done to assist the young engineer after he leaves college to further prepare himself in his profession. This matter is now being given consideration by the Divisions, and they will be prepared to assist the Society in its general plans for improving the status of the engineer.

A brief review of each Division's activities during the year follows.

SUMMARY OF DIVISION ACTIVITIES

Aeronautic Division, during the present year, held its national meeting in Buffalo, June 6–8, presenting 33 papers, and a Pacific Coast Aeronautic Meeting at Berkeley, Calif., June 9–10, presenting 12 papers; assisted Local Sections in holding aeronautic meetings in New York, Cleveland, Tulsa, Cincinnati, and St. Louis; and held a session at the Annual Meeting in cooperation with the American Institute of Physics.

The Spirit of St. Louis Medal, awarded for meritorious services in behalf of aeronautics, which was founded by the St. Louis Section, was presented for the second time at the national meeting in Buffalo, the recipient being Paul W. Litchfield, for his work in encouraging and sponsoring airship design and construction in this country.

A Special Subcommittee on Wage Incentives in Aviation has been active during the year and presented a report at Buffalo on Wage Incentives in the Aeronautic Industry. Another activity is the Special Committee on Aircraft Safety and Inspection, under the A.S.M.E. Standing Committee on Safety, which reported at the Buffalo meeting on an "Inspection Manual for Maintenance of Conventional Aircraft." A draft of the Manual met with approval from the industry.

During the coming year the Aeronautic Division will have a session at the Annual Meeting and is planning to hold its national meeting as part of the Semi-Annual Meeting in Chicago in June, 1933, with an international program.

During the last year the Society appointed a representative on the American Committee on Marking of Obstructions to Air Navigation, of the Department of Commerce, and the Division is cooperating in this work.

Applied Mechanics Division held its national meeting in New Haven, Conn., June 23–25, presenting 27 papers. This meeting was coordinated with the American Physical Society's summer meeting, and one session was held jointly. The Division also sponsored three sessions during the last Annual Meeting and arranged a symposium of two sessions at the Semi-Annual Meeting at Bigwin on June 27–30. It will also sponsor, at the 1932 Annual Meeting, a special symposium of three sessions on Working Stresses. Its 1933 national meeting will be held as part of the Semi-Annual Meeting in Chicago, for which joint sessions will be arranged with other Divisions and with other societies.

The Division has three special subcommittees as follows: Vibration, which is sponsoring presentation of papers on this subject and helping to coordinate the research work being done; Plasticity, which sponsored sessions at the New Haven meeting and is planning additional sessions in cooperation with the Iron and Steel Division for the Semi-Annual Meeting in Chicago; and a Survey Committee on Impact Testing, which will participate in the Working Stresses symposium and is planning special activities during the coming year.

Fuels Division cooperated in the Mid-West Bituminous Conference held at Purdue University, April 14–15, 1932, and had a session at the last Annual Meeting. It is sponsoring sessions for the 1932 Annual Meeting and is planning to hold its national meeting as part of the Semi-Annual Meeting in Chicago. The Division has a recently appointed Special Advisory Committee on Boiler Furnace Explosions. The Division also assists the Pure Air Committee which grew out of its former Subcommittee on Smoke Abatement. This Pure Air Committee has a special Subcommittee on Standards for Setting Heights which will hold a conference during the 1932 Annual Meeting.

Hydraulic Division arranged sessions at the meeting at Bigwin in June and at the last Annual Meeting. The Division also has an active Subcommittee on Translation of Foreign Publications. The Division plans to have a symposium on water hammer at the Semi-Annual Meeting in Chicago and is sponsoring two sessions for the 1932 Annual Meeting.

Iron and Steel Division held a meeting in April, 1932, in cooperation with the Pittsburgh Section and the Engineering Society of Western Pennsylvania, and held two sessions at the last Annual Meeting. The Division held no national meeting, but instead is sponsoring three sessions for the Annual Meeting in 1932, and is planning to have three sessions at the Semi-Annual Meeting in Chicago. The Division initiated a Special Research Committee on Heavy Duty Anti-Friction Bearings, which has been reporting progress at its meetings for the last few years. The Division is also cooperating with the Applied Mechanics Division on the question of plastic deformation of metal, so as to aid in developing a research project that can secure the support of the iron and steel industry.

Machine Shop Practice Division held a special meeting of two sessions and a luncheon in Buffalo on October 3, in cooperation with the Buffalo Section during the Metal Industries Exposition. Sessions were arranged at the Bigwin Meeting and at the last Annual Meeting. The Division has two subcommittees, one on Machine Design and another on Foundry Practice. The latter committee has sponsored sessions at the last two Annual Meetings. Through this Division papers are presented by the Special Research Committee on Cutting of Metals, which has regularly sponsored sessions. During the coming year, the Machine Shop Practice Division will hold three sessions at the Annual Meeting and plans to hold several sessions at the Semi-Annual Meeting in Chicago. If conditions should warrant it, possibly two technical sessions will be held at any exposition of interest to their field that may be held next fall.

Management Division, in cooperation with the Materials Handling Division, held a Management, Maintenance, and Materials Handling Congress in Detroit, May 4–5, under the auspices of the Detroit Section. It also sponsored sessions at the Bigwin and last Annual Meetings. The Division has several active subcommittees. That on waste elimination has been active for some years in stimulating factory elimination-of-waste campaigns, and sponsored again this year an elimination-of-waste campaign during the month of April and also a session on the elimination of waste at the Detroit meeting. They again issued this year a small waste unit to assist small companies in putting on a factory waste campaign. The Subcommittee on Maintenance participated in the Detroit Meeting. Its Subcommittee on Economics and Business Stabilization has been very active. The Special Research Committee on Measures of Management has recently taken over as one of its activities the further investigation of the application of the replacement-of-equipment formula which was developed by the Materials Handling Division. In the Metropolitan Section the Division sponsors informal evening conferences on management. The Division is represented on the International Management Institute. This year it has formed a special Subcommittee on Organization and Operating Machine Shops and it is planning subcommittees on marketing and human relations. During the coming year the Division is planning sessions for the Chicago Meeting, in addition to three sessions at the Annual Meeting.

Materials Handling Division held its national meeting in Detroit, May 4–5, as part of the Three-M Congress. It sponsored a session at the last Annual Meeting and will hold one this year jointly with the Railroad Division. During the last year there has been formed a Materials Handling Institute, and the Division is cooperating with this Institute to encourage materials-handling progress. The Division has a special subcommittee known as the Materials Handling Manufacturer's Committee which during the last year developed and reported on standards on cranes and on the capacity of containers. The Division originally had a Replacement of Equipment Committee, which has been reorganized as a Subcommittee of the Special Research Committee on Measures of Management, under the sponsorship of this Division and the Management Division.

Oil and Gas Power Division held its national meeting at Pennsylvania State College on June 8–11, with 11 papers presented. It also had a session at the last Annual Meeting and at the Semi-Annual Meeting. It has one special Subcommittee on Oil Engine Power Costs which each year for the last four years has prepared a report on oil power costs. This report has received a good deal of attention and favorable comment. More than a hundred plants report in detail their cost of oil power, and these data are assembled in extensive tables and charts. The Division also initiated a Special Research Committee on Diesel Fuel Oil Specifications, which usually reports at Division meetings. The Division is planning to hold a national meeting next year and will have a session at this annual meeting.

Petroleum Division has a number of special subcommittees. Several of these are located in Tulsa, Oklahoma, and are assisted by the Field Secretary there. In March the Tulsa subcommittees held a special conference of one day, presenting a number of technical papers on production and pipe-line problems, and in October a conference on metallurgical problems. In the East the Division has special subcommittees, on Lubrication Engineering, Petroleum Refining, and Petroleum Utilization. The Lubrication Engineering Committee held a session at the last annual meeting and two special conferences, one on railroad lubrication in cooperation with the Railroad Division and the other on mechanism of lubrication. This committee will have a session at the Annual Meeting and it is also preparing an Industrial Lubrication Manual, which is being reviewed and criticized by some sixty representatives in different fields. During the coming year the committee is planning activities in railroad lubrication and wire rope lubrication in cooperation with the Special Research Committee on Wire Rope. It is also planning to hold a conference on lubrication problems in cooperation with the Pennsylvania State College, there next May. The Petroleum Refining Committee has been active during the past year in preparing recommendations on the testing of heat-exchange equipment for oil-refining service which is now available, and it also sponsored a session at the Process Meeting held in Buffalo. The Subcommittee on Petroleum Utilization sponsored a Metropolitan Section Meeting on the problems of firing Bunker C Oil.

The Petroleum Division is planning to hold a national Meeting in Tulsa next May at the time of the International Petroleum Exposition.

Power Division held sessions at the Annual and Semi-Annual Meetings. It has two subcommittees, one on Central Station Power and the other on Industrial Power. The Industrial Power Committee has three special subcommittees, which will report at a luncheon meeting during the Annual Meeting. Several of the Society's special research committees sponsor sessions jointly with the Division.

Printing Industries Division held its national meeting in New York on March 14 to 15, presenting 11 papers. Several group conferences were held at that time, as a result of which special committees are being considered. The Division will hold a session at the Annual Meeting and plans to hold its next national meeting during the Semi-Annual Meeting in Chicago. The Division has affiliated with the Inter-Society Color Council to assist in encouraging progress in color measurement and standards.

Process Industries Committee held the first national Process Meeting in Buffalo, June 6–8, at which 11 papers were presented. At the Buffalo Meeting a Special Subcommittee on Cotton-Seed-Oil Processing made a report, as a result of which the Process group is now recommending that this subcommittee become a special research committee of the Society. At the Buffalo Meeting there were also sessions on pulverizing and dust problems. As a result of the interest shown, it was decided to organize a special committee on pulverizing and grinding to stimulate activities in that field with a possibility of later forming a special research committee. A special Subcommittee on Unit Costs has been organized for the purpose of analyzing unit cost operations in processing and also a Committee on Air Conditioning was formed. During the last year both the New York Section and the Buffalo Section have sponsored local informal process meetings. A request for the formation of a sanitary subcommittee is being considered. There is also a joint committee with the American Institute of Chemical Engineers to coordinate activities.

Railroad Division held sessions at the Semi-Annual and Annual Meetings and was joint sponsor with the Lubrication Engineering Committee of the Petroleum Division of a conference on railroad lubrication on February 19 in New York. A session is being arranged for the Chicago Semi-Annual Meeting. The Railroad Division is continuing the work of developing its organization so that the railway-mechanical engineer can utilize the information and data developed by the other professional divisions and also by the various technical committees of the Society. The railroad mechanical-department officer is primarily concerned with the maintenance of locomotives and cars. There are also railway-mechanical engineers who are engaged in the design and manufacture of rolling stock and equipment for railroad transportation. The registration in the Railroad Division is made up of mechanical engineers from both these groups. The mechanical engineer engaged in the maintenance of railroad rolling equipment has under his supervision machine shops, power plants, and forge and heat-treating shops, as well as work which pertains to practically every branch of mechanical engineering served by the other professional divisions. Thus, the Executive and General Committees of the Railroad Division have found it necessary to so organize their work and activities as to coordinate with and utilize the work of the Society as a whole.

Textile Division held a Southern Textile Meeting in Greenville, S. C., on October 19, with the Greenville Section and a New England Textile Meeting in Boston with the Boston Local Section on October 27. The meetings each consisted of one session and a dinner or luncheon. The Greenville meeting was held during the Greenville Southern Power Exposition. The Division held a session at the last Annual Meeting and will have one at this Annual Meeting.

Wood Industries Division will hold its national meeting in Jamestown, N.Y., on November 15–16, at which 14 papers are to be presented. This meeting will be held in cooperation with the National Association of Furniture Manufacturers. The Division has several subcommittees, one of which is a Survey Committee for research projects. This Committee will sponsor a session at the Jamestown meeting. Another subcommittee, on the Manufacture of Doors, will report at the Jamestown Meeting. The Wood Industries Division has reported at its meetings two special research committees, one on Saws and Knives and the other on Existing Supplies of Hard Woods.

Respectfully submitted,

Walter F. Dixon, *Chairman*
William A. Shoudy
Park T. Sowden
Clair B. Peck
Walter Samans.

LOCAL SECTIONS

Scope of Service

Local Sections have been urged to economize in every possible way with regard to their activities, but the use of some of the Society's funds has been necessary to meet the obligation of the Society through its Sections to participate in matters relating to the welfare of the membership. Especially is this true with regard to the collection of funds for relief, and the organization of committees to handle unemployment and of other groups to cooperate with Governmental agencies in the furtherance of construction projects which would require the employment of engineers. Likewise, the Sections have been urged to develop activity in the matter of uniformity in laws for the registration of engineers, so that the respective states in which they are located would adopt laws in accordance with the recommendations contained in the Model Law prepared by the Committee representing most of the leading national engineering societies.

Economic Operation of Local Sections to Meet Existing Conditions

When the budget for 1931–1932 was originally adopted in the spring of 1931, a tentative provision was made for financing Local Sections on the same basis as during the previous year. Subsequently, however, it was found necessary to reduce the appropriations to meet the decreased income. This resulted in a reduction for the Sections of $12^1/_2$ per cent of the original allotment. Great credit is due the Sections for the fine cooperation which they gave in effecting economies without impairing the quality of their meetings.

Meetings and Membership Chart

Collectively 434 meetings were held by the Local Sections during 1931–1932. The number of meetings held by each individual Section is shown in the accompanying chart (Table 1). This table also details the membership of the respective Sections on October 1, 1931, and October 1, 1932, the net increase, the percentage of membership increase, etc.

New Membership

The potential membership of the Society continues to be enormous. However, with industrial conditions as they exist, many, of course, who are interested are unable to afford the cost. Therefore, it has seemed unwise to make any drive for members. The membership development work has been maintained, however, through consistent quiet effort on the part of the individual Sections and through special attention to Professional Divisions, especially when any of them held a national meeting. The Committee believes that as soon as there is a noticeable upturn in business it will be wise to inaugurate a membership drive.

Prospective Sections

Few industrial areas of the United States remain to be provided with Local Sections. Ft. Wayne, Ind., Central Illinois (headquarters probably at the University of Illinois), Nashville, Tenn., and Central Wisconsin are interested.

In view of the need for pursuing economy, the Committee on Local Sections has felt that it was unwise to undertake the establishment of any new Sections during the past year.

Local Sections Visited by the Committee

Thirty-two Local Sections were visited during the past year by a member of the Local Sections Committee. (See Table 2.)

In 1930, after consulting with delegates from Group VII, the Committee decided to recommend the appointment of William Lyle Dudley of Seattle. This decision was based on two points: First, that it would give representation on the Standing Committee from the Far West, and second, it was agreed that in lieu of Mr. Dudley's attendance at three of the four annual meetings of the Committee he would travel within Group VII, so as to keep contact with the Local Sections and to some extent also with the Student Branches in that area. The Committee regrets that illness made it impossible for him to travel during 1932 but is glad that he has recovered sufficiently to plan future visits.

TABLE 1 MEMBERSHIP IN LOCAL SECTIONS, OCTOBER 1, 1932

Total membership in Society, Oct. 1, 1931, 19,979; Oct. 1, 1932, 20,057. Total number of Student Branches, 108.

EMPLOYMENT SERVICE

The Engineering Societies Employment Service maintained its full efficiency in spite of the falling off of income from contributions and subscriptions to the Employment Bulletin. The Finance Committee and Council, with full appreciation of the need to maintain the Employment Service, increased the appropriation for next year by approximately 25 per cent. There have been constant requests made to the Local Sections to join with the other engineering groups of their respective communities to foster the Employment Service. Partly as a result of this there have been developed in a number of cities special committees which are dealing with the unemployment problem. Some idea of the demands made upon the Service is indicated by the fact that in the New York office alone an average of 700 unemployed were interviewed each week during the month of August, 1932. It is the hope of the Committee that members of the Society will think first of its Employment Service when in need of technical assistance.

MID-WEST AND MID-CONTINENT OFFICES

The Mid-West Office has continued to assist the Local Sections and Student Branches within its territory in every possible way. Marked savings in operating expenses have been effected by cooperative speaking tours for Local Section and Student Branch meetings.

Efforts have been made to induce groups of members in districts where Local Sections do not exist to effect some sort of organization, if it is nothing more than a luncheon committee, for the purpose of developing professional consciousness and acquaintanceship with the problems of other engineers. Two cities in the Middle West offer excellent possibilities for the development of such committees during the coming season.

Considerable assistance has also been rendered by the Mid-West Office in unemployment relief work, and closer contacts established with industry and individuals in the interest of technical committee activity. The Mid-West Office is being approached to an ever greater extent for A.S.M.E. information and assistance.

The Mid-Continent Office has devoted special effort to organizing research committees for investigating and reporting on problems and developments in the oil industry, increasing public and society interest in A.S.M.E. undertakings, rendering assistance in outlining programs for general meetings and in securing men of national recognition for the presentation of papers at the meetings, tying in the four Student Branches with Sectional activities, providing prominent speakers for student meetings, and organizing a club for junior engineers in Tulsa.

At the present time three major research investigations are being conducted by the A.S.M.E. in this section at no extra cost to the Society; all equipment, materials, and investigators' time being furnished by manufacturers, companies in the industry, and the universities.

This office has also rendered assistance in unemployment relief, and has established itself as a valuable point of contact for the Society in that territory.

COOPERATION WITH 1931–1932 BUDGET COMMITTEE

The Committee on Local Sections has done everything possible to maintain the Sections at their present efficiency, despite curtailed funds. The Local Sections Department has reduced its expenditures without seriously restricting constructive work in the Sections. The Committee thoroughly appreciates the fact that the Sections form the links of the Society's chain, and is confident that adequate financial assistance will be tendered them as soon as conditions improve.

COOPERATION WITH STUDENT BRANCHES

Many Local Sections, realizing an important obligation to the Student Branches, have entered actively into the work and have arranged for an interchange of attendance at the Sections and Student Meetings. Many of the Sections have offered prizes to win the interest and active participation of undergraduates. Through the splendid cooperation of one of the Sections, the first District Student Branch Conference was held this year and proved to be one of the outstanding successes of the new Student Branch plan.

COOPERATION WITH THE PROFESSIONAL DIVISIONS

The Local Sections have availed themselves of every opportunity to cooperate with the Professional Divisions. The larger Sections, such as the Metropolitan and Philadelphia, have worked with the Professional Divisions in planning Section meetings, and other Sections have supported the Professional Divisions in their meetings and in other Division activities.

Elimination of Waste. Seven Sections cooperated with the Management Division in organizing campaigns and meetings on the subject of Elimination of Waste, as listed below.

Section	Date of Meeting	Subject
Detroit	May 4–5, 1932	National Meeting, Management, Materials Handling, Maintenance Divisions
Greenville	Apr. 7, 1932	Elimination of Waste in Industry
Hartford	June 8, 1932	Management of Soviet Plants
Los Angeles	Feb. 17, 1932	Some New Ideas on Economic Theory, with Reflections on the Old
Metropolitan	Jan. 6, 1932	Planning and Scheduling
	Jan. 21, 1932	Planning the Merchandise Line
	Feb. 3, 1932	Glorifying Manufactured Products with Color
	Feb. 17, 1932	Purchasing Power and Its Relation to Marketing
	Mar. 2, 1932	Factory Waste Elimination Campaign
	Mar. 16, 1932	Consumer Expenditures
	Apr. 6, 1932	Value of Graphic Charts in Production
	Apr. 20, 1932	Knowledge of Markets and Distribution and Its Relation to Production
	May 4, 1932	Effect of Motion Study on Plant Layout
St. Louis	Feb. 26, 1932	Management
Western Washington	Oct. 23, 1931	Industrial Management

Professional Division Meetings. Local Sections cooperated in the following Division Meetings held between September 1, 1931, and September 1, 1932.

Cleveland Aeronautic Meeting, September 4, 1931

Iron and Steel Division and Machine Shop Practice Division, cooperating in Metal Congress, Boston, Mass., week of September 21, 1931

New England Textile Meeting, Providence, R. I., October 6, 1931

National Wood Industries Meeting, Winston-Salem, N. C., October 15–16, 1931

National Printing Industries Conference, New York, March 14–15, 1932

Iron and Steel Meeting, Pittsburgh, Pa., April 28, 1932

Materials Handling, Management, and Maintenance Congress, Detroit, Mich., May 4–5, 1932

National Aeronautic Meeting, Buffalo, N. Y., June 6–7, 1932

National Process Meeting, Buffalo, N. Y., June 6–7, 1932

National Oil and Gas Power Meeting, Pennsylvania State College, June 8–11, 1932

Pacific Coast Aeronautic Meeting, University of California, Berkeley, Calif., June 9–10, 1932

Applied Mechanics National Meeting, New Haven, Conn., June 23–25, 1932.

TOURS AND TRANSPORTATION SERVICE

The Committee on Local Sections arranged for reduced fares to the Annual, Semi-Annual, and other National Meetings of the Society during the year, thereby saving thousands of dollars to the members of the Society.

In connection with the Semi-Annual Meeting held at Bigwin, Ontario, Canada, a tour of the St. Lawrence-Saguenay Rivers was planned but because business conditions resulted in only a few reservations for the trip, it had to be canceled. Several of those interested, however, took part in sections of this tour and their transportation was arranged for by the Headquarters Office.

TOUR OF THE INSTITUTION OF MECHANICAL ENGINEERS

Although the visit of about 125 members and ladies of the Institution of Mechanical Engineers of Great Britain was not handled entirely by the Local Sections, they cooperated, especially at Rochester and Schenectady, in the entertainment of the party. Also, in a number of individual cases they provided opportunities for these visitors to inspect plants in which they were especially interested.

FOREIGN RELATIONS

In addition to the cooperation given by the Local Sections in connection with the I.M.E. tour, 42 other visitors were received from nine foreign countries, as follows:

Australia	1	France	4
Austria	1	Germany	10
Belgium	1	Sweden	2
England	20	Turkey	1
	Switzerland	2	

Letters of introduction to various companies and plants throughout the United States were prepared for each visitor.

Of the 20 visitors from England 13 were students of the Liverpool University, Liverpool, England. These students were interested in

* Annual Meeting.

the following phases of engineering, and letters to plants were given accordingly:

Civil Engineering	2	Mechanical Engineering	4
Electrical Engineering	4	Mining Engineering	1
General Engineering	2		

There has also been an opportunity to serve more of our members than heretofore by giving them letters of introduction which aided them in their visits to plants in the United States and to European countries.

During the past year letters of introduction have been written for 33 members of the Society. Thirteen of these were members going abroad and letters were given to foreign plants, companies, and societies according to what countries were to be visited. Letters for these members were issued to sixteen foreign countries.

The other 20 members were furnished with introductions from headquarters, to plants in the United States.

In each instance a copy of the letter of introduction was mailed in advance to the person addressed in the letter.

Respectfully submitted,

James M. Todd, *Chairman*
Harry R. Westcott — William Lyle Dudley
Jiles W. Haney — W. W. Macon.

MEMBERSHIP

The Committee on Membership held 13 regular meetings and 12 by proxy during the fiscal year 1931–1932.

The number of applications considered in the transaction of its work and a summary showing the action taken follow:

Applications pending, October 1, 1931	218
Applications received during fiscal year 1931–1932	1379
Total applications handled during year 1931–1932	1597
Recommended for membership	1302
Transfers denied	3
Deferred	3
Withdrawn	34
Applications pending, October 1, 1932	255
Total applications handled during year 1931–1932	1597

Those recommended for membership were divided into the following grades:

Members	166
Transfers to Member	80
Associates	11
Transfer to Associate	1
Associate-Members	112
Transfers to Associate-Member	98
Juniors	190
Juniors R5-Rule 1 (Southern Group)	184
Juniors R5-Rule 1	460
Total recommended	1302
Transfers	179
Total new members recommended	1123

During the fiscal year 1931–1932 the Membership Committee made the following recommendations:

Elections declared void	98
Resignations accepted	380

Respectfully submitted,

H. W. Butler, *Chairman*
H. Webster — H. A. Lardner
O. E. Goldschmidt — R. H. McLain.

AWARDS

During the past year the Committee has procured the dies for the Warner Medal, executed by Julio Kilenyi. The Committee has had the hearty cooperation of Mrs. Worcester R. Warner in this work and has her approval of the final medal.

The Committee recommended that the Council approve the Charles T. Main Award to Marshall Anderson of the University of Michigan for his paper on "Apprenticeship and Vocational Training." This was deemed the best paper of the seven submitted for the award.

The Committee recommended that the student award be given to H. E. Foster, Jr., of the University of Tennessee, for his paper on "Factors Affecting Spray Pond Design." Mr. Foster is an undergraduate student.

The Committee also recommended for the student award William A. Mason of Stanford University for his paper on "An Experimental Investigation of the Flame Propagation in Internal-Combustion Engines." Mr. Mason is a graduate student.

Altogether, there were 35 student papers presented by graduates and undergraduates, seven of which were by joint authors.

The Committee recommended for the Junior Award Edward M. Wagner of Stanford University for the thesis on "Frictional Resistance of a Cylinder Rotating in a Viscous Fluid Within a Coaxial Cylinder." Five papers were presented to the Society for the Junior Award.

The Committee recommended for the Melville Award Alexey Stepanoff for his paper on "Leakage Loss and Axial Thrust in Centrifugal Pumps." This was selected from three papers offered for the Melville Award.

Respectfully submitted,

Arthur M. Greene, Jr., *Chairman*
Kenneth H. Condit — William L. Batt
Frank L. Eidmann — David B. Rushmore.

CONSTITUTION AND BY-LAWS

The Committee on Constitution and By-Laws is now engaged in the study of the By-Laws and Rules with a view to their revision and possible condensation and expects to make a definite report on its findings later in the year.

Respectfully submitted,

Thos. C. McBride, *Chairman*
R. S. Neal — P. R. Faymonville
H. H. Snelling — Jas. A. Hall.

RELATIONS WITH COLLEGES

The Committee on Relations with Colleges inaugurated the new Student Branch policy in the 15 colleges in Group IV, in the Southeastern States, in October, 1931. Messrs. Maxwell or Gordon of the Committee and also its secretary visited the Branches at the University of Virginia, Virginia Polytechnic Institute, University of North Carolina, North Carolina State College, Clemson College, Georgia School of Technology, University of Florida, Alabama Polytechnic Institute, Mississippi State College, Louisiana State College, University of Alabama, University of Tennessee, Vanderbilt University, University of Louisville, and University of Kentucky. A full day was spent at Chattanooga with the officers of the Local Section, arranging plans for the first Student Conference to be held in April, 1932.

In the majority of the colleges both the faculty and student body enthusiastically approved the adoption of the new policy, but there were a few cases where local conditions made necessary somewhat extended conferences to adjust the procedure to meet existing regulations. Successful adoption was finally achieved in every instance with the result that the trip was considered to have been well worth the time, effort, and money expended on it.

Wherever possible throughout the trip, the representatives of the Committee on Relations with Colleges met with the Local Sections groups and enlisted their aid in the installation and functioning of the new Student Branch plan.

Southern Student Branch Conference

The first Southern Student Branch Conference was held at Chattanooga, Tenn., April 3–5, 1932, with headquarters at the Hotel Patten. Mileage was paid for a student delegate from each Branch. More than 100 students and 31 engineers registered, and in addition 40 students from the University of Tennessee participated in the plant visits but did not attend the meetings. There were meetings of two Standing Committees, the Committee on Relations with Colleges and the Committee on Local Sections, and also a joint meeting of these Committees.

Two splendid technical sessions were held, at which papers were presented by Student Members from each of the fifteen southern Branches. The George Hillyer, Jr., Award (fifty dollars in gold), inaugurated through the generous gift of his widow, was awarded for the first time to J. C. Whitehurst of North Carolina State College for his paper entitled "Practical Economics, a Necessity for the Engineer." Two other prizes were made possible through contributions from several Southern Local Sections, augmented by funds available for the meeting. Twenty-five dollars in gold was awarded to R. H. Hughes of Clemson College for his paper on "The Usefulness of Dynamite to the Engineer" and ten dollars in gold went to W. W. Knight of Georgia Institute of Technology for his contribution, "Light for Radiation End." Other papers presented by Student Members were as follows:

"Progress of Safety in Aviation," J. C. Barrett, Jr., Alabama Polytechnic Institute

"Progress in Industrial Management," E. R. Owens, University of Alabama

"Engineering Safety in Transportation," R. S. Thompson, University of Florida

"Diesel Engines," W. L. Albert, University of Kentucky

"Steam Distillation of Wood Naval Stores Products," R. M. Dreyfus, Louisiana State University

"The Modern Diesel Engine," F. S. Cornell, University of Louisville

"Procedure Control of Pipe Line Welding With Acetylene Torch," T. H. Suttle, Mississippi State College

"The Deceleration Method of Testing for Losses and Moment of Inertia of a Turbo-Generator," E. L. Midgett, University of South Carolina

"Design and Construction of Spray Ponds," H. E. Foster, University of Tennessee

"Carrier Centrifugal Refrigeration," J. P. Turner, Vanderbilt University

"Fuels for Internal-Combustion Engines," S. C. Smith, Virginia Polytechnic Institute

"Bremo Bluff—an Outstanding Central Station," W. D. Thornhill, University of Virginia.

Two formal luncheons and a banquet were also part of the meeting, as well as a breakfast attended by Honorary Chairmen and faculty members of the Student Branches.

Nine plants in Chattanooga and vicinity opened their doors for inspection trips and local engineers were generous in providing private cars for these excursions, as well as for a fifty-mile trip to points of historic and scenic interest.

At the meeting of the Committee on Relations with Colleges held during the Chattanooga Student Conference, the many details regarding the operation of the new plan were discussed and a course of action decided upon. The Committee voted to recommend to the Council that the plan be continued in the fifteen southeast Student Branches, and be extended during the 1932-1933 school year to include Student Branches in the following geographical groups:

Group I, New England and New York State outside of the Metropolitan area; Group II, Metropolitan areas of New York and Philadelphia, also Bethlehem and Easton, Pennsylvania; Group V, Indiana, Illinois, Michigan, Wisconsin, Iowa, Minnesota, and St. Louis, Missouri.

EXTENSION OF NEW STUDENT PLAN

Chairman Maxwell presented to the Council at the Bigwin Meeting a report on the success of the new Student Branch plan and its recommendation for the extension of the plan next year. The Council approved this recommendation and the Committee began (in September, 1932) to visit the Student Branches in the new territory of Group V. The Student Branches visited up to the end of the fiscal year received and accepted the new plan in the same fine spirit which had been evidenced in the Southeast at the beginning of the year.

There are at present 16 Student Branches in Group I, 17 in Group II, and 15 in Group V. Messrs. Maxwell and Church volunteered to visit the Student Branches in Groups I and II and Messrs. Abbott and Prentice those in Group V. Mr. Gordon will continue his special interest in Group IV.

Membership Under Old and New Policies. The following table gives the actual enrolment in Student Branches under the old plan and the new. The figures given for Group IV are actual, but those for the other groups are actual figures only for before the establishment of the new policy, the figures under "after" being estimated on the basis of the Group IV figures. This basis seems justified, inasmuch as the average student attending college in the South is, without doubt, no better off than the average student attending institutions in the other three groups.

	Before	After
Group IV—Alabama Polytechnic Institute	16	7
University of Alabama	19	28
Clemson College	19	34
University of Florida	20	19
Georgia Institute of Technology	83	43
University of Kentucky	39	37
Louisiana State College	33	19
University of Louisville	13	17
Mississippi State College	24	32
North Carolina State College	31	46
University of North Carolina	16	16
University of Tennessee	15	19
Vanderbilt University	31	23
Virginia Polytechnic Institute	35	21
University of Virginia	11	16
Group IV—Total	405	377
Group I—	737	679
Group II—	924	840
Group V—	927	853
Total	2993	2749

Expenditures Under New Policy. The original budget granted by the Council to take care of the inauguration of the new policy among the Student Branches in Group II was $2850. This was later reduced to $2500 by the Finance Committee. Up to June 1 $2007.84 had been expended. This expenditure would have been higher but for the fact that the Branches called for only $262.50 of the $375 which was allotted to them for local operation. The net amount expended by the Society outside of headquarters administration was $469.84. Administration expenses were decreased, in spite of the additional work required because of the installation of the new policy in Group IV.

The estimated enrolment involving 63 Student Branches in the new policy in the next year will be approximately 3000. Therefore the Committee has made a survey upon which it bases its recommendation that *Mechanical Engineering* be included in the new policy to the student paying $3.00 annual dues. The Committee found that this could be done within the funds received on the basis of 3000 Student Members if the advertising pages were omitted. It was the Committee's opinion that the advertising section could be omitted without detriment to the Society's income from advertising, providing a special cover was used on the copies distributed to Student Members. However, the Committee welcomed the cooperation of the Publications Committee, which desires to include the advertising pages. The Committee wishes to point out that if this is done, it should of course build for good-will among our advertisers; and even if it does not warrant an immediate increase in advertising rates, it will at least help to postpone the necessity for reducing advertising rates. Likewise it will accelerate the date when an increase in advertising rates may be made effective, consistent with improvement in the general industrial conditions of the country.

The Committee on Relations with Colleges likewise recommended that there be established a special two-page Student Branch supplement for insertion in the *A.S.M.E. News*. It suggests that this college news insert be printed in sufficient quantity to take care of the student enrolment, plus members of Council, faculty members, and other members of the Society who are especially interested in the progress of the Student Branches and who request it. It is recommended that the supplement be shipped in bulk with the copies of the *News* to each Student Branch Honorary Chairman. In this way no complications will have to be overcome regarding second-class postal regulations.

The Committee was granted a special budget of $9000 for the year 1932–1933 with which to promote the new policy in Groups I, II, and V.

General Conditions. In the 108 Student Branches there were enrolled a total of 4754 students during 1931–1932. These Branches reported a total of 896 meetings, and all meetings held may not have been reported. Local Sections have increased their interest in and support of Student Branch activities and many of them have held special meetings for Student Branch Members and offered prizes for competition within the Student Branches in their respective territories. The increased number of Student Members being transferred to Junior Membership from the colleges in Group IV was such as to nearly balance the total number of applications acted upon by the Membership Committee as compared with last year, as shown in the report of that Committee.

The many benefits accruing to the Student Branch movement because of the extensive visits made during the previous year by President Roy V. Wright, were clearly indicated in the fine manner in which the Student Branches functioned throughout the country.

The Committee wishes to record its appreciation of the intimate interest and cordial support which members of the Council and officers of the Society have given to this very important phase of the Society's activities.

Respectfully submitted,

Maxwell Carson Maxwell, *Chairman*
Donald B. Prentice William L. Abbott
E. F. Church, Jr. Lewis F. Gordon.

EDUCATION AND TRAINING FOR THE INDUSTRIES

Objective. The Committee on Education and Training for the Industries emphasizes the importance of organized instruction within the industry, for foremen and workmen, and the coordination of that training with existing public and private agencies for improving the skill of industrial workers.

Methods. By answering inquiries from individuals and firms, by sending literature, by programs suggested to Local Sections, and by organized discussion at meetings of the Society, the Committee has disseminated information and provoked discussion of means and methods by which better training for workers can be provided. Correct methods save time, materials, and machines.

The papers presented at meetings have had a wide discussion by and circulation to the membership of the Society and to those outside.

Programs. The program presented at the Annual Meeting, December 3, 1931, jointly with the Management Division, included opening remarks by Erik Oberg, representing Roy V. Wright, President of the Society, and two papers, one on "Foreman Training," by U. J. Lupein, of Cheney Brothers, and the other on "Modern Industrial Training," by George Saylor, of the Lunkenheimer Company.

The following program has been prepared for the Annual Meeting, 1932: "Foreman Training in the United States," by E. S. Cowdrick, Standard Oil Company of New Jersey; "The Fundamental Principles of Training in Industry," by G. Guy Via, supervisor of training, Newport News Shipbuilding & Dry Dock Co.; "Survey of Adult Technical Education in the Greater New York Industrial Area," by O. W. Eshbach, Personnel Department, American Telephone & Telegraph Co.

There has been a very satisfactory response to a letter which was sent to each Local Section chairman, giving him information concerning the purposes of the Committee and offering assistance in preparing programs on subjects in the field of training for the industries which were appropriate to the industries in his vicinity.

Respectfully submitted,

R. L. Sackett, *Chairman*
C. F. Bailey John T. Faig
S. S. Edmands Harold S. Falk.

LIBRARY

The Library Committee represents the Society upon the directorate of the Engineering Societies Library, which is owned jointly by this Society, the American Society of Civil Engineers, the American Institute of Mining and Metallurgical Engineers, and the American Institute of Electrical Engineers.

The statistical and fiscal year of the library is the calendar year. This report, therefore, is based upon the operations of 1931.

During that year more than 42,000 members made use of the library. Thirty-six per cent of these were non-visitors, who relied upon the staff to supply the desired information. The number of members visiting the library, and the total number assisted, both exceeded all previous records.

The current year shows continued increase in visitors. It is obvious that many members are employing enforced leisure in professional study and that the professional library is finding, as public libraries are, that it has a useful function in counteracting the depressing influence of unemployment.

Almost eight thousand books were added during 1931, and the collection, now containing more than 145,000 books and pamphlets, is one of the largest engineering libraries in existence.

The income of the Library Board has been barely sufficient to carry on with efficiency the lines of work that have been developed in previous years. New developments which seem desirable must await more favorable times.

The Chairman of the Library Committee, who served as Chairman of the Library Board during 1931, was reelected to that position for 1932.

Respectfully submitted,

Alten S. Miller, *Chairman*
Geo. F. Bateman E. P. Worden
W. M. Keenan Calvin W. Rice.

RESEARCH

Relying, as it does to a great extent, on the support of industry, it was only natural to expect that the Society's research activities should fall off during the past year owing to the business depression. Nevertheless, the receipts and disbursements of the special and joint research committees were only 20 per cent below those of last year, a far better record than was enjoyed by industry as a whole. This record is an indication also of industry's belief in the value of research in poor times as well as in good times.

Financial Record

Receipts from industry and other sources outside the Society have totaled $40,500 during the year, while disbursements were approximately $44,000. The difference was made up from accumulated balances. Of the total contributions received, however, $5,000 came from The Engineering Foundation, the joint agency of the Founder Societies which provides funds for the aid of their research projects. The Society itself spent about $10,000 in administrative and secretarial support of this cooperative research work. The ratio between outside contributions and Society contributions was, therefore, four to one—better than in the previous year.

Some 25 technical societies, trade associations, and government bureaus cooperated with the committees as joint sponsors, financial supporters, and collectors of technical data.

Committee Activity

The special and joint research committees totaled 28 at the end of the year. Two, the Joint Research Committee on Welding of Pressure Vessels and the Special Research Committee on Airplane Vibration with Special Reference to Instruments, completed their work and were discharged. One new committee was set up, with the Society of Automotive Engineers and the A.S.M.E. as joint sponsors, to study combustion in Diesel engine cylinders. A total of 460 men, representative of manufacturers, users, and independent interests, are serving on these committees, 50 per cent of whom are non-members of the Society. It seems fair to say that the value of time spent and traveling expenses incurred by these men in volunteer committee work far exceeds the direct money contributions received by the committees. Forty-four committee meetings were held during the year.

The pressure of business duties unfortunately made it necessary for F. C. Biggert, vice-president, United Engineering & Foundry Co., to resign his membership from the main Research Committee, which supervises the Society's research activities for the Council. G. M. Eaton, director of research, Spang-Chalfant & Co., Inc., and long an active member of the Society, was appointed by President Lauer in Mr. Biggert's place.

Experimental Work

The contributed funds are spent chiefly on experimental work in various institutional laboratories throughout the country. It was necessary to drop only five men from the payrolls during the year, a total of twenty men being maintained on whole or part time at nine laboratories. These are: Bureau of Standards, Washington, D. C., and Columbus, Ohio; Battelle Memorial Institute; Massachusetts Institute of Technology; University of Michigan; University of Illinois; Ohio State University; Union College; and Carnegie Institute of Technology. The additional number of laboratories—university, institutional, and industrial—cooperating with the committees without receiving financial support from them are too numerous to list here. According to a list recently published by the National Research Council, the A.S.M.E. is one of the principal supporters of research fellowships in the research institutions of the United States.

Publications

The progress reports and related papers growing out of the committees' activities covered some 320 pages of *Mechanical Engineering* and the Transactions; a list of these will be found in the appendix to this Report. This material is being bound into a new section of the Transactions called "Research Papers," the publication of which was authorized by the Council during the year. These "Research Papers" will not be distributed to the members of the Society but will be included in the bound volume of Transactions. This collection of papers will, however, be offered for sale under a separate cover as an A.S.M.E. Research Publication. It will take the place of the "A.S.M.E. Research Reports and Papers" which have been published for sale over the past few years.

In addition to this series of Research Papers another research publication was produced under the title "Report of Tests on Steam Equipment for Drilling Rotary-Drilled Oil Wells." This pamphlet reports the result of one committee's work in the oil fields. In addition, the Society published, jointly with the American Society for Testing Materials, the "Symposium on the Effect of Temperature on the Properties of Metals." This volume of 800 pages contains the papers with discussion presented at the Symposium held in Chicago in June, 1931, under the auspices of the Joint A.S.M.E.-A.S.T.M. Research Committee dealing with this problem.

The Bibliography on Riveted Joints has been completed by A. E. R. de Jonge, who has been making an exhaustive search of the literature on the subject during the past three years for the main Research Committee. Some 1350 references have been prepared, most of which have been fully abstracted. Publication is being delayed owing to lack of funds.

Items of current interest on the activities of the various committees have appeared from time to time in the *A.S.M.E. News* and *Mechanical Engineering*.

INTERNATIONAL COOPERATION

Contacts with foreign groups working on similar problems have been maintained and developed further by our committees during the year. This has been accomplished through the exchange of reports, correspondence, and personal visits by individual representatives. The Institution of Mechanical Engineers in Great Britain and the Verein deutscher Ingenieure in Germany act as the coordinators in their respective countries. Recent developments give promise for the setting up of similar contacts with French workers.

SPECIAL AND JOINT COMMITTEE REPORTS

Lubrication. (1)* A. E. Flowers, Chairman. The experimental work on journal bearing problems at the Bureau of Standards was terminated about the middle of January owing to lack of funds. A report on this investigation was presented at the 1931 Annual Meeting by S. A. and T. R. McKee, entitled "Pressure Distribution in Oil Films of Journal Bearings." A paper, "Optimum Conditions in Journal Bearings," by Albert Kingsbury, a member of the Committee, was presented at the same meeting.

The mathematical studies on viscosity at high pressure were completed and the results were published in the *Journal of Rheology*, July, 1932, under the title "High-Pressure Capillary Flow," by M. D. Hersey and G. H. S. Snyder.

Fourteen original papers on lubrication, many of which are out of print or buried in various publications, have been assembled and edited preparatory to republication.

Fluid Meters. (2) R. J. S. Pigott, Chairman. The Committee has progressed with the revision of the fourth and final edition of "Fluid Meters, Part 1, Theory and Application" and the manuscript of Part 3, on "Influence of Installation" is now receiving final review before publication.

Early in the year, a joint committee, composed of members of the Fluid Meters Committee and of a similar committee of the American Gas Association, was organized to harmonize existing values of orifice coefficients. This joint committee sponsored a series of tests at the Ohio State University under the supervision of Prof. S. R. Beitler. The object of these tests was to determine the variation of the coefficient of discharge of sharp-edged concentric orifices with pipe size and for the various types of pressure taps. These tests have been completed and the results are expected to clear up existing discrepancies in the coefficients.

The subcommittee formed in the Mid-Continent area last year to determine the accuracy of existing coefficients and correction factors for the flow of oil through orifice plates, flow nozzles, and venturi tubes at varying temperatures and viscosities has been active during the present year. Equipment amounting in value to approximately $7,000 has been contributed by industry for these tests. This apparatus has been set up at the University of Oklahoma and the experimental investigation will be started in October under the supervision of Prof. W. H. Carson.

Eight committee meetings were held during the year, and the Committee contributed two papers at the Fluid Meters Session which it sponsored at the 1931 Annual Meeting of the Society. These were "A Study of Primary Metering Elements in 3-In. Pipe," by S. R. Beitler, P. Bucher, and T. C. Barnes, Jr., and "Flow of Steam Through Square-Edged Orifices in a 4-In. Line," by W. W. Frymoyer and A. Herschel.

Thermal Properties of Steam. (3) Alex Dow, Chairman. The Third International Steam Tables Conference scheduled to be held in America in September, 1932, was postponed because the economic conditions made it impossible for the foreign cooperating organizations to participate.

Dr. F. G. Keyes, at Massachusetts Institute of Technology, reports that his experimental work on specific volumes is completed and that correlation of results is proceeding satisfactorily.

At the Bureau of Standards, tests have been going on, under the direction of Dr. N. S. Osborne, with a new steel calorimeter in the range between 800 lb per sq in. and the critical point. He is measuring the total heat of the liquid, the latent heat, and the pressure-temperature relationship for saturated steam.

Doctor Osborne has also completed a series of measurements on vapor pressures practically to the critical point and has prepared a report for presentation at the 1932 Annual Meeting. He has correlated his results with the data of Doctor Keyes and those which have been recently reported by the British and German workers, and has paved the way for a further revision of the international skeleton tables.

Five reports were presented by the Committee at the Steam Tables Session which it sponsored at the A.S.M.E. 1931 Annual Meeting. A similar session will be conducted next December.

Owing to the effective appeals of Chairman Dow, industry has continued financial support of this Committee, thus enabling it to carry forward its program without interruption. Nearly $150,000 has been spent on this project to date.

Strength of Gear Teeth. R. E. Flanders, Temporary Chairman. A series of tests on the Lewis Gear Testing Machine, designed by the committee and temporarily located at Massachusetts Institute of Technology, of the surface fatigue limits of gear materials have been conducted throughout the year by Prof. Earle Buckingham. A machine to facilitate the measurement of surface endurance by the use of small rolls as samples instead of gears is now being constructed in one of the cooperating commercial laboratories.

Professor Buckingham is ready to proceed with studies of dynamic loading on helical gears when samples are available. It is contemplated that these tests on helical gears will contribute further data to those recently obtained by a study of spur gears. He is continuing also a further study of the mechanical phases of wear.

Cutting of Metals. (4) F. C. Spencer, Chairman. During the year this Special Research Committee has been reorganized, and is now composed of the chairman, the secretary, and the chairmen of the four subcommittees.

The experimental program on cutting fluids under Prof. O. W. Boston at the University of Michigan has been stopped for lack of funds. A progress report, entitled "Performance of Cutting Fluids in Drilling Various Metals," by O. W. Boston and C. J. Oxford, will be presented at the 1932 Annual Meeting.

The Subcommittee on Metal Cutting Materials has been continuing its study and correlation of data regarding the new cutting alloys secured through answers to a questionnaire. A report on the types of these alloys available and the extent of their application was presented at the 1931 Annual Meeting. The following three papers, dealing with various phases of the subcommittee's program, have been prepared for presentation at the 1932 Annual Meeting: "Effect of Lathe Cutting Conditions on the Hardness of Carbon and Alloy Steels," by T. G. Digges; "Grinding Cemented Tungsten and Tantalum Carbide Tipped Tools Efficiently and Economically," by J. M. Highducheck; and "What Can Be Accomplished With Modern Machine Tools and Cemented Carbide Cutting Tools," by A. A. Merry.

The manuscript of the "Bibliography on Milling," compiled for the Committee at Purdue University by Prof. J. D. Hoffman, has been completed and is now in the hands of the Society for publication. It contains 200 selected and abstracted references covering the period 1904–1931.

A Subcommittee on Metal Cutting Data has been organized, with King Hathaway as chairman, to make accessible to men engaged in machine shop operation reliable data in conveniently usable form as to the proper feeds and speeds of machine tools in the cutting of various metals. This subcommittee, with the assistance of Carl

---

*** See Appendix to this Report.**

Barth, plans to develop a series of practical handbooks covering drilling, milling, engine lathe, planer work, etc. These books will be based upon the ideas advanced by F. W. Taylor in his "Art of Cutting Metals."

Two papers, "The Elements of Milling," by O. W. Boston and C. E. Kraus, and "Tungsten-Carbide and Other Hard Cutting Materials," by Coleman Sellers, 3d, were contributed by the Committee for the Metal Cutting Session sponsored jointly by the Committee and the Machine Shop Practice Division at the 1931 Annual Meeting. The Committee will sponsor, jointly with the same Division, two sessions at the 1932 Annual Meeting; the four papers already mentioned have been prepared for these sessions.

Mechanical Springs. (5) J. R. Townsend, Chairman. The experimental program of the Committee on Mechanical Springs which has been supervised by Prof. M. F. Sayre at Union College has been completed. This study covered the elastic behavior of spring materials. He will submit a proposed new code of design for springs, based on this work, at the 1932 Annual Meeting.

At the Bureau of Standards, Dr. D. J. McAdam, with the assistance of a young engineer whose services were contributed by one of the steel companies, is completing a survey and digest of all available information, published and unpublished, on the fatigue and other mechanical properties of all known spring materials. This work, which was begun for the Committee by Doctor McAdam while at the U. S. Naval Experiment Station at Annapolis, has recently contributed much useful data.

During the year, Prof. J. B. Reynolds, at Lehigh University, has been conducting an investigation to determine the eccentricity effects and stress effects on coiled springs resulting from different types of end restraint.

Several industrial laboratories are cooperating with the Committee in tests of the fatigue life of large size helical springs as affected by the grade or analysis of material, the heat treatment applied, the proportions of the springs, and other critical variables. A similar program on wire springs is under way.

From month to month Dr. W. G. Brombacher has continued to compile and distribute to committee members and financial supporters a bibliography on the current literature on springs.

Reports on the Committee's work were presented at an open meeting of the Committee held during the 1931 Annual Meeting, and there will be further reports at a Mechanical Springs Session during the 1932 Annual Meeting. Four committee meetings have been held during the past year.

Effect of Temperature on the Properties of Metals. (6) (Joint Committee with American Society for Testing Materials.) H. J. French, Chairman. This Committee has been successful in raising 60 per cent of the $20,000 fund needed to support certain special experimental work in institutional laboratories. Accordingly, a research was started at the University of Illinois under the direction of Prof. H. F. Moore to determine the endurance properties of austenitic chromium nickel steels at elevated temperatures. These tests will be coordinated with creep tests being made at the Battelle Memorial Institute under Dr. H. W. Gillette. The purpose of this investigation is to determine whether the limiting stresses, for design purposes, are the fatigue stresses or creep stresses, and to determine the temperature ranges within which these considerations are important. The amount of work being done in the industrial laboratories which are cooperating with the committees on similar studies, has been somewhat reduced because of the business depression. Several useful reports on the results of this cooperative work have, however, been made and were presented at the June meeting of the Committee held in connection with the Annual Meeting of the American Society for Testing Materials.

A plan is in operation by which important articles relating to the effect of temperature on the properties of metals are abstracted regularly and published monthly under a separate heading in the abstract section of *Metals and Alloys.* This provides continuous contact with the progress made in the United States and foreign countries as recorded in the technical literature.

The sponsor societies published in March an 800-page volume containing the papers and discussion presented at the Symposium on Effect of Temperature on the Properties of Metals which was conducted by the Committee during the June, 1931, Annual Meeting of the A.S.T.M.

Condenser Tubes. (7) A. E. White, Chairman. Progress Report No. 5 of the Committee was prepared by Bert Houghton, Vice-Chairman of the Committee, and was presented at the 1931 Annual Meeting. It included results of a comparison of the service life of certain alloys; a report on marine practice embodying the experience of a large steamship company as to the effect of air and other entrained gases on tube corrosion; a discussion of end corrosion; condenser water box and pump design; and some interesting cases of tube failures.

Owing to lack of funds to defray the expenses of an investigator to institute and supervise a field study of condenser tube corrosion, the Committee is attempting to carry on its work by correspondence. To this end a questionnaire has been circulated among the larger power plants throughout the country requesting information regarding the effect of entrained air and other gases in the circulating water, the hydrogen-ion concentration of the water, velocity of the water through the tubes, and the kind of tube material used, so that the effect of these factors upon condenser tube corrosion may be coordinated.

Boiler Feedwater Studies. (8) (Joint Committee with the American Boiler Manufacturers' Association, the American Railway Engineering Association, the American Society for Testing Materials, the American Water Works Association, and the National Electric Light Association.) S. T. Powell, Chairman. The experimental programs initiated last year at the Ohio State University and the University of Michigan have been continued by this Committee with the financial aid of The Engineering Foundation. Prof. C. W. Foulk is conducting the investigation at Ohio State University on priming and foaming of boiler waters, and Prof. A. H. White at the University of Michigan is directing a careful study of all known methods of boiler-water analysis with a view to recommending tests suitable for referee and control purposes. Both investigations are being carried on as research fellowships. Progress reports were presented at the A.S.M.E. 1931 Annual Meeting and also at meetings of some of the other sponsor societies during the year.

The Committee is now laying plans for an experimental study of sodium sulphate solubility equilibria in an effort to throw more light on the general problem of embrittlement.

Boiler Furnace Refractories. W. A. Carter, Chairman. Close to $50,000 has been raised and spent by this Committee during the past seven years. Experimental work has been financed throughout the present year at the U. S. Bureau of Standards Ceramic Station, Columbus, Ohio. The University of Illinois and Battelle Memorial Institute have continued their cooperative programs.

At the University of Illinois laboratory slag tests on a series of eight representative fireclay bricks and six representative coal ashes have been completed under Prof. R. K. Hursh's direction. A new design of the slag testing furnace was developed and the furnace is now being rebuilt.

At the Bureau of Standards laboratory slag tests on a special series of fireclay bricks and two coal ashes to check the results obtained at the University of Illinois have been carried out. Work has steadily progressed also in the development of the equilibrium diagrams for silica, alumina, lime, and iron oxide. T. A. Klinefelter directs the work at this laboratory.

Battelle Memorial Institute brought its laboratory slag test program to a close during the year. Dr. H. E. Simpson reported the results in a paper read before the American Ceramic Society in February, 1932.

Elevators. M. H. Christopherson, Chairman. Tests on elevator safeties were continued at the Bureau of Standards under the Research Fellowship established by the Committee.

Buffer tests, as required by the American Standard Safety Code for Elevators, are now being carried out at the Bureau by the Committee's Research Fellows. The Committee held eight meetings during the year to direct this work. The elevator industry has contributed to date $80,000 to cover the expenses of this investigation.

Worm Gears. Earle Buckingham, Chairman. This study of the nature and influence of contact conditions on capacity and efficiency of worm gear drives has been carried on in cooperating industrial laboratories. Copies of the resulting data are sent the Chairman for study and analysis. Business conditions, however, have retarded the work materially. A special testing machine for worm gears, similar in principle to the Lewis Spur Gear Testing Machine, has been designed by the Chairman and built by a cooperating company, in whose plant it is now in use. This machine will be loaned to the Committee for use by Professor Buckingham at the Massachusetts Institute of Technology when conditions are such that it can be used there to better advantage than in its present location. A mathematical analysis of contact on Hindley worm gears was made during the summer.

Existing Supplies of Hardwoods. The test program at the University of Michigan on sample logs of tropical hardwoods has progressed slowly during the year. There are on hand at the University samples of a total of 46 species of tropical woods obtained from 10 different countries. Work on five of the species has been completed; on seventeen species it is well advanced; while work has been begun on several more. In all, twelve thousand tests and determinations—mechanical and related physical tests and determinations, and moisture content determinations—have been made to date in addition to the extensive task of preparing the test specimens, making and checking the mathematical computations involved, etc.

Prof. W. Kynoch, who is conducting the program under the direction of Prof. D. M. Matthews, estimates that it will take at least two years more to complete the tests with the present limited equipment and personnel.

Strength of Vessels Under External Pressure. W. D. Halsey, Chairman. Proposed methods of computation have been submitted by both T. McL. Jasper of A. O. Smith Corporation, and Commander H. E. Saunders of the U. S. Navy Model Basin, based on their recent experimental work. Comparison is now being made of these two methods and a meeting of the Committee has been called for December, 1932, at which time it is hoped a decision will be reached as to an acceptable method of design for plain cylindrical vessels subject to external pressure.

Absorption of Radiant Heat in Boiler Furnaces. W. J. Wohlenberg, Chairman. The committee is continuing to collect and analyze data available from installed furnaces in the power industry. Sufficient material, however, has not as yet been accumulated to warrant a published report.

Velocity Measurement of Fluid Flow. W. F. Durand, Chairman. An accurate and compact device for adjusting and reading the phase relationship of sound waves in two tubes was constructed by Professors H. E. Hartig and H. B. Wilcox at the University of Minnesota. This will be set up and tested during the next few months.

Measures of Management. (9) W. E. Freeland, Chairman. A report on the Committee's investigation of the problem of selection and replacement of equipment was presented by H. O. Vorlander and F. E. Raymond at the 1931 Annual Meeting under the title "Economic Life of Equipment."

The Committee is cooperating with and sponsoring research projects of merit in the management field, all for the purpose of placing management on a more scientific basis. Some of these projects are (1) cooperation with Prof. R. M. Barnes, University of Iowa, in his study of the ability of experienced time study observers to judge skill and effort of workers, (2) cooperation with Prof. T. H. Brown, Harvard Graduate School of Business Administration, who is undertaking to discover the character of the statistical summaries needed to control various parts of the business enterprise, and to indicate in connection with such summaries how standards of performance might be built up for a particular business, (3) cooperation with Prof. R. C. Davis, Ohio State University, on determination of fundamental considerations underlying the successful development of operating organization and control in any field of business activity; and (4) cooperation with Prof. E. D. Smith, Yale University, in the determination of causes of human problems and other effects of technological developments in industry.

Diesel Fuel Oil Specifications. L. H. Morrison, Chairman. Arrangements have been made with the Submarine Base at New London to carry out a series of tests in an effort to discover the effect of variations in the viscosity and Conradson carbon of fuel oils on the operation of Diesel engines. The work is now under way.

The laboratories of several of the large oil companies have continued their studies of the physical and chemical properties of Diesel fuels in an attempt to discover the characteristics of motor fuel unsatisfactory for engine operation.

C. LeMaistre, director of the British Standards Institution, visited the United States in May and discussed with the Committee the plans of a similar research work under way in Great Britain. Arrangements were made for the exchange of data between the two groups, which it is hoped will lead to international agreement on specifications for fuel oil.

Diesel Fuel Combustion. (Joint Committee with the Society of Automotive Engineers.) O. D. Treiber, Chairman. This Committee is an outgrowth of the Subcommittee on Combustion of the foregoing A.S.M.E. Special Research Committee on Diesel Fuel Oil Specifications. Its purpose is to conduct a study of combustion in a Diesel engine cylinder. Because of business conditions it has not been possible to raise funds from industry to support the experimental work at the Bureau of Standards as originally planned. Several engine builders having suitable experimental equipment are, therefore, undertaking these studies according to a revised plan laid out by the Joint Committee.

Wire Rope. W. H. Fulweiler, Chairman. More than 100 samples of worn rope removed from service have been sent in from the field to the National Bureau of Standards for examination and test according to the program laid out by this Committee. Rope users in all the important fields of wire rope application are cooperating in the collection of samples. The associations of insurance companies, elevator manufacturers, and building owners have been especially active in this direction.

The details of a test program have been decided upon after a careful review of all the suggestions presented by representative rope manufacturers and users, and the tests are now in progress at the Bureau under the direction of H. L. Whittemore. The program calls for a very careful physical examination and tension tests of the rope samples, and an attempt will be made to relate the breaking strength results to the amount of wear and the number of broken wires observed in the samples before the tests. It is hoped by the Committee that a definite relation can thus be established between the number of broken wires and the wear of wire rope and its remaining useful life.

Heavy Duty Anti-Friction Bearings. (10) W. Trinks, Chairman. Experimental work on the strength of roll necks and a study of power requirements of rolling mills, as affected by the use of different types of roll neck bearings, were completed during the year. Progress reports describing this work were distributed to contributors.

A study of the relative suitability of the various types of roll neck bearings for different rolling mill applications, considering load-carrying capacity, rate of wear, coefficient of friction, requirements of lubrication and maintenance, and probable length of life, is under way. A progress report, which is a comparative study of the common types of roll neck bearings with respect to total costs of operation, is nearing completion.

A technical session on Steel Mill Bearings, jointly sponsored by the Committee and the Iron and Steel Division, was held during the 1931 Annual Meeting. At the Annual Meeting this year, a paper, "The Strength of Roll Necks," which has been written by Chairman Trinks and J. H. Hitchcock, Research Associate, will be presented during one of the sessions.

A campaign for funds to permit the completion of the program early in 1933 was successful. Some $7,500 has been contributed by industry to this project, which has been carried on at the Carnegie Institute of Technology.

Removal of Ash as Molten Slag From Powdered-Coal Furnaces. (11) K. M. Irwin, Chairman. Mr. Irwin, mechanical engineer, Philadelphia Electric Company, was elected chairman of this Committee to replace P. B. Rice, who had resigned.

Fluxing tests have been carried on in a large gas furnace at the Bureau of Mines Experimental Station at Pittsburgh, under the direction of P. Nicholls, using ash with iron ore, iron ore and limestone, and salt cake and limestone, respectively, as fluxes. Studies of the fluxing effect of silica, magnesium oxide, and calcium chloride were also made. Further work was undertaken for the Fe_2O_3-CaO diagram to check and better establish the field in the region of the 2650 to 2550 lines. In addition, a study was made of the relationship between fluid temperature and ash cone-fusion temperature.

This year also an extensive investigation was started on the effect of the state of the iron in slag on the flow temperature.

A progress report, "Fluxing of Ashes and Slags as Related to the Slagging Type Furnace," was presented at the session sponsored jointly by the Committee and the Fuels Division at the 1931 Annual Meeting.

Automatic Oil Pipe Line Pumping Stations. W. G. Heltzel, Chairman. Reports have been completed on the relative cost of using Diesel, electric, and gas prime movers in driving an automatic 40,000-barrel, 750-lb pressure, 10-in. main line pumping station. The pioneer station built by the Committee on the Petroleum Exposition Grounds at Tulsa, Okla., in 1930, has been improved upon so much by the oil producers, who became interested in its possibilities, that it is now practically obsolete. This station will be rebuilt on the basis of the experience gained in the field and will be in operation at the time of the next Petroleum Exposition in May, 1933.

Methods and Apparatus for Noise Measurement. W. B. White, Chairman. The activity of this Committee and of several similar groups in other societies developed the need for coordination of these efforts, as far as their standardization aspects were concerned. A Sectional Committee was, therefore, organized during the year under the procedure of the American Standards Association, and will undertake the preparation of standards of terminology, units, scales, and methods of measurements in the field of acoustics. This A.S.M.E. Research Committee is ably represented on the Sectional Committee and will contribute its data through them.

Rotary Drilling of Oil Wells. (12) D. L. Trax, Chairman. The Committee has completed studies and prepared reports on the operating efficiency of both steam equipment and electrical equipment when used in the rotary drilling of oil wells. The steam equipment report has been published by the Society as one of its series of A.S.M.E. Research Publications. Publication of the electric drilling report has been delayed pending a study of the reception accorded the steam drilling report. The Committee is now engaged in the collection of efficiency data on the use of Diesel, gas, and gasoline engines as prime movers.

Critical Pressure Steam Boiler. (13) A. A. Potter, Chairman. Experimental work has been under way throughout the year on the 3500-lb forced circulation steam generator at Purdue University. The papers, "Characteristics of a High-Pressure Series Steam Generator," by A. A. Potter, H. L. Solberg, and G. A. Hawkins, and "Once-Through Series Boiler for 1500 to 5000 Lb Pressure," by H. J. Kerr, presented at the December, 1931, Annual Meeting, describe this boiler and the results of studies completed on the effect upon operating conditions of changes in pressures, temperatures, and air supply with automatic and hand control. A condensing calorimeter designed for the determination of the enthalpy of high-pressure superheated steam has been constructed and calibrated, and fifty tests have been made on steam at pressures between 1900 and 3500 lb per sq in. Studies of flow in parallel circuits and of the friction of steam in pipes at pressures up to 3500 lb and 830 F are also under way. A progress report on this investigation will be presented at the 1932 Annual Meeting.

Respectfully submitted,

W. H. Fulweiler, *Chairman*
A. D. Bailey G. M. Eaton
A. A. Potter D. B. Bullard.

APPENDIX

The papers, reports, and special publications resulting from the work of the committees during the year are listed below. The numbers refer to the committees responsible for them.

(1) "Pressure Distribution in Oil Films of Journal Bearings," by S. A. McKee and T. R. McKee. Research Papers (A.S.M.E. Trans.), RP-54-8
"Optimum Conditions in Journal Bearings," by Albert Kingsbury. Research Papers (A.S.M.E. Trans.), RP-54-7
"High-Pressure Capillary Flow," by M. D. Hersey and G. H. S. Snyder. *Journal of Rheology*, July, 1932
"Lubrication Research of the A.S.M.E.," by A. E. Flowers and M. D. Hersey. *Mechanical Engineering*, April, 1932

(2) "A Study of Primary Metering Elements in 3-In. Pipe," by S. R. Beitler, Paul Bucher, and T. C. Barnes, Jr. Research Papers (A.S.M.E. Trans.), RP-54-3
"Flow of Steam Through Square-Edged Orifices in a 4-In. Line," by W. W. Frymoyer and A. Herschel. Research Papers (A.S.M.E. Trans.), RP-54-6

(3) "Progress in Steam Research:" "Work at the U. S. Bureau of Standards," by N. S. Osborne and H. F. Stimson; "Work at Massachusetts Institute of Technology," Parts 1 and 2, by F. G. Keyes and L. B. Smith; "Other Current Steam Research," by Harvey N. Davis. *Mechanical Engineering*, February, 1932
"A Steam Chart for Second-Law Analysis," by J. H. Keenan. *Mechanical Engineering*, March, 1932

(4) "The Elements of Milling," by O. W. Boston and Charles E. Kraus. Research Papers (A.S.M.E. Trans.), RP-54-4
"Tungsten-Carbide and Other Hard Cutting Materials," by Coleman Sellers, 3d. Research Papers (A.S.M.E. Trans.), RP-54-14

(5) "Design and Investigation of a Spring in Which All Coils Nest Simultaneously," by J. B. Reynolds and O. B. Schier. Research Papers (A.S.M.E. Trans.), RP-54-11

Report of A.S.M.E.-A.S.T.M. Joint Research Committee on Effect of Temperature on Properties of Metals. A.S.T.M. Proceedings, June, 1932

(7) "Corrosion Tests on Condenser Tubes." Progress Report No. 5 of the Special Research Committee on Condenser Tubes. Abstract will appear in *Mechanical Engineering*. Photo-offset

(8) "Foaming and Priming of Boiler Water," by C. W. Foulk. Research Papers (A.S.M.E. Trans.), RP-54-5
"Determination of Carbonate, Hydroxide, and Phosphate in Boiler Waters," by W. C. Schroeder and C. H. Fellows. Research Papers (A.S.M.E. Trans.), RP-54-13
"The SO_4–CO_3 Ratio for the Prevention of Sulphate Boiler Scale," by Everett P. Partridge, W. C. Schroeder, and R. C. Adams, Jr. Research Papers (A.S.M.E. Trans.), RP-54-10

(9) "Economic Life of Equipment," by H. O. Vorlander and F. E. Raymond. Research Papers (A.S.M.E. Trans.), RP-54-2 and Management (A.S.M.E. Trans.), July, 1932

(10) "Application of Tapered Roller Bearings in Merchant-Bar Mills," by S. M. Weckstein. Iron and Steel (A.S.M.E Trans.), April, 1932
"Application of Celoron Bearings to Roll Necks," by Arthur J. Schmitt. Iron and Steel (A.S.M.E. Trans.), April, 1932

(11) "Fluxing of Ashes and Slags as Related to the Slagging Type Furnace," by P. Nicholls and W. T. Reid. Research Papers (A.S.M.E. Trans.), RP-54-9

(12) "Reports of Tests on Steam Equipment for Drilling Rotary-Drilled Oil Wells." Report of the Special Research Committee on Rotary Drilling of Oil Wells. A.S.M.E. Research Publication

(13) "Characteristics of a High-Pressure Series Steam Generator," by A. A. Potter, H. L. Solberg, and G. A. Hawkins. Research Papers (A.S.M.E. Trans.), RP-54-1b
"Once-Through Series Boiler for 1500 to 5000 Lb Pressure," by H. J. Kerr. Research Papers (A.S.M.E. Trans.), RP-54-1a.

STANDARDIZATION

The A.S.M.E. Standardization Committee presents the following as its report for the year October 1, 1931, to October 1, 1932.

Organization

During the past year the Society accepted one joint sponsorship with the Society of Automotive Engineers under the procedure of the American Standards Association for the Standardization of Classification and Designation of Surface Qualities, in March, 1932. The work of organizing this Sectional Committee has been carried forward during the summer in anticipation of a meeting in October. Sixty organizations were invited to appoint official representatives on this Committee and so far twenty-three have made favorable replies.

To date the Society has accepted sponsorship or joint sponsorship for a total of 30 sectional committees under the procedure of the ASA. These sectional committees have subdivided themselves into 253 subcommittees and subgroups in order that the work assigned to them may be carried forward more promptly and effectively. This number includes the organization of three new Technical Committees of the Sectional Committee on the Standardization of Small Tools and Machine Tool Elements. The total number of members of these committees is now 1118, of which 403 are members of the A.S.M.E.

In addition to the 30 sectional committees for which the Society holds sponsorship or joint sponsorship, the A.S.M.E. was represented this year on 29 other committees by 39 of its members.

Eighty-one standards committee meetings were held during this year.

Standards Approved

Four standards were completed under the ASA procedure and published by the Society in pamphlet form within the dates covered by this report. These were:

800-Lb Hydraulic Cast-Iron Pipe Flanges and Flanged Fittings (B16b1-1931)
Rolled Threads for Screw Shells of Electric Sockets and Lamp Bases (C44-1931)
Rotating Air Cylinders and Adapters (B5.5-1932)
Symbols for Mechanics, Structural Engineering, and Testing Materials (Z10a-1932).

In addition to these the following ten standards were completed by the several committees for which the A.S.M.E. holds sponsorship or joint sponsorship. Of these all but the standard for Wrench

Head Bolts and Nuts and Wrench Openings have been approved and submitted to the ASA.

Engineering and Scientific Charts for Lantern Slides
Abbreviations for Scientific and Engineering Terms
Shaft Couplings
Spur Gear Tooth Form (including Composite, Full Depth, and Stub Involute Systems for $14^{1}/_{2}$ deg and 20 deg)
Steel Flanged Fittings and Companion Flanges (revision of 1927 edition with addition of Steel Companion Flanges and Base Fittings)
Wrench Head Bolts and Nuts and Wrench Openings (revision of 1927 edition)
Ball and Roller Bearings (revision of 1930 edition)
Graphical Symbols Used for Electric Power and Wiring
Graphical Symbols Used for Electric Traction including Railway Signaling
Graphical Symbols Used in Radio.

PUBLICITY

The Committee's record for publicity has been maintained. During the year 23 pages of text pertaining to the Society's work in standardization were published in *Mechanical Engineering.* Part of this material was published in the Engineering and Industrial Standardization section of that journal, and the remainder consisted of abstracts of preliminary proposals issued from time to time by the committees. Three thousand and twenty-seven copies of preliminary drafts of proposed standards were distributed within the twelve months to consumer and producer interests and to the technical press.

In an attempt to meet the recommendations made by those who attended the "Standards Luncheon" in New York in December, 1931, who urged in no uncertain terms greater publicity on the accomplishments of their committees, the A.S.M.E. Standardization Committee developed three special display advertisements of three natural groupings of American Standards now available. These advertisements were printed in 2 issues of *Civil Engineering,* 2 issues of *Mining and Metallurgy,* 1 issue of *Industrial and Engineering Chemistry,* 1 issue of the *Journal* of the American Ceramic Society, 2 issues of *Science News Letter,* 4 issues of *Refrigerating Engineering,* 1 issue of *Machinery,* 5 issues of the *Bulletin* of the Heating and Piping Contractors National Association, and 5 issues of *Mechanical Engineering.*

Another effort to increase the knowledge of American Standards has been directed this year toward the vocational schools and high schools having vocational education departments. The Committee was greatly assisted in this by Frank Cushman, chief of the Industrial Education Service of the Federal Board for Vocational Education. In all, something over 400 letters were written to the directors, supervisors, teacher-trainers, principals, and instructors of these schools situated in practically every State of the Union. The responses to these letters so far received have been most enthusiastic and cordial. So it is expected that the coming year will show interesting developments in this direction.

During the brief visit of Charles le Maistre, director of the British Standards Institution, to the United States in May, 1932, the Committee arranged an informal luncheon in his honor which was attended by a number of members of the Society and others interested in national and international standardization. Mr. le Maistre was spending a few weeks in our country following a seven months' visit to Australia, New Zealand, and Canada in connection with an effort to bring about closer cooperation between the activities of the national standardizing bodies in these British Dominions and with the B.S.I. He described in a vivid way some of the experiences of his trip and conveyed the greetings of his Institution.

SECTIONAL COMMITTEE AND SUBCOMMITTEE REPORTS

Shafting. C. M. Chapman, Chairman. The Sectional Committee on Standardization of Shafting has been active during this past year in completing a revision of the several standards on shafting and keys developed by it and approved some years ago. The Committee held two meetings in October and November, 1931, at which the work of revision was concluded with the exception of a few controversial points. Through a questionnaire sent out to industry these questions have been settled and the revision is now ready for final approval by the Committee membership. Immediately upon its release the proposal will be submitted to the sponsor and the American Standards Association for approval and adoption.

Allowances and Tolerances for Cylindrical Parts and Limit Gages. E. J. Kearney, Chairman. The past year has been one of preparation for the Sectional Committee on Allowances and Tolerances for Cylindrical Parts and Limit Gages. At its second meeting in December, 1931, the Chairman was instructed to appoint a subcommittee to consider the basic hole, basic shaft, and G M systems of allowances and tolerances and to prepare a preliminary draft proposal for review and study by the members of the Sectional Committee. The Chairman of this Subcommittee is R. E. W. Harrison, and his colleagues are F. E. Banfield, F. O. Hoagland, J. O. Johnson, P. V. Miller, D. W. Ovaitt, E. Pugsley, and H. L. Van Keuren.

At this meeting the proposal submitted by the International Standards Association's Technical Committee on Fits, copies of which had been mailed to the membership in July, 1931, was referred to the Subcommittee for study. The paper, in which this proposal was described and interpreted, had been prepared by John Gaillard of the staff of the American Standards Association. It was printed in the July, 1931, issue of the ASA Bulletin and the August, 1931, issue of *Mechanical Engineering.*

In the December, 1931, issue of the ASA Bulletin, H. W. Bearce, a member of the Sectional Committee, published an article bearing on a phase of the Committee's work. It is entitled "Unilateral and Bilateral Tolerances for Machine Parts and Gages."

During the year Chairman Harrison has organized the work of his Subcommittee by correspondence and completed a definite outline of its scope. This outline, including a statement of policy set up by the Subcommittee, was published in the October issue of *Mechanical Engineering* and the October issue of the ASA Bulletin.

Ball and Roller Bearings. F. W. Gurney, Chairman. Slight revisions and extensions of the American Standard for Ball and Roller Bearings (B3-1930) were completed by the Sectional Committee and finally approved at its meeting held in New York on May 11, 1932. These proposed changes and additions were approved by the two sponsor organizations, the S.A.E. in June, 1932, and the A.S.M.E. in August. The revised standard is now before the ASA for review.

At its May meeting the Committee gave consideration also to a proposal for a series of standard taper roller bearings (dated March, 1932) which had been submitted as the American proposal for an international standard. It was decided to take no further action toward the development of an American Standard until the results of the International Conference on Ball and Roller Bearings held in Milan, Italy, in June, 1932, were known. The Committee was represented at the Conference by E. Wooler, one of its members.

Some progress has been made also during the year by the Committee in the development of standard nomenclature for ball and roller bearings.

Gears. B. F. Waterman, Chairman. In July, 1932, the Sectional Committee on the Standardization of Gears gave its approval to the proposed American Standard for Spur Gear Tooth Form, $14^{1}/_{2}$-deg and 20-deg Full Depth Involute System. This new standard then received the approval of the A.G.M.A. and the A.S.M.E. in their capacities as joint sponsors. Consequently, the standard is now before the ASA for approval. When published the Committee plans to combine this standard with the present American Standard for Spur Gear Tooth Form, $14^{1}/_{2}$-deg Composite System and 20-deg Stub Involute System (B6b-1927).

The proposed American Recommended Practice on Gear Materials and Blanks of Alloy Steel, Cast Steel, Forged and Rolled Carbon Steel, also Bronze and Brass, has just been released by the Subcommittee and is now ready for vote on approval by the Sectional Committee.

Copies of an A.G.M.A. Recommended Practice on Inspection of Gears were sent in August to the members of the Subcommittee at work on this phase of the project as a basis for its preliminary report.

Pipe Flanges and Fittings. C. P. Bliss, Chairman. The Sectional Committee on Pipe Flanges and Fittings held a meeting in April, 1932, to pass upon the proposed American Standard for Steel Flanged Fittings and Companion Flanges. This proposal is a revision and amplification of the present American Tentative Standard for Steel Pipe Flanges and Flanged Fittings (B16e-1927) and is the result of a great deal of painstaking work and cooperation on the part of the membership of Subcommittee No. 3 on Steel Flanges and Flanged Fittings. In July this revised standard was approved by letter ballot of the Sectional Committee. It has been since approved by the three sponsor organizations and transmitted to the American Standards Association.

In addition, the proposed American Standard for 800-lb (Hydraulic) Cast-Iron Flanged Fittings developed by Subcommittee No. 1, A. M. Houser, Chairman, and approved by the Sectional Committee last year, was granted the designation of American Standard in December, 1931, by the American Standards Association.

At the April meeting of the Sectional Committee the proposed standard for Screwed Pipe Plugs developed by Subcommittee No. 2 on Screwed Fittings, Stanley G. Flagg, Chairman, was also discussed and it also was approved subsequently by letter ballot.

Three other projects have been advanced considerably during the past year but are not yet ready for final approval. These are (1) the proposed standard for welding flanges under development by Subcommittee No. 3, (2) a proposed standard series of face-to-face dimensions for ferrous flanged valves being developed by Subcommittee No. 5, of which F. H. Morehead is Chairman, and (3) a revision of the port openings of the 125-lb Cast-Iron Flanged Fittings in sizes 14 to 24 inches, which was assigned to Subcommittee No. 9, with W. W. Hubbard as Chairman.

Bolt, Nut, and Rivet Proportions. A. E. Norton, Chairman. An extensive revision of the American Tentative Standard for Wrench Head Bolts and Nuts and Wrench Openings was approved by letter ballot of the Sectional Committee on Bolt, Nut, and Rivet Proportions in July, 1932. This revision was undertaken by Subcommittee No. 2, H. A. Spanagel, Chairman, and includes the addition of a heavy series of bolt heads and nuts and the extension and revision of the existing regular and light series. Subcommittee No. 2 held two meetings during the year, one in December, 1931, and the second in April, 1932. The revised standard, as approved by the Sectional Committee, was submitted to the sponsor organizations in September, 1932, and upon release will be transmitted to the ASA for approval and designation as an American Standard.

Subcommittee No. 1 on Large and Small Rivets, J. E. Kiernan, Chairman, met in April of this year to review the tentative draft of the standard for Large Rivets in the light of a number of objections which had been received from the manufacturers. At this meeting certain changes in the proposed head designs were agreed upon and the tolerances were modified to meet commercial requirements. Agreement on all outstanding points was reached at that time and a revised draft has been prepared and will be distributed shortly to the Subcommittee members for their final approval prior to a redistribution to industry for comment.

The proposed standard for Socket Type Set and Cap Screws prepared by Subcommittee No. 9, of which H. Koester is Chairman, should be available in October, 1932, for distribution to industry for comment. While this Committee has held no meetings during the year, its work has progressed very satisfactorily by correspondence. In January, 1932, a tentative draft of the standard based on the Committee's previous deliberations was distributed to the membership for criticism. The suggestions received were summarized by Chairman Koester and a second draft prepared.

Small Tools and Machine Tool Elements. C. W. Spicer, Chairman. At its December 2, 1931, meeting the Sectional Committee on Small Tools and Machine Tool Elements approved the appointment of three new technical committees to develop standards for rotating tool shanks, nomenclature for small tools and machine tool elements, and multiple spindle drilling heads. These committees have since been organized and the progress made in each case is detailed later. The proposed Standard for Rotating Air Cylinders and Adapters was approved by the Sectional Committee in January, 1932.

Technical Committee on T-Slots. E. Oberg, Chairman. Technical Committee No. 1 had its Standard for T-Slots, Their Bolts, Nuts, Tongues, and Cutters approved in March, 1927. Early in this year one of the large manufacturers of milling machines submitted to the Committee a suggestion that the depth of engagement of the present standard tongue be increased. The Committee held a meeting in December, 1931, to discuss this point and J. B. Armitage was appointed a committee of one to make some tests and to submit drawings to other members of the committee for their consideration with the view of making any necessary changes in the present standard.

Technical Committee on Machine Tapers. F. S. Blackall, Jr., Chairman. Mr. Blackall was appointed Chairman of this Technical Committee in February, 1932, upon the resignation of E. F. DuBrul. The Committee held a meeting in April, 1932, at which the report of its Subgroup on Dimensions, Tolerances, and Gages was received by the Technical Committee. After a full discussion, however, the proposed standard tables of dimensions of a series of small angle tapers was laid on the table for the present, and it was moved that this subgroup be relieved from further consideration of this subject and discharged. Then a subgroup was appointed to develop a proposal for an American Standard steep taper with a hold-back device.

Technical Committee on Spindle Noses and Collets. J. E. Lovely, Chairman. Up to December, 1931, E. F. DuBrul served as Chairman of this Technical Committee. Upon his resignation a new chairman in the person of J. E. Lovely was appointed. The Technical Committee's progress is dependent upon the work of Subgroup No. 8 which has held several meetings during the past year and has called a meeting for October 9, 1932. This Subgroup has been testing out a newly designed spindle nose before releasing it to industry as a proposed standard for criticism and comment.

Technical Committee on Designation and Working Ranges of Machine Tools. B. S. Dayton, Chairman. In May, 1932, B. S. Dayton was appointed chairman of the Technical Committee upon the resignation of E. F. DuBrul. No progress has been reported by this committee since its meeting in October, 1930.

Technical Committee on Twist Drill Sizes. C. J. Oxford, Chairman. While this Committee has held no meetings during the current year, through the efforts of C. W. Spicer, Chairman of the Sectional Committee, considerable progress has been made toward the acceptance of the principles on which the Technical Committee based its proposal last year.

Technical Committee on Drill Bushings. C. E. Rundorff, Chairman. The Committee's efforts to complete its proposal for an American Standard for Drill Bushings have been unsuccessful because of the absence of certain authentic data. It has been decided, accordingly, to distribute a tentative proposal to industry for comment on these points, the principal one of which is the determination of the proper values for the hole tolerances.

Technical Committee on Punch and Die Sets. S. Diamant, Chairman. A meeting of Technical Committee No. 9 on Punch and Die Sets was held in November, 1931. At this meeting the Committee authorized the consolidation of the data before it into a tentative proposal in the form of tables for distribution to industry for criticism and comment. Under the direction of the Chairman such a draft proposal was prepared. It includes introductory notes, cuts, and tabulated dimensions for the five types of punch and die sets and details of the holding clamps. In June, 1932, copies of this proposed standard, together with a questionnaire, were mailed to approximately 600 manufacturers and users of this type of equipment for study and comment. Replies of a constructive nature have been received from more than 35 per cent of those to whom the proposal was sent. The comments and suggestions contained in these replies will form the basis of the revision of the first tentative draft which will be reviewed by the Committee at its next meeting.

Technical Committee on Circular Forming Tools and Holders. W. C. Mueller, Chairman. The replies received to the questionnaire sent out in July, 1931, were analyzed and thoroughly discussed at the December, 1931, meeting of the Committee held in New York. During the remaining months of the year this project has been further developed by correspondence among the members of the Technical Committee.

Technical Committee on Chucks and Chuck Jaws. J. E. Lovely, Chairman. Two proposed standards have been developed by Technical Committee No. 11, one for Rotating Air Cylinders and Adapters and the other for Chucks and Chuck Jaws. The first of these was approved in September, 1932, as American Standard by the ASA. A meeting of the Committee was held in December, 1931. The progress toward the completion of the proposal for chucks and chuck jaws has been dependent upon the studies and decisions of Technical Committee No. 4 on Spindle Noses and Collets. While considerable progress has been made toward the development of standard designs for spindle noses and chucks, certain refinements and adjustments are still necessary.

Technical Committee on Cut and Ground Thread Taps. C. M. Pond, Chairman. Since the approval of the American Standard for Cut and Ground Thread Taps in April, 1930, and its adoption by industry, the desirability of reducing the overall length and thread length of hand taps has been raised. Accordingly, in January, 1932, a canvass was made, the results of which have been sent to the members of the Committee by the Chairman for study.

During the year the Committee has developed also standard dimensions for pulley taps, tapper taps (machine screw size), bent shank tapper taps (cut and ground thread), and taper and straight pipe taps which will be submitted for approval as American Standards. These tables constitute a supplement to the 1930 standard.

Technical Committee on Splines and Splined Shafts. C. W. Spicer, Chairman. The type of splines which is preferred by industry in general has been undergoing a change during the past few years. For this reason the Committee has decided to mark time for the present until this situation has cleared.

Technical Committee on Milling Machine Tables. G. A. Bouvier, Chairman. This Committee decided at its meeting in December, 1931, to concentrate its efforts upon standards for slot spacing for the five different ranges of table widths. A tentative draft proposal for standard knee type milling machine tables in line with the discussion at the December meeting are now before the Committee members for study and comment.

Technical Committee on Rotating Tool Shanks. E. J. Bryant, Chairman. The first meeting of this Committee was held in April, 1932, at which three subgroups were appointed to develop the sections on (*a*) drill reamers and tap shanks, diameters and squares; (*b*) bit brace shanks; and (*c*) shanks on socket wrenches with driven nuts and screw driver shanks for rotating drivers. To carry this program forward adequately an increase in the size of the Committee seemed necessary. This has been accomplished during the year and these subgroups are at work drafting the three sections of the tentative proposal.

Technical Committee on Nomenclature for Small Tools and Machine Tool Elements. H. E. Harris, Chairman. This Committee, authorized at the December, 1931, meeting of the Sectional Committee, has held two meetings, one in February and the other in April, at which two subgroups were appointed to develop standard nomenclature for all types of small tools and machine tool elements. The Subgroup for Lathe and Planer Tools has already submitted a tentative list of terms and definitions.

Technical Committee on Multiple Spindle Drilling Heads. G. A. Bouvier, Chairman. One of the three technical committees authorized at the December, 1931, meeting of the Sectional Committee was the Technical Committee on Multiple Spindle Drilling Heads. Its first meeting was held in April, 1932, at which time a tentative program for work was proposed and adopted.

Scientific and Engineering Symbols and Abbreviations. J. F. Meyer, Chairman. During the year five standards have been completed and approved by the Sectional Committee on Scientific and Engineering Symbols and Abbreviations.

The first of these, Symbols for Mechanics, Structural Engineering and Testing Materials, was approved by the ASA in January, 1932, and was subsequently published in pamphlet form.

The proposed American Tentative Standard, Abbreviations for Engineering and Scientific Terms, was transmitted to the ASA by the five sponsor bodies in June, 1932. However, action by that Association has been delayed pending the approval of some minor changes and additions to the standard which the Committee has been requested to make.

The remaining three standards, Graphical Symbols Used for Electric Power and Wiring, Graphical Symbols Used in Radio, and Graphical Symbols Used for Electric Traction Including Railway Signaling, were presented in July, 1932, to the ASA for final approval. It is expected that approval by this body will be completed in a few weeks.

Plain and Lock Washers. C. W. Squier, Chairman. A meeting of the Sectional Committee on the Standardization of Plain and Lock Washers was held in October, 1931, at which time the revision of the personnel of the Committee was discussed and the addition of six members representing the manufacturers was approved. The tentative proposal of the Subcommittee on Lock Washers developed under the chairmanship of C. H. Loutrel was approved for distribution to industry for criticism and comment. This was done in December, 1931, and the Subcommittee met in April, 1932, to consider the criticisms and comments which had been received. At this meeting it was decided to include with the new series recommended in December the three series of the S.A.E. standard. A redraft of the proposal on this basis is now in progress.

In order to further the work of drafting a preliminary proposal for a standard on plain washers Chairman Squier was authorized at the October, 1931, meeting of the Sectional Committee to appoint a temporary chairman of Subcommittee No. 1 with instructions to develop a proposal with all possible speed. Some progress in this direction has been made.

Code for Pressure Piping. E. B. Ricketts, Chairman. The Editing Committee has reviewed the parts of the proposed American Standard Code for Pressure Piping dealing with (*a*) power piping, (*b*) district heating piping, and (*c*) fabrication details, including hangers, welded joints, and joints other than welded. The Sectional Committee met in December, 1931, and again in April, 1932. On both of these occasions several of the subcommittees also held meetings. A. Iddles, Chairman of the Subcommittee on Gas and Air Piping, has been developing this section of the Code in close coöperation with the group in the American Gas Association specially interested in the transportation of natural gas. It is now anticipated that this part of the Code will be completed very shortly. The part dealing with oil piping, which was prepared by a Subcommittee of which A. D. Sanderson is Chairman, was reported completed at the April meeting.

Drawings and Drafting Room Practice. F. DeR. Furman, Chairman. A meeting of the Editing Committee of the Sectional Committee on Drawings and Drafting Room Practice was held in New York in December, 1931. This Editing Committee is now at work on the unification of the reports of the several subcommittees covering specifications for paper and cloth, method of indicating dimensions, lettering, layout, line work, and graphical symbols.

Subcommittee No. 6, of which T. E. French is Chairman, distributed to industry for criticism and comment a proposal covering Graphical Symbols for Drawings in July, 1932. This proposal includes sets of symbols for plumbing fixtures, conventional rivet layouts, heat power apparatus, electric power apparatus, pipe and pipe fittings, and heating and ventilating layouts. Letters of criticism and comment are still being received as a result of the distribution of approximately 500 copies of this preliminary report.

Graphic Presentation. E. F. DuBrul, Chairman. The most tangible result of the work of the Sectional Committee on Graphic Presentation during the past year was the completion of the monograph on Engineering and Scientific Charts for Lantern Slides. This proposal originated in the Subcommittee on Engineering and Scientific Charts, of which W. A. Shewhart is Chairman. The original draft was formulated by a subgroup consisting of H. F. Dodge, C. D. Hanscom, and L. Stone. One of the early drafts was discussed at an open meeting of the Committee held in New York on December 3, 1931. The final draft after approval by the members of the Sectional Committee and the sponsor society was transmitted to the ASA on August 24, 1932.

The joint subcommittee, of which A. H. Richardson is chairman, has continued its work during the year and now expects to submit a draft of the proposal for preferred practice in graphic presentation in the very near future.

Pipe Threads. E. M. Herr, Chairman. The Sectional Committee on Standardization of Pipe Threads has been engaged for the past few years in a revision of the American Standard for Pipe Threads (B2-1919). Subcommittee No. 2 on Taper Pipe Threads, under the chairmanship of S. B. Terry, has, with the exception of one point, completed its revision of the taper thread specifications. This year, of the pipe thread group of committees, Subcommittee No. 2 met in December, 1931, and agreed upon the few points then in question, but decided to postpone final approval of the revised proposal until the proposed inclusion of limit gages had received the vote of the entire Subcommittee membership. This vote was taken and indicates unanimous approval of the addition of the alternative design of gage. Since completion of the revision of the Taper Pipe Thread Standard as authorized at the December meeting, however, the Chairman has made a further effort to bring the A.P.I. and American Standard thread lengths into closer agreement. Release of the revised standard for review by industry and the members of the Sectional Committee will be withheld in consequence of this action until a definite agreement on the question of thread lengths can be reached within the Subcommittee membership.

Wrought Iron and Wrought Steel Pipe and Tubing. H. H. Morgan, Chairman. In June, 1932, a meeting of the Sectional Committee on Wrought Iron and Wrought Steel Pipe and Tubing was held during the A.S.T.M. Annual Convention at Atlantic City. This meeting received a joint report prepared by Subcommittee No. 2 on Pipe and Tubing for Low Temperature Service, J. J. Shuman, Chairman, and Subcommittee No. 3 on Pipe and Tubing for High Temperature Service, J. R. Tanner, Chairman. This report, dated June, 1932, was in the nature of a tentative proposal which had resulted from the agreements reached in the discussion during the December, 1931, joint meeting of these committees in New York.

This report was thoroughly discussed by those present at the June, 1932, meeting and the Subcommittees were requested to prepare and distribute for general criticism and comment a proposed standard schedule of pipe sizes and thicknesses. This proposal will be ready for review shortly.

Speeds of Machinery. A. E. Hall, Temporary Chairman. The Subcommittee on Questionnaire and Canvass to Industry under the Chairmanship of F. S. English reviewed and correlated the replies received to its inquiry sent out in March, 1931, and met in October to discuss the content of its first tentative proposal. This proposal in revised form was reviewed by Subcommittee No. 1 at a meeting held in December, 1931, and a new series of speed numbers was developed which has since undergone slight modifications as the result of correspondence.

Screw Threads for Hose Couplings. H. W. Bearce, Chairman. Two meetings of the Sectional Committee on Screw Threads for Hose Couplings were held during the year in New York, the first on December 2, 1931, and the second on April 22, 1932. The Committee is now preparing a revision of its draft standard, dated March, 1932, on which it expects to take final action at a meeting scheduled for the week of October 17, 1932.

Plumbing Equipment. W. C. Groeniger, Chairman. While the Sectional Committee on Plumbing Equipment has held no meetings this year, its eight subcommittees have been at work and have made some progress.

A report has been received from A. R. McGonegal, Chairman of the Subcommittee on Traps, to the effect that the work on the proposed standard for brass lavatory and sink traps, brass traps, lead traps, vitreous china traps and interceptors, catch basins, and miscellaneous traps has been completed. The work on a draft proposal for cast-iron traps has yet to be formulated.

At the October, 1931, meeting of the Subcommittee on Brass Plumbing Products, of which J. L. Murphy is Chairman, it was voted to drop the work on water works brass goods and brass valves. Two new subgroups were appointed at this meeting to develop proposals for (*a*) minimum requirements for brass alloys used in the manufacture of brass plumbing products and (*b*) roughing-in dimensions. The proposal of the Subgroup on Compression Cocks, Washer Screws, Faucets and Tail Piece Parts, L. A. Cornelius, Chairman, was approved for distribution to industry for criticism. R. H. Zinkil, Chairman of the Subgroup on Fixture Connections and Fixture Valves, Waste Holes, Plugs and Connections, Overflows, reported completion of this group's recommendations and a progress report was received from R. L. Ottke on Nomenclature.

In January, 1932, Subcommittee No. 7 on Copper Water Tube Fittings, F. L. Riggin, Chairman, met to discuss the comments received on the October, 1930, draft of its proposed Standard for Brass Fittings for Flared Copper Tubes distributed to industry in February, 1931. Certain changes were made in the proposal and new printer's proofs were prepared for final review by the members of the Subcommittee prior to submittal to the Sectional Committee for approval.

Four meetings have been held by Subcommittee No. 8 on Cast Iron Soil Pipe and Fittings, J. J. Crotty, Chairman, during the year. The discussion at the first three meetings related to the standard for cast-iron fittings. At the September, 1932, meeting the Committee made a careful study of wall thicknesses of soil pipe. In order that it may complete its work without further delay the committee plans to meet every two weeks this fall.

Standardization and Unification of Screw Threads. R. E. Flanders, Chairman. The Sectional Committee on Screw Threads held a meeting in April, 1932, at which the progress made by the several subcommittees to date was carefully reviewed. One of the principal items on the agenda was the report of the Subgroup on Screw Thread Survey of the United States. At the request of this Subgroup D. R. Miller and I. H. Fullmer of the Gage Section of the Bureau of Standards had been invited to attend this meeting and made a complete report on the measurement of the screws and a preliminary report on the nuts. A summary of this report prepared by Earle Buckingham, a member of the Subgroup, was published in the September, 1932, issue of *Mechanical Engineering* and the October issue of the S.A.E. *Journal*. A complete and detailed report is in preparation which will be published in pamphlet form for general distribution. The Sectional Committee plans a revision of the present American National Standard for Screw Threads based on the final results of the survey as set forth in this report. All fundamental changes will, of course, be made with the full knowledge and cooperation of the National Screw Thread Commission.

At this meeting, also, recommendations were received regarding the adoption of three special pitch series, 8, 12, and 16 threads per inch, to replace the fine thread series above 1$^1/_2$ inch diameter.

Subcommittees Nos. 2, 3, and 5 held a joint meeting with R. E. Flanders as Acting Chairman the day following that of the Sectional Committee. At this meeting it was agreed to include the 8, 12, and 16 pitch series in their recommendations to meet certain well defined industrial needs. Certain other phases of the subject, including a report on minor diameters of nuts by E. H. Ehrman and the possibility of revising to some extent the tolerances prescribed by the four classes of fit, were considered. It is expected that definite action will be taken on these points as soon as the several Subcommittees concerned have had an opportunity to review the final report of the Screw Thread Survey. Subcommittee No. 4, of which Earle Buckingham is Chairman, has been active during the year in preparing a preliminary proposal on acme threads. At a meeting held in April a report prepared by C. W. Bettcher was adopted as the basis for discussion of this proposal and it was decided to include specifications for four classes of acme threads, namely, general purpose, fine threads, 29-deg stub threads, and 60-deg stub threads. The immediate activities of the Committee are being directed toward the development of the general purpose type and a subgroup of three members has been appointed to expedite this department of the work.

Rolled Threads for Screw Shells of Electric Sockets and Lamp Bases. R. E. Myers, Chairman. The American Standard for Rolled Threads for Screw Shells of Electric Sockets and Lamp Bases was approved by the ASA and published in final pamphlet form in December, 1931. The personnel of the Sectional Committee is identical with that of the U. S. National Committee, Advisory Committee No. 6, Lamp Caps and Holders, of the International Electrotechnical Commission. Close touch with developments in the international field is accordingly maintained.

Stock Sizes, Shapes and Lengths for Hot and Cold Finished Iron and Steel Bars. F. H. Frankland, Temporary Chairman. There has been no occasion for activity on the part of this Sectional Committee, as the work of none of its three Subcommittees is as yet ready for release. However, Subcommittee No. 2 on Cold Finished Steels, L. E. Creighton, Chairman, held a meeting in New York in October, 1931. This Committee is cooperating closely with the Cold Finished Steel Bar Institute in the preparation of this part of the proposal for an American Standard and, although nothing of a tangible nature has been released, it is expected that a preliminary report will be presented within a reasonable time.

Pressure and Vacuum Gages. M. D. Engle, Chairman. The Subcommittee on Definitions, C. H. Schwep, Chairman, issued a questionnaire in December, 1931, and from the replies received a list of definitions was developed which the Subcommittee revised at its meeting held in New York on April 22, 1932. Copies of the revised list of definitions have been sent out to industry for criticism and comment.

During the month of August this Subcommittee also distributed to a number of manufacturers for critical review copies of a proposed specification form and proposed rules for installation and use of pressure and vacuum gages.

The Subcommittee at work on setting up gage and mounting dimensions, H. B. Reynolds, Chairman, held a meeting in New York on October 23, 1931, and the Subcommittee on Accuracy and Test Methods, O. J. Hodge, Chairman, met on December 3, 1931. Both of these Committees are making progress in the development of their preliminary proposals.

Foundry Equipment and Supplies. E. S. Carman, Chairman. The rounding out of the personnel of the Sectional Committee on Foundry Equipment and Supplies entailed a considerable amount of correspondence during the early part of the year. Good progress was made in this direction, however, with the result that the personnel of three subcommittees were named in April, 1932. Efforts were made to hold organization meetings of these subcommittees during the convention of the American Foundrymen's Association, joint sponsor for this project, in Detroit, in May, 1932, but this proved inadvisable because of prevailing economic conditions. Subcommittee No. 1, with LeR. M. Sherwin as Chairman, reports that a considerable amount of progress has been made in the development of its work by correspondence.

An A.F.A. recommended practice for colors of foundry patterns in wood was presented in August, 1932, by that association to the ASA for approval and recognition as an American Recommended Practice. This designation was granted the following month. Pattern markings are included within the scope of this Sectional Committee, so future revisions of this Recommended Practice will be undertaken by it.

Leather Belting. The Chairmanship of the Sectional Committee on Leather Belting is temporarily vacant due to the death of the former Chairman, J. C. Mattern, which is sincerely regretted by the members of the Committee. At the next meeting a successor to this office will be elected. Subcommittee No. 1 on Specifications, with R. C. Bowker, Chairman, held a meeting in November, 1931, at which a general outline of the specifications for leather belting was agreed upon. In accordance with this action the Chairman prepared a preliminary draft of the proposed standard specifications which, on May 26, 1932, was distributed to the Committee members for criticism and comment. On the basis of these comments the draft is being revised prior to distribution to industry for review. During the past year Subcommittee No. 2 on Recommendations for Selection, Care, and Installation, G. A. Schieren, Chairman, has been active in compiling data for inclusion in its recommended practice. This part of the work, it is anticipated, will be ready for submission to the members of the Sectional Committee at an early date.

Classification and Designation of Surface Qualities. The sponsorship for this project was accepted by the Society of Automotive Engineers and the A.S.M.E. in March, 1932. The scope of this project is intended to include standards of quality of finish for machined surfaces, ground surfaces, methods of inspection for the quality grades standardized, and designations of quality grades for use in specifications and on drawings.

A.S.M.E. Committee on Shaft Couplings. D. J. McCormick, Chairman. The proposed American Standard for Shaft Couplings, which had been distributed to industry for comment in the summer of 1931 and published in the October, 1931, issue of *Mechanical Engineering*, was revised in line with the comments received and finally approved by the Committee late in November. In February, 1932, this proposal received the approval of the A.S.M.E. Standardization Committee and in the following April it was approved and adopted by the A.S.M.E. Council as an A.S.M.E. Standard. Immediately upon ratification by the Council the proposal was transmitted to the ASA for approval and designation as an American Standard under the "proprietary standards" method. It was found, however, upon investigation by the ASA, that certain interested organizations were opposed to approval under the "proprietary standards" method in this instance, and the "existing standards" method was offered as a substitute. After carefully weighing all considerations bearing on the case, the Society indicated its willingness to concede this point. As no objections of a technical nature are anticipated, it is expected that the standard for Shaft Couplings will receive the approval of the ASA and designation as an American Standard within the coming month.

Development of Applications for Statistics in Engineering and Manufacturing. W. A. Shewhart, Chairman. In the early part of this year the Chairman of this Joint Committee was invited to give a series of three lectures at the University of London on the role of statistical method in economic industrial standardization. These lectures were delivered in London in May, 1932. While abroad Dr. Shewhart visited several of the industrial laboratories and plants in Great Britain and Germany where work of this character is under way. Arrangements were made also through the sponsor societies and the American Standards Association for him to discuss the work of the committee with the officers of some of the engineering societies in these countries. While in England he had the privilege of attending a round table conference called under the auspices of the British Standards Institution and similar in character to the one held in New York in December, 1929, by the sponsor societies of the U. S. Committee. At the British conference a resolution was passed organizing a committee under the chairmanship of B. H. Wilsdon, of the British Government Building Research Laboratories, to consider undertaking the development of applications of statistical method in engineering and to cooperate with our committee in this effort. While he was in Germany a similar round table conference was called by the president of the Deutscher Normenausschuss which resulted in the formation of a committee under the chairmanship of Dr. W. Hellmich, Managing Director of the Normenausschuss and Co-Director of the Verein deutscher Ingenieure, as chairman, with much the same objective as the British and American committees.

The United States Joint Committee plans to serve in every way possible as a clearing house of information and in particular to issue, from time to time, reports in the columns of the journals of the A.M.S., the ASA, the A.S.T.M., and the A.S.M.E., the sponsor societies, calling attention to the progress that has been made in this particular field. It plans also to cooperate with (*a*) other committees representing societies and industries in America, such as that of the American Society for Testing Materials, on the interpretation and presentation of data, and (*b*) the general committees referred to in this report sponsored by the British Standards Institution and the Deutscher Normenausschuss.

Respectfully submitted,

LEWIS K. SILLCOX, *Chairman*
WILLIAM S. MONROE CLARENCE W. SPICER
EARLE BUCKINGHAM ALFRED IDDLES.

SAFETY

Throughout the year the standing committee on Safety has continued to arrange for joint safety sessions with the A.S.M.E. Professional Divisions when desired, to promote the development of safety codes, and to continue cooperation with the American Society of Safety Engineers, the engineering division of the National Safety Council.

Safety Education. During the December, 1931, meeting of the Committee instruction in industrial safety in trade schools and colleges was discussed at length. This discussion resulted in the appointment of W. M. Graff as a committee of one to cooperate with the committee of six, Prof. J. W. Hallock, Chairman, appointed by the Society for the Promotion of Engineering Education and W. Dean Keefer, Secretary of the National Safety Council. Contact was made with the S.P.E.E. Committee through one of its members, J. P. Jackson, a former chairman of the A.S.M.E. Standing Committee. As a direct result of these conferences a group of suggestions to college deans and professors concerning courses of study was incorporated in the report of the S.P.E.E. Committee.

Aircraft Safety. A special committee appointed to develop recommendations for aircraft safety and inspection distributed in May, 1932, some three hundred copies of a tentative draft of the proposed "Inspection Manual for Maintenance of Conventional Aircraft." With the exception of the reports on airport and hangar inspection, this material is a compilation and rearrangement of a number of inspection forms used at the present time by leading aircraft operators. It is the intention of the committee to revise the Manual from time to time.

Of the 44 safety code committees now functioning under the procedure of the American Standards Association five are sponsored solely or jointly by the A.S.M.E. These are:

Sectional Committee on a Safety Code for Mechanical Power Transmission Apparatus
Sectional Committee on a Safety Code for Elevators
Sectional Committee on a Safety Code for Machinery for Compressing Air
Sectional Committee on a Safety Code for Conveyors and Conveying Machinery
Sectional Committee on a Safety Code for Cranes, Derricks, and Hoists.

Personnel. The Sectional Committees on safety codes sponsored by the A.S.M.E. now have a membership of 210, 84 of which are members of the Society. These five Committees have subdivided their work among 22 subcommittees and subgroups, making a total of 27 committees at work on this safety program.

Publicity. During February, 1932, Ernest Hartford, Assistant Secretary, A.S.M.E., on behalf of the A.S.M.E. participated in the planning for the Greater New York Safety Conference held in the Pennsylvania Hotel the week of the 21st of February. One evening that week he gave a radio address over WNYC outlining the part that safety codes and standards play in promoting accident prevention work.

Elevators. S. W. Jones, Chairman. Following the approval, in July, 1931, of the American Standard Safety Code for Elevators, Dumbwaiters, and Escalators (a revision of the 1925 Code), it became evident that the Committee would be called on for interpretations of the rules forming this code. After a full discussion of all aspects of the problem, it was decided that requests for interpretations should be sent to John Dickinson, Secretary of the Committee. They would then be considered at the next meeting of the Subcommittee on Research, Interpretations, and Recommendations, M. H. Christopherson, Chairman, and a tentative reply mailed to the inquirer. At annual or semi-annual intervals these interpretations will be sent to the members of the entire Sectional Committee for approval after which they will be published in *Mechanical Engineering* and issued as an addenda to the Code. Copies of these interpretations will then be sent to each jurisdiction using the code. The Subcommittee held eight meetings during the year.

With the adoption of the Safety Code for Elevators by many states and cities of the country, has grown a demand for an arrangement whereby elevator safeties and buffers may be tested and certified by a recognized and impartial testing laboratory. The National Bureau of Standards enjoys this distinction and, since it had been cooperating with this Committee in the research side of its activities, the necessary facilities and personnel were available for the conduct of these certification tests. Following conferences with the Director of the Bureau of Standards, the Committee announced its willingness to accept the responsibility of arranging for and supervising such tests for the manufacturers. This action received hearty approval on the part of the manufacturers and a number of them have already submitted their buffers for test and certification.

Work on the Elevator Inspectors' Handbook has been advanced considerably during the year by the Subcommittee of which K. A. Colahan is Chairman. A tentative draft (August, 1932) of this handbook is now being reviewed by the members of this Subcommittee. It consists of Part I, "Routine Inspection," and Part II, "Initial or Data Inspection," with an appendix covering an inspection form and tables in which are set forth safety factors and clearances.

Cranes, Derricks, and Hoists. J. C. Wheat, Chairman. During the year the Subcommittee on Editing completed its work of editing and correlating the sections of the code and released the first draft to Chairman Wheat. All agreed, however, that this editing process had revealed certain weaknesses and gaps in the Code as it stands. On August 29, therefore, a letter was written to all members of the Sectional Committee submitting a copy of the edited code and asking them to send their comments direct to Lieut. Commdr. P. J. Searles, Chairman of the Editing Committee. The Chairman hoped that by bringing certain detailed points still in doubt to the attention of the members of the entire Sectional Committee by correspondence, the work of the Committee would be completed before the end of the year without the calling of a meeting.

Boiler Code. For many years the Society has sponsored the work on the "A.S.M.E. Boiler Code" in its eight subdivisions. Although this part of the technical committee work is handled by the Special Boiler Code Committee, it is mentioned here so as to complete this report of the Society's activity in the field of industrial safety.

In addition to these Committees, the Society has representation on 26 other safety code committees. Seventeen of them have completed their codes. These committees are as follows:

Sectional Committee on Safety Code for—

- Abrasive Wheels
- Amusement Parks
- Correlating Committee
- Aeronautics
- Floor Wall Openings, Railings, and Toe Boards
- Industrial Sanitation
- Lighting Factories, Mills, and Other Work Places
- Forging and Hot Metal Stamping
- Ladders
- Logging and Sawmill Machinery
- Textiles
- Underground Power Transmission and Power Equipment for Metal Mines
- Machine Tools
- Paper and Pulp Mills
- Power Presses, and Foot and Hand Presses
- Rubber Machinery
- Walkway Surfaces
- Laundry Machinery and Operation
- Window Washing
- Color for the Identification of Gas Mask Canisters
- Construction Work
- Protection of Industrial Workers in Foundries
- Prevention of Dust Explosion
- Ventilation
- Mechanical Refrigeration

Special ASA Committee on Low Voltage Electrical Hazard.

Respectfully submitted,

Harold W. Mowery, *Chairman*
Martin H. Christopherson   Lewis Price
Thomas A. Walsh, Jr.   Wesley M. Graff.

POWER TEST CODES

The Committee on Power Test Codes presents the following report for the year ending September 30, 1932.

Test Codes Completed

During the year just closed three sections of Instruments and Apparatus were completed and issued in pamphlet form, namely, Part 9, Heat of Combustion; Part 12, Measurement of Time; and Part 18, Humidity Determinations. This means that 20 of the proposed 23 test and supplementary codes and 15 of the proposed 35 sections of Instruments and Apparatus have been completed and published during the period 1922–1932.

Personnel Changes

The Committee records with deep regret the deaths during the year of two of its members who have been active in the work of the Individual Committees: Max E. R. Toltz, who was a member of Committee No. 15 on Steam Locomotives; and William B. Chapman, who was a member of Committee No. 16 on Gas Producers.

A reorganization of Committee No. 5 on Reciprocating Steam Engines was undertaken during the year and Prof. Alexander G. Christie was appointed to succeed William C. Brown as Chairman. The personnel of this Committee now includes Harte Cooke, Alexander G. Christie, Kenneth Davidson, Herman Diederichs, Henrik Greger, Thomas Hall, John A. Hunter, Herman G. Mueller, Bruno V. E. Nordberg, Jr., J. F. Max Patitz, Alex V. Saharoff, A. G. Witting, and J. C. Workman.

Due to a contemplated revision of the Test Code for Steam Turbines, the enlargement of the personnel of Committee No. 6 was reviewed by the Main Committee this year and the following experts in the field of turbine testing have been added: Messrs. Oliver D. H. Bentley, Alexander G. Christie, Vincent M. Frost, Arthur E. Grunert, James N. Landis, Richard O. Muller, and T. E. Purcell. E. H. Brown has relinquished his membership on Committee No. 6 since his present work is foreign to this subject.

G. T. Felbeck has been appointed to membership on Committee No. 9 on Displacement Compressors and Blowers, while J. F. G. Miller has been released from membership.

At the time of the December, 1931, meeting of the Main Committee, the November, 1931, draft of the proposed Test Code for Complete Steam-Electric Power Plants was presented but not approved for a number of reasons. It seemed desirable, also, to dissolve Committee No. 11 with thanks for the work it had done and to organize a new Committee. The personnel of the reorganized Committee No. 11 is as follows: Ward F. Davidson, G. H. Fellows, R. A. Forseman, Vincent M. Frost, W. W. Johnson, Edw. W. Norris, C. U. Savoye, David S. Wegg, and Herbert S. Whiton, with Frank M. Van Deventer as Chairman.

The following appointments were made to the recently reorganized Committee No. 18 on Hydraulic Power Plants: Charles M. Allen, Harold L. Doolittle, William F. Durand, Norman R. Gibson, James P. Growdon, Thomas H. Hogg, Daniel J. McCormack, Lewis F. Moody, R. V. Terry, and William M. White, with Ely C. Hutchinson as Chairman.

It was with considerable regret that the Committee accepted the resignation of R. J. S. Pigott from Committees No. 2 on Definitions and Values and No. 19 on Instruments and Apparatus.

The Main Committee on Power Test Codes and the 20 Individual Committees now include in their personnel 118 members of the Society and 24 non-members.

Committee Activity

As usual the four quarterly meetings of the Main Committee were held in October, December, March, and June.

Regularly called committee meetings were held during the year by Committee No. 10 on Centrifugal and Turbo-Compressors and Blowers; Committee No. 12 on Condensers, Water-Heating and Cooling Equipment; and Committee No. 18 on Hydraulic Power Plants and Their Equipment. Several of the other committees have carried on extensive correspondence relative to work on their codes.

The preliminary draft of the Test Code for Gaseous Fuels was completed within the year. In the preparation of this Code, due to the rather wide variety of constituents encountered in the fuel, it has seemed desirable to avoid as much as possible the more or less empirical formulas for volume-weight conversion, air requirements, and products of combustion, as well as similar equations for heat losses. There has been an endeavor to develop these items on the pound-mole basis, referring all calculations to international atomic weights, thus developing a system applicable to the combustion of any fuel wherein the results are secured in a logical manner from primary data.

A preliminary draft of a proposed revision of the Test Code for Reciprocating Steam Engines has been completed and is being worked over for final review by the members of Committee No. 5 before it is submitted to the Main Committee for approval.

During the year a preliminary draft of a revised Test Code for Steam Turbines has been in preparation, since recent developments in the art and practice warranted a revision and extension of the scope and nature of the Code. In the preparation of the present Code the Committee deliberately avoided treatment of extraction and mixed-pressure turbines because their use was not sufficiently general and had not covered sufficient time for the development and crystallization of the testing practice. Further, the Committee had refused, up to that time, to recognize methods of measurement which it believed were still in the experimental or research stage of development, such, for example, as the use of thermocouples for measuring steam temperature, the use of nozzles for measuring steam flow, and the use of absolute-pressure manometers for measuring exhaust pressure. However, a number of these methods have now received general acceptance and are to be recognized in the revised draft now in preparation. With the inclusion of bleeder and mixed-pressure turbines in the Code, it becomes imperative that rules be given for making corrections of departure of test conditions from the operating conditions specified in the guarantees.

The preliminary draft of the Test Code for Centrifugal Compressors, Exhausters, and Fans has been distributed for criticism and comment to a group of individuals who are known to be interested in the subject. The present Code has been formulated in two parts, the first dealing with compressors and exhausters and the second with fans. It is expected that this Code will be in shape for a public hearing at the coming Annual Meeting of the Society in December, 1932. Prompted by the activities of Committee No. 10,

H. F. Hagen, one of its members, has prepared a paper on "Pulsation in Air Flow From Fans and Its Effects on Test Procedure," and Prof. L. S. Marks, a member of the Main Committee, also has developed a paper, entitled "Influence of Bends in Inlet Ducts on the Performance of Induced Draft Fans." Since it is likely that the presentation of these papers will prompt discussion having a bearing on the proposed new test code, the Main Committee recommended that the papers be presented to the members of the Society in conjunction with this Public Hearing.

While the Test Code for Condensing Apparatus provides for the conduct of performance tests for all types of condensing apparatus with their auxiliaries, it covers only a test of the condenser with the surface condition of the tubes as it happens to be at the time of the test. Since compliance with the contract and acceptance should be based on new or clean tubes it often becomes desirable to determine the degree of cleanliness of the transfer surfaces. During the past year, at the request of the Main Committee, Committee No. 12 on Condensers, Water-Heating, and Cooling Equipment has been giving the problem careful consideration and study. It is recognized, however, that the subject is a difficult one and some little time will elapse before an accepted method will be developed for inclusion in the Test Code.

Committee No. 18 on Hydraulic Power Plants has been developing a first draft of a proposed revised Test Code for Hydraulic Power Plants and Their Equipment. It is the Committee's hope to set up a test code which can be bound in with a contract so that the contract, specification, and test code will form a complete document. In order to meet the present demands of the industry, the Committee plans to develop the Test Code in two separate parts, one covering the rules for acceptance tests, and the other, rules for operating tests after acceptance.

A résumé of the progress which has been made during the past year in the preparation of the various parts and chapters of Instruments and Apparatus is as follows: Part 4, Head Measuring Apparatus, appeared in the June, 1932, issue of *Mechanical Engineering;* Part 12, Measurement of Time, in the October, 1931, issue; Part 18, Humidity Determinations, in the November, 1931, issue; and Part 21, Leakage Measurement—Chapter 2 on Boiler and Piping Leakage and Chapter 3 on Steam Engine Leakage, in the January, 1932, issue. The development of the following parts and chapters has progressed appreciably within the past year: Part 3, Temperature Measurement—Chapter 2 on Radiation Pyrometers, Chapter 4 on Resistance Thermometers, and Chapter 8 on Optical Pyrometers; Part 4 on Head Measuring Apparatus; Part 5 on Measurement of Quantity of Material; Part 6 on Electrical Measurements; Part 10 on Flue Gas Analysis; Part 14 on Mechanical Measurements; Part 15 on Measurement of Surface Areas; and Part 19 on Concentration of Dilute Solutions.

Some time ago Committee No. 19 on Instruments and Apparatus informed the Main Committee that it had been greatly handicapped in certain parts of its work by the lack of information which would enable it to state the degree of precision and accuracy of the various types of measuring instruments employed in the measurement of the quantities involved in acceptance tests. As one means of relieving this situation the Committee suggested that the determination of these data would furnish excellent material for research work for senior students in technical colleges and universities. The Main Committee was in accord with the suggestion and requested that a list of short-time assignments for individuals be prepared for distribution to the interested colleges and universities for their review.

Abstracts of preliminary drafts of the Power Test Codes and other related material have been prepared and published in *Mechanical Engineering* during the year. This material has filled ten pages.

Special Problems

One of the two problems brought to the attention of the Power Test Codes Committee this year was the desirability of its taking up the formulation of a code for the determination of solid matter and undesirable chemical substances in flue gases. This proposal was carefully considered and the Committee decided that preparatory to the development of such a code, a thorough investigation of the subject should be made by the A.S.M.E. Pure Air Committee.

Consideration was given also to a communication received from the A.S.M.E. Boiler Code Committee relative to the present method of calculating boiler heating surface. The sections of the Code on Definitions and Values and the Test Code for Stationary Steam-Generating Units deal with this quantity and the Committee decided to make no changes in the methods there described.

Principles Underlying the A.S.M.E. Power Test Codes

During the past two years the members of the Committee have given considerable thought to the revision of the statement of principles which underlie the formulation and use of the A.S.M.E. Power Test Codes. At the May 25, 1931, meeting the Main Committee appointed a special committee consisting of F. Hodgkinson, Chairman, C. Harold Berry, C. F. Hirshfeld, E. B. Ricketts, and William Monroe White to study this subject in a broad way and to prepare a revised statement if that was found to be desirable. The report of this Special Committee was approved and adopted by the Main Committee at its October 5, 1931, meeting and copies were distributed to the entire membership of the Committee on Power Test Codes for their future guidance. At that time the Main Committee also reaffirmed the fundamental objectives and purposes of the Power Test Codes as adopted in 1918.

International Electrotechnical Commission

Through membership on the U. S. National Committee of the I.E.C., the Society and the Main Committee on Power Test Codes have been actively engaged in assisting to bring about international agreements on acceptance tests for steam turbines and internal-combustion engines. The Secretariat for the Advisory Committees on Steam Turbines, Internal-Combustion Engines, and Hydraulic Turbines is held by the United States. The Society was represented this year on the U. S. National Committee by Harvey N. Davis, Francis Hodgkinson, and Ely C. Hutchinson, with C. Harold Berry and Paul Diserens as alternates.

I.E.C. Steam Turbines

The Secretariat reported last year that complete documents for Part I, "Specification," and Part II, "Rules for Acceptance Tests," were agreed to at the Stockholm meeting in July, 1930. These publications were issued by the Central Office in July, 1931. As reported last year, also, the following subjects still are before Advisory Committee No. 5: (1) the Supplementary Notes on Instruments and Methods of Measurement; (2) recommendations of I.S.A. on Velocity Measurements of Fluids; (3) consideration of proposals contained in a paper by Mr. Darrieus on "A Rational Definition of Steam Turbine Efficiencies;" and (4) consideration of increasing the Scope of the Rules beyond that which had been previously agreed to. It is believed that, with the recommendations which have been received thus far from the member countries on these several subjects, the work of the Secretariat has progressed as far as is possible without a meeting of Advisory Committee No. 5 and it is thought that such a meeting might advantageously be called during the year 1933.

I.E.C. Internal-Combustion Engines

During the past year the Secretariat has prepared a document for Part I, "Specification" for the I.E.C. Publication on Internal-Combustion Engines based on the Recommendations received from the several member countries since the Stockholm, 1930, meeting of Advisory Committee No. 19.

Proposals by the U. S. National Committee for Part II, "Rules for Acceptance Tests" were submitted at Stockholm but were not discussed. It was agreed, however, that the member countries would send their recommendations and comments thereon to the Secretariat to the end that amendments may be made to the proposals, reconciling as far as possible the views of the respective nations. France, Germany, and Sweden have requested an extension of time, which the Secretariat has granted to September 1, 1932, following which the Secretariat will prepare a document reconciling as far as possible the views of the member countries. With the completion of this task after that date, the work of the Secretariat will have gone as far as possible without a meeting of Advisory Committee No. 19 and it is thought that such a meeting might be called advantageously during the year 1933.

Organization of Electrical Standards Committee

From time to time during the past six years a number of efforts have been made to unify and simplify the organization for standardization in the electrical industry. This unification involved the joining of the present U. S. National Committee of the International Electrotechnical Commission with the other groups which formed the Electrical Advisory Committee affiliated with the American Standards Association. At its October 5, 1931, meeting the Main Committee on Power Test Codes carefully reviewed the steps in this development which had been taken and considered the possible effect of the newly organized Electrical Standards Committee on the work of the A.S.M.E. Committees on Power Test Codes and Boiler Construction Codes.

The Main Committee then addressed a communication to the A.S.M.E. Council relative to the full meaning of the "Scope" of the Constitution of the Electrical Standards Committee. The recommendations offered were accepted at the October 9, 1931, meeting of the Executive Committee of the Council. The Executive Committee approved also the recommendation of the A.S.M.E. representatives on the U.S. National Committee, I.E.C., that the Constitution of the E.S.C. provide that the A.S.M.E. be designated as a member of the U.S.N.C. with three representatives.

An official letter of interpretation from the American Standards Association has been received giving assurance that the Electrical Standards Committee will not concern itself with projects dealing with apparatus and operation on the prime mover side of the generator coupling. Likewise unanimous approval was given by the E.S.C. and the ASA to the amendment to the Constitution of the former providing for the addition of three representatives of the A.S.M.E.

Respectfully submitted,

Fred R. Low, *Chairman*
C. Harold Berry
Albert T. Brown
Edwin H. Brown
Alexander G. Christie
Harte Cooke
Paul Diserens
Robert H. Fernald
Edwards R. Fish
C. F. Hirshfeld
Francis Hodgkinson
Ozni P. Hood
George A. Horne
Ely C. Hutchinson
David S. Jacobus
Lionel S. Marks
Lewis F. Moody
Irving E. Moultrop
Henry B. Oatley
Geo. A. Orrok
Reginald J. S. Pigott
Edwin B. Ricketts
Edward N. Trump
William Monroe White
Walter J. Wohlenberg.

PROFESSIONAL CONDUCT

The Committee has had only routine matters to consider during the past year, none of which involved serious misconduct on the part of any of our members.

The Committee has received criticisms of the form of the present Code of Ethics and has under consideration certain modifications which may be submitted to Council in due course. These changes are intended to further dignify and add to the appeal of the Code.

Respectfully submitted,

A. G. Christie, *Chairman*
D. Robert Yarnall
James H. Herron
H. S. Philbrick
E. R. Fish.

BOILER CODE

The Boiler Code Committee submits the following report for the fiscal year ending September 30, 1932.

During this period the Committee held nine regular meetings, one of which was a three-day meeting, and several Executive Committee meetings, which were devoted to interpretations of the various sections of the Code and to the formulation of revisions and addenda thereto. Forty-four interpretations were added during the past fiscal year, making a total of 731 interpretations now in force.

The Committee has been requested to formulate rules for the design and bolting of flanges and has given consideration to the problem. In view of the work being carried on by the Sectional Committee on Standardization of Pipe Flanges and Fittings, further consideration by the Boiler Code Committee has been postponed until the report of the Sectional Committee is available.

The Committee has devoted careful study to a problem in regard to conformity to the Code of two mercury boiler equipments for use in power generating stations. As this was a new and distinct step in power plant development, the boilers and parts could not be made to meet the Code requirements in all respects, and as the boilers were to be installed in states requiring compliance with the Code rules, special action was necessary by the authorities in charge of the enforcement of the Code. It was explained that in dealing with new types of apparatus not covered by its Codes, the Boiler Code Committee had on several occasions taken the position that it favors having trials made by responsible parties in order to extend the knowledge of the art, and that the Committee had recommended to the authorities in charge of enforcement of the Code that permission be given to install new types of apparatus as special cases with the understanding that those making an installation assume any risk that might be involved through its being of a special design not fully covered by the Codes. Recommendation was made to the chief boiler inspectors of the states in which the boilers were to be installed that each of the units be accepted as a special case.

In all of the Codes for Unfired Pressure Vessels that have been issued a statement is made that the rules are not applicable to certain vessels, some of which are used in the petroleum industry. The American Petroleum Institute is now cooperating with The American Society of Mechanical Engineers and a Joint Committee is preparing rules for the construction of vessels for flammable liquids and gases.

F. A. Page, chief boiler inspector of the State of California, submitted proposed revisions of the California Air Tank Safety Orders to the Boiler Code Committee for comments and suggestions. The Boiler Code Committee made a number of recommendations and explained certain provisions of its Code for Unfired Pressure Vessels. It advised Mr. Page that the Joint Committee of the American Petroleum Institute and The American Society of Mechanical Engineers is working on rules to meet the special requirements of the petroleum field and suggested that the State of California wait until the results of the work of this Joint Committee are available before endeavoring to cover the entire field of unfired pressure vessels.

Revised rules covering the reinforcement of openings have been embodied in the Code. A great amount of painstaking work was done in preparing these rules by the Subcommittee on Reinforcements, as well as by the Boiler Code Committee itself, and there is a general agreement that the revised rules are much better than those previously used.

In addition to the foregoing decisions many revisions have been made which either amplify or clarify the new welding rules which were adopted and incorporated in the Code last year.

A number of revisions have been made in the Materials Specifications Section of the Code. Many of the specifications appearing in this section have been adopted from the American Society for Testing Materials. Therefore, as a result of the continued cooperation with that society, when changes are made by the A.S.T.M. in these identical specifications, corresponding changes are made in the A.S.M.E. Code to bring them into conformity.

The Committee has also made numerous revisions and additions to the various sections of its Code as a result of suggestions from manufacturers, inspectors, users, and others. These revisions were formally adopted by the Council on August 17, 1932, and distributed in pink-colored addenda sheets.

At the request of the Boiler Code Committee, the Council made the following appointments: R. E. Cecil and A. C. Weigel as members of the Main Committee; J. W. Lockett as a member of the Subcommittee on Heating Boilers to succeed W. A. Nevin; C. A. Adams, A. W. Limont, Jr., H. S. Smith, and D. B. Wesstrom as members of the Subcommittee on Unfired Pressure Vessels. J. A. Dixon resigned from the Subcommittee on Welding.

Respectfully submitted,

F. R. Low, *Chairman*
D. S. Jacobus, *Vice-Chairman*
C. W. Obert, *Hon. Secretary*
H. E. Aldrich
W. H. Boehm
R. E. Cecil
F. S. Clark
F. W. Dean
W. F. Durand
E. R. Fish
V. M. Frost
C. E. Gorton
A. M. Greene, Jr.
F. B. Howell
J. O. Leech
E. F. Miller
M. F. Moore
I. E. Moultrop
C. O. Myers
H. B. Oatley
James Partington
C. L. Warwick
A. C. Weigel
H. LeRoy Whitney.

REGISTRATION OF ENGINEERS

The Committee on Registration of Engineers has been cooperating with the joint committee of the various engineering societies which has been formulating a Model Law for the registration of professional engineers and architects, and since the last Annual Meeting a member of the Committee has been officially representing our Society at the joint conferences.

The Model Law has been printed and distributed to the various organizations interested, and one of the major societies has officially approved it. The Committee will recommend to the Council at its Annual Meeting this year that the A.S.M.E. also approve the Model Law. This action will not commit the Society to a policy of advocating registration laws but only of cooperating to the extent that legislation shall be carried along rational lines.

The Committee desires again to call the attention of the membership to the fact that a majority of the states have registration laws and the movement is being extended. Each member should study the laws in his state and ascertain whether his work is of such a nature that he should be registered. The Committee cannot issue blanket recommendations which will cover all the members living in the United States, and, in fact, would not attempt to interpret some of the laws as now written.

We have found many mechanical engineers inclined to disregard the law. This is a hazardous thing to do. Even though failure to register may result in no immediate difficulty, the lack of a license may be a bar to promotion to a position of greater responsibility. A license cannot be obtained quickly, but may require several months or even several years, as it is becoming more difficult each year to acquire a license in some states.

Respectfully submitted,

John H. Lawrence, *Chairman* C. F. Hirshfeld
D. S. Kimball V. M. Palmer
Paul Doty J. M. Todd.

ECONOMIC STATUS OF THE ENGINEER

At the Annual Meeting in 1931 this Committee rendered two reports, one the report on 1930 Earnings of Mechanical Engineers, the other a recommendation for the establishment of a joint agency of engineering bodies through which the general status of the profession could be improved.

The Earnings Report, presented at the 1931 Annual Meeting business session, has had a profound effect on thought about the status of the engineer, the process of educating engineers, and the steps that must be taken to advance the broad status of the profession. An authoritative interpretation was presented at the Corvallis meeting of the Society for the Promotion of Engineering Education. A paper dealing with the fundamental philosophy of the engineer as an administrator was presented at the Cleveland Meeting of the American Institute of Electrical Engineers. Both of these papers dealt very largely with the conclusions of the Report. The significance and portent of some of the results of the studies have been brought to the attention of deans of engineering schools by correspondence. The Local Sections of the Society have held a score or more of meetings at which the findings have been discussed and the comments indicate that the investigation has been very much worthwhile. The underlying statistics for the Report have been consulted by several agencies which are engaged in similar studies for other professions. Slides of the curves are available for the use of any who wish to present the findings of the Committee before audiences. In following up this phase of its activity the Committee is developing a plan for selecting career consultants who will be available to younger members of the Society wishing advice and guidance.

The Committee's finding that the task of improving the earnings of the engineer involves improving his professional and social status, led to the conclusion that the united profession must further education, subsequent training, and some form of professional recognition. The Council approved this view and authorized the necessary conferences. As a result, the Engineers' Council for Professional Development organized on October 3, 1932.

During the year the Committee has arranged for the appointment of an ex-officio member from the Committee on Relations with Colleges, inasmuch as a great deal of the work of the Committee will have a relationship to the educational work of the Society.

The death of Col. W. A. Starrett was a great loss to the Committee. His high ideals for the status of the engineer, and his vigor of thought and expression were of tremendous value.

Respectfully submitted,

C. F. Hirshfeld, *Chairman* H. L. Whittemore
Dexter S. Kimball W. E. Wickenden
H. B. Oatley C. N. Lauer
J. M. Todd } *Ex-Officio.*
M. C. Maxwell }

Reports of Meetings

THE following pages present brief reports of meetings of the Society and of its Professional Divisions during 1932. More detailed accounts were published in *Mechanical Engineering* and the *A.S.M.E. News*. The meetings reported here are:

MEETINGS OF THE SOCIETY

Semi-Annual, Bigwin Inn, Lake of Bays, Ontario, Canada, June 27–July 1, 1932
Annual, New York, N. Y., December 5–9, 1932

MEETINGS OF THE PROFESSIONAL DIVISIONS

Aeronautic, Berkeley, Calif., June 9–10, 1932
Aeronautic, Buffalo, N. Y., June 6–7, 1932
Applied Mechanics, New Haven, Conn., June 23–25, 1932
Iron and Steel, Pittsburgh, Pa., April 28, 1932
Machine Shop Practice, Buffalo, N. Y., October 3, 1932
Management and Material Handling (M-M-M Congress), Detroit, Mich., May 4–5, 1932
Oil and Gas Power, State College, Pa., June 8–11, 1932
Printing Industries, New York, N. Y., March 14–15, 1932
Process Industries, Buffalo, N. Y., June 6–7, 1932
Textile, Boston, Mass., October 27, 1932
Wood Industries, Jamestown, N. Y., November 15–16, 1932.

Semi-Annual Meeting

BIGWIN INN, LAKE OF BAYS, ONTARIO, CANADA, JUNE 27–JULY 1, 1932

The majority of those attending the 1932 Semi-Annual Meeting reached Toronto on the morning of June 27 and were given an opportunity to inspect the harbor developments there before going on to Bigwin Inn in the afternoon. The first evening was spent in an informal get-together, the technical sessions not beginning until the second day.

A Business Meeting was held on the morning of June 28 at which an announcement was made that the 1933 Semi-Annual Meeting would be held in Chicago during the week of June 26, 1933, at the time of the Century of Progress. At the close of the Business Meeting the Council went into its first session since December, 1931. After a résumé of the activities of the executive committee, which had met monthly during the intervening time, the Council took up the subject of the budget for the fiscal year starting October 1, 1932. The new budget provided for a reduction in expenditures of 34 per cent over the year 1929–1930, for the development in three new areas of the Student Branch program tried out in the South during the past year, and for writing off the loan to The Engineering Index except for items actually in inventory. The Council also approved the formation of a joint council, to be called the Engineers' Council for Professional Development, to establish standards of admission into the profession. The proposal to establish such a council grew out of the work of the Committee on the Economic Status of the Engineer.

The Nominating Committee, meeting on Tuesday and Wednesday, selected the following candidates for new officers of the Society in 1932–1933:

President, A. A. Potter
Vice-Presidents, Harold V. Coes, James D. Cunningham, C. F. Hirshfeld
Managers, Alex D. Bailey, John A. Hunter, R. L. Sackett

The following delegates to the American Engineering Council were nominated:

B. M. Brigman, W. S. Conant, Hugo Diemer, W. A. Hanley, Ernest Kreher, G. E. Pellissier, J. W. Roe, B. R. Van Leer, T. R. Weymouth, D. Robert Yarnall

Dr. J. M. R. Fairbairn, chief engineer of the Canadian Pacific Railway, was toastmaster at the main entertainment event, the banquet and dance on Thursday evening. The speakers were Past-President Wm. L. Abbott, Dr. Lillian M. Gilbreth, and George D. Y. Leacock. Special recognition was made of the services to the Society of Prof. Robert W. Angus, and prizes were awarded for the sports events to which the afternoons of the meeting were largely devoted. Other social events included a masquerade dance.

A conference of Local Sections Delegates took place on Wednesday morning, and honorary chairmen of Student Branches held a luncheon conference on Thursday.

As the following list of papers indicates, the sessions reflected engineering practices in Canada and Great Britain, as well as in the United States.

Tuesday Morning, June 28

APPLIED MECHANICS (I)

Symposium on Use of Models in Engineering

Use of Models in Aerodynamics and Hydrodynamics, O. G. Tietjens
Determination of the Speed and Power of Ships From Model Experiments, H. C. Sadler
Use of Models Under Centrifugal Force, Philip B. Bucky

RAILROAD

Roller Bearings for Railroad Service, T. V. Buckwalter
The C. P. R. Multipressure Locomotive No. 8000—
  Its Construction and Operation, H. B. Bowen*
  Its Machinery, Locomotive Chassis, and Tender, J. B. Ennis
  Its Steam Generating System, F. A. Schaff

MACHINE SHOP PRACTICE (I)

Oxygen Machine Cutting in Great Britain, C. G. Bainbridge**
Developments in the Design and Application of Gearing, Henry E. Merritt**

Wednesday Morning, June 29

APPLIED MECHANICS (II)

Symposium on Use of Models in Engineering

Model Testing as Applied to Strength of Materials, R. E. Peterson
Use of Models in Vibration Research, J. P. Den Hartog
Use of Models in Studies of Stresses in Structures, Geo. Beggs
Use of Models in Determining the Strength of Thin Wall Structures, Harold E. Saunders and Dwight F. Windenburg

HYDRAULIC (I)

Hydraulic Practice in Europe, R. W. Angus*
Hydro-Electric Development in Canada, T. H. Hogg*

MANAGEMENT

Current Problems of Industrial Management, Jas. D. Mooney
Is There Any Basis Left for the Taxable Value of Manufacturing Properties? Chas. T. Main

OIL AND GAS POWER AND RAILROAD

British High-Speed Oil Engines, J. L. Chaloner**
Surface-Volume Ratio as a Critical Factor in Automotive Diesel Combustion Chambers, Julius Kuttner

---

* Contributions from Canada.
** Contributions from Great Britain.

Wednesday Evening, June 29

Standards of Qualifications for Engineers

Present Status of Professional Engineering in Canada, Col. Ibbotson Leonard*

Thursday Morning, June 30

Power (I)

British Practice in Steam Turbine Design, F. W. Gardner**
Steam Turbine Plant Practice in the United States, Vern E. Alden and W. H. Balcke

Machine Shop Practice (II)

Research on Steels and Forgings for Greater Density, Machinability, and Durability, Fred W. Cederleaf and W. E. Sanders
Life of Tools Machining Free Cutting Brass, L. D. Spence and Jas. A. Hall

Hydraulic (II)

Hydraulic Jump in Sloping and Horizontal Flumes, R. W. Ellms
Investigation of Flow Conditions in a Centrifugal Pump, Karl Fischer and D. Thoma

Friday Morning, July 1

Power (II)

Economic Balance Between Steam and Hydro Capacity, K. M. Irwin and Joel D. Justin

Annual Meeting, New York, N. Y.

DECEMBER 5–9, 1932

The Fifty-Third Annual Meeting brought to the Engineering Societies Building more than 2100 members of the A.S.M.E. and their friends during the week of December 4, 1932. The Local Sections delegates met in conference on Sunday, December 4, and continued throughout the day Monday and on Tuesday morning. Among the subjects discussed was the Junior Division of the Los Angeles Section, organized in January, 1932, to promote greater activity among the Junior and Student members in that Section and reported as providing a forum where these younger engineers may secure experience and confidence helpful to them when participating in meetings with older members. The delegates passed a resolution asking for a revision of the Constitution, By-Laws, and Rules to give constitutional status to the Local Sections Delegates Conference, and voted for the discontinuance of the *A.S.M.E. News* in view of the reduced publications budget. The regular Nominating Committee for officers for 1933–1934 was selected and a Committee of the Conference was appointed to meet with the Revenues Committee to consider the financial problems of the Society. A more complete report of the conferences was published in the *A.S.M.E. News* for December 22, 1932.

This issue also contained a summary of the meeting as a whole, particularly the non-technical events, and the January, 1933, issue of *Mechanical Engineering* will include details of the technical sessions, the program for which was as follows:

Monday Morning, December 5

Working Stress Symposium (I)

(Auspices of Applied Mechanics Division)

Theories of Strength, A. Nadai
Working Stresses for Columns and Thin-Walled Structures, S. Timoshenko
The Fatigue of Metals—Its Nature and Significance, H. F. Moore
Stress-Concentration Phenomena in Fatigue of Metals, R. E. Peterson

Locomotives

(Auspices of Railroad Division)

Horsepower and Tractive Effort of Steam Locomotives (Locomotive Ratios), A. I. Lipetz
Progress Report of Railroad Division, presented by L. K. Sillcox

Soaking Pits and Radiant Heat

(Auspices of Iron and Steel and Fuels Divisions)

Use of Blast-Furnace Gas in Soaking Pits, G. T. Hollett
Effect of Reradiation on Heat Transmission in Furnaces and Through Openings, H. C. Hottel and J. D. Keller

Monday Afternoon, December 5

Working Stress Symposium (II)

(Auspices of Applied Mechanics Division)

Applications of Creep Tests, Gleason H. MacCullough
Factors Affecting Choice of Working Stresses for High-Temperature Service, P. G. McVetty
Metals at High Temperature—Test Procedure and Analysis of Test Data, Ernest L. Robinson

Special Design of Cars

(Auspices of Railroad Division)

Car Design of the Future, C. E. Barba
Development of Special Rail Equipment, R. C. Pierce

Metals

(Auspices of Iron and Steel Division)

The Rolling and Extrusion of Aluminum and Its Alloys, Robert L. Streeter
Carburizing With Butane Gas, C. W. Spicer
Progress Report of Iron and Steel Division

Power Test Code Public Hearing

(American Society of Heating and Ventilating Engineers Cooperating with the A.S.M.E. in Sponsoring this Session)

Influence of Bends in Inlet Ducts on the Performance of Induced-Draft Fans, L. S. Marks, John Lomax, and Randolph Ashton
Pulsation of Air Flow From Fans and Its Effect on Test Procedure, Harold F. Hagen
Public Hearing on Test Code for Centrifugal Compressors, Exhausters, and Fans

Tuesday Morning, December 6

Industrial Power

(Auspices of Power Division)

Observations of Liquid Water in Steam Passages and Means for Effecting Separation, Carl C. Thomas
High-Pressure Steam-Generator Research (Progress Report of Investigation at Purdue Univ. by A.S.M.E. Special Research Comm. on Critical-Pressure Steam Boilers), H. L. Solberg, G. A. Hawkins, and P. A. Willis
Progress Report of Power Division, presented by Alfred Iddles

Working Stress Symposium (III)

(Auspices of Applied Mechanics Division)

Working Stresses—A General Review of the Fundamental Aspects of the Problem, C. Richard Soderberg
Notched-Bar Tests, Max Moser
Allowable Working Stresses Under Impact, N. N. Davidenkoff
Progress Report of Applied Mechanics Division, presented by George B. Pegram

Materials Handling on Railroads

(Auspices of Materials Handling Division)

Factors Affecting Shipping Other Than the Cost of Transportation, Matthew W. Potts and John A. Cronin
Effect of Transportation Requirements on the Evolution of Freight Cars, C. B. Peck
Progress Report of Materials Handling Division, presented by G. E. Hagemann

---

* Contribution from Canada.
** Contribution from Great Britain.

Cutting Metals (I)

(Auspices of Machine Shop Practice Division and Special Research Committee on Cutting of Metals)

Performance of Cutting Fluids in Drilling Various Metals (Progress Report No. 4 of Subcomm. on Cutting Fluids of Comm. on Cutting of Metals), O. W. Boston and Carl J. Oxford
Effect of Lathe Cutting Conditions on the Hardness of Carbon and Alloy Steels, T. G. Digges

Tuesday Afternoon, December 6

Heat Transmission and Stokers

(Auspices of Fuels Division)

The Measurement of Metal Temperatures on the Heat-Receiving Side of Heat-Exchanging Apparatus, Arthur Williams
Stoker Developments at The Detroit Edison Company's Delray Power House No. 3, Paul W. Thompson and Fred J. Chatel
Discussion of the Present Status of Fuel-Burning Equipment, Geo. A. Orrok, A. G. Christie, and James N. Landis
Progress Report of Fuels Division, presented by Ralph A. Sherman

Cutting Metals (II)

(Auspices of Machine Shop Practice Division and Special Research Committee on Cutting of Metals)

What Can Be Accomplished With Modern Machine Tools and Cemented Carbide Cutting Tools, Arthur A. Merry
Grinding Cemented Tungsten- and Tantalum-Carbide-Tipped Tools Economically, J. M. Highducheck

Mechanical Springs

(Auspices of Special Research Committee on Mechanical Springs)

Number of Active Coils in Helical Springs, R. F. Vogt
Fatigue Tests of Helical Springs, and Number of Inactive Coils in Compression (Progress Report of Subcomm. on Heavy Railroad Springs), C. T. Edgerton
Progress Reports of Other Committee Studies, D. J. McAdam, Jr., and M. F. Sayre

Roll Neck Bearings

(Auspices of Iron and Steel Division and Special Research Committee on Heavy Duty Anti-Friction Bearings)

The Morgoil Roll-Neck Bearing, F. P. Dahlstrom
Strength of Roll Necks (Report of Special Research Comm. on Heavy Duty Anti-Friction Bearings), W. Trinks and J. H. Hitchcock

Wednesday Morning, December 7

Symposium on Long-Time Planning

(Auspices of Management Division)

The Problem of Business Stability, Sumner H. Slichter
Trade Associations—Their Part in Coordinate Planning, Edgar L. Heermance
Planning in Industry—Successful Plans Adopted and Results, Thomas B. McCabe, Howard E. Blood, Frank D. Geraghty, W. B. Flanders, W. T. Conlon, E. E. Yake, and Paul Diserens

Foundry

(Auspices of Machine Shop Practice Division)

Special Steels for Castings, R. A. Bull
Malleable Iron as a Component Part of Machines and Structures, Enrique Touceda
Progress Report of Machine Shop Practice Division, presented by R. E. W. Harrison

Flow Measurement and Hydraulic Design

(Auspices of Hydraulic Division)

Problems of Modern Pump and Turbine Design, Wilhelm Spannhake
A Symposium on Water Measurement—Discussion of "Research Institute for Hydraulic Engineering and Water Power" (Trans. A.S.M.E., HYD-54-3, May 15, 1932), by Hunter Rouse, led by Chas. M. Allen

Dyeing

(Auspices of Textile Division)

Peroxide Bleaching of Textiles, and Outlines of Its Recent History, Present Applications, and Immediate Prospects, Harry G. Smolens
Elements of Cost in Dyeing Cotton Piece Goods, J. Andrew Clark
Progress Report of Textile Division, presented by W. L. Conrad

Wednesday Afternoon, December 7

Industrial Management Today

(Auspices of Management Division)

The Economic Characteristics of the Manufacturing Industries, Walter Rautenstrauch
Dissolving of Concentrated Industries, Harold V. Coes
Management Essentials for Recovery, Carle M. Bigelow

Small-Boat Diesels

(Auspices of Oil and Gas Power Division)

Diesels for Small Boats, A. B. Newell
Progress Report of Oil and Gas Power Division, presented by P. H. Schweitzer

Steam Tables Research

(Auspices of Special Research Committee on Thermal Properties of Steam)

Report of the Progress at the Massachusetts Institute of Technology, F. G. Keyes and L. B. Smith
Report of the Progress in Steam Research at the Bureau of Standards, N. S. Osborne
Progress in Steam Table Experiments, J. H. Keenan
High-Pressure Steam Research at the Masaryk Academy of Work in Prague, Czechoslovakia (up to Nov. 1, 1932), Jaroslav M. Havlicek
The Pressure of Saturated Water Vapor in the Range 100 C to 374 C, N. S. Osborne, H. F. Stimson, E. F. Fiock, and D. C. Ginnings

Flow of Fluids

(Auspices of Hydraulic Division)

A Study of the Data on the Flow of Fluids in Pipes, Emory Kemler
A Tribute to John Ripley Freeman and His Hydraulic Accomplishments, Blake R. Van Leer
Progress Report of Hydraulic Division (presented by title)

Thursday Morning, December 8

Central Station Power

(Auspices of Power Division)

Stresses in Boiler Tubes Subjected to High Rates of Heat Absorption, Wm. L. DeBaufre
A System for the Measurement of Steam With Flow Nozzles for Turbine Performance Tests, Sanford A. Moss and Wistar Johnson
Performance of Modern Steam-Generating Units, C. F. Hirshfeld and G. U. Moran

Progress in Management

(Auspices of Management Division)

Ten Years' Progress in Management, 1923–1932, Leon P. Alford
Applications of the Kmh Method of Analyzing Manufacturing Operation, Leon P. Alford and J. E. Hannum
Informal Discussion of Engineering and Its Effect on Economic Conditions, Dexter S. Kimball
Progress Report of Management Division (presented by title)

Aeronautics

(Auspices of Aeronautic Division)

Airfoil Theory, With Special Reference to Aileron Rolling and Hinge Moments, Albert Toussaint
The Relation of Weather to Ocean Flying, James H. Kimball
Progress Report of Aeronautic Division

Thursday Afternoon, December 8

LUBRICATION TESTING

(Auspices of Petroleum Division)

Some Problems on the Lubrication of Vertical Journal Bearings, A. I. PONOMAREFF and E. D. HOWE
Chemical Mechanism of Lubrication, WILLIAM F. PARISH and LEON CAMMEN
Progress Report of Petroleum Division (presented by title)

EDUCATION AND TRAINING FOR THE INDUSTRIES

(Auspices of Committee on Education and Training for the Industries)

The Engineer's Interest in Foreman Training, EDWARD S. COWDRICK
Fundamentals of Training, G. GUY VIA
Adult Technical Education, O. W. ESHBACH

Preceding the sessions on Tuesday, Wednesday, and Thursday mornings, Dr. S. Marion Tucker, Head of the Department of English of The Polytechnic Institute, Brooklyn, N. Y., gave a series of lectures on "Talking With an Audience."

Both the Towne and Thurston Lectures were on the program, the former being presented by A. W. Robertson, Chairman of the Board of Directors of the Westinghouse Elec. & Mfg. Co., New York, and the latter by Dr. W. F. G. Swann, Director of the Bartol Research Foundation of The Franklin Institute, Swarthmore, Pa. Mr. Robertson took for his subject "The Scientific Approach to Human Affairs," and Dr. Swann spoke on "Recent Advances in Physics." Another special lecture was that by H. W. Heinrich, Assistant Superintendent, Engineering and Inspection Division, Travelers Insurance Company, Hartford, Conn., on "Conservation an Essential in Industrial Recovery."

The annual Business Meeting was held on Monday afternoon, preceding the sessions, and adjourned to Tuesday evening, when the report of the Local Sections Delegates naming the 1933–1934 Nominating Committee was presented and approved.

The 1932 Council held sessions for the transaction of regular business on the first day of the meeting and at an adjourned meeting on Friday morning received a resolution from the Hydraulic Division proposing joint action with the American Society of Civil Engineers and the Boston Society of Civil Engineers in regard to traveling scholarships in hydraulics, as a memorial to John R. Freeman, past-president and honorary member of the Society. The new Council for 1933 organized on Friday.

Wednesday was Student Branch Day, the program for which included participation in the morning excursion, a luncheon, and an afternoon session at which Student Branch activities were discussed, the 1932 Charles T. Main paper presented, and addresses made by Dr. Lillian M. Gilbreth, consulting management engineer, Montclair, N. J., and William A. Hanley, director of engineering, Eli Lilly & Co., Indianapolis, Ind.

The social events of the meeting began with a card party on Monday evening, sponsored by the Woman's Auxiliary to the A.S.M.E., the proceeds to be used for unemployed engineers. On Tuesday evening Conrad N. Lauer presented his presidential address, the subject of which was "Unifying the Engineering Profession," honorary membership was conferred posthumously on John R. Freeman, and the Melville, Charles T. Main, Junior, and Student Awards were announced. A reception and dance followed.

The Annual Dinner was held at the Hotel Astor on Wednesday evening. General James G. Harbord, Chairman of the Board of Directors, Radio Corporation of America, New York, gave an address on "Industrial Rehabilitation." James D. Cunningham, Manager, A.S.M.E., was the toastmaster. The address to new members was delivered by Roy V. Wright, past-president, and the president-elect, Dean A. A. Potter, was presented and spoke briefly.

A large number of committee meetings were held during the week, and an interesting program of excursions included trips to several generating stations, and the S.S. *Europa*, Seatrain Lines, Inc., and S.S. *Conte di Savoia*. Thursday evening, as usual, was reserved for college reunions. The events for ladies included trips to the Morgan Library, Wanamaker's, and the Museum of the City of New York. An informal tea was given on Thursday afternoon at the Engineering Woman's Club, and the Annual Business Meeting and Luncheon of the Auxiliary was held on Tuesday at the Pan-Hellenic Hotel.

Meetings of the Professional Divisions

Aeronautic Division

BERKELEY, CALIF., JUNE 9–10, 1932

More than 200 attended the Pacific Coast Aeronautic Meeting held under the auspices of the Aeronautic Division on June 9 and 10 at the University of California.

The afternoon of the first day was devoted to an excursion to the San Francisco Bay Cities Airdrome, Oakland Airport, Boeing School, and Stanford University. At a dinner held in San Francisco that evening, E. T. Allen, formerly test pilot of the Boeing Airplane Company, was the principal speaker.

The *A.S.M.E. News* of July 22, 1932, comments upon the three technical sessions, at which the following papers were presented:

Thursday Morning, June 9

AERODYNAMICS

Description and Calibration of 10-Foot Wind Tunnel at California Institute of Technology, C. B. MILLIKAN and A. L. KLEIN
The Effects of Fillets on Wing-Fuselage Interference, A. L. KLEIN
The Present State of the Turbulence Problem, WALTER TOLLMEIN
Wind Tunnel Tests of a 1/75 Scale Model of the Goodyear Zeppelin Airship "Akron" Z.R.S. 4 With Normal and Ring Tail Surfaces, REINHOLD SEIFERTH (presented by title)

Friday Morning, June 10

STRUCTURES

Rules for the High and Low Angle of Attach Loading Conditions, A. S. NILES
Survey of the Problems of Thin Walled Structures, E. E. SECHLER, L. H. DONNELL, TH. VON KARMAN
Principle of Similitude as Applied to Research on Thin Sheet Structures, J. E. YOUNGER
The Application of the Hardy-Cross Method of Moment Distribution, H. A. WILLIAMS

Friday Afternoon, June 10

TRANSPORTATION AND MANAGEMENT

Spin Flight Testing of Three Similar Airplanes, E. T. ALLEN
Development of Transport Airplanes, C. N. MONTEITH
Safety in Air Transportation, C. E. JOHNSON
The Technic of Mechanical Engineering Laboratory Instruction at the University of California, L. M. K. BOELTER

Aeronautic Division

BUFFALO, N. Y., JUNE 6–7, 1932

The Sixth National Meeting of the Aeronautic Division and the First National Process Meeting of the Process Industries Committee (see page 11) were held under the auspices of the Buffalo Section, with joint entertainment features. Several hundred were registered for the meetings, which were reported in the *A.S.M.E. News* of June 22, 1932.

The morning of June 7 was devoted to inspection trips, the aeronautic group visiting the plants of the Irving Air Chute Company, Consolidated Aircraft Company, Hall-Aluminum Aircraft Corporation, and Curtiss Aeroplane & Motor Co., where lunch was served.

The banquet on the evening of the 7th was the occasion for the presentation of the Spirit of St. Louis Medal to Paul W. Litchfield, president of the Goodyear Tire & Rubber Co., Akron, Ohio, and of the Goodyear-Zeppelin Corporation, for meritorious services in the advancement of airship design and construction in America. The speakers at the banquet were the Honorable W. Irving Glover, second assistant postmaster general, on "Future Transportation," and Dr. A. Stuart Hunter, secretary of the Society of Rheology, on "The Scientist in Industry." Theodore P. Wright presented the medal to Mr. Litchfield.

The third day of the meeting was devoted to a trip to Niagara Falls, with visits to a number of plants along the way.

Another feature of the meeting was an exhibit of engineering aeronautic problems, including photographs, structural forms, and other interesting specimens arranged by the Buffalo Committee.

The program for the technical sessions follows. It will be noted that the Aero Club of Buffalo joined in the session on airship and airplane carriers on Monday evening.

Monday Morning, June 6

Aerodynamics

Photogrammetric Measurement of Airplane Landing Speeds, Volney C. Finch
Some Observations on Spins, J. M. Gwinn, Jr.
A Study of Airplane Performance Parameters, Frederick R. Weymouth
Wind Loads on Airship Hangars, H. MacT. Sylvester

Navigation

Recent Advances in Weather Service in Relation to Aerial Navigation, Willis Ray Gregg
A Sonic Marker Beacon for Fog Aviation, Chester W. Rice
Aircraft Sextant, P. V. H. Weems
Parachutes in Relation to Passenger Air Transport, Guy M. Ball

Monday Afternoon, June 6

Metal Construction

Steel Airplane Construction, E. J. W. Ragsdale
Developments in Aluminum Alloys in Relation to Economies in Aircraft Construction, C. F. Nagel, Jr., and G. O. Hoglund
Evolution of Metal Construction, Gardner W. Carr (presented by title)
A Comparative Study of Welded and Riveted Fuselages, Philadelphia Aeronautic Society. Presented by Louis C. Rosenstein and C. Bennett
Monocoque Aircraft Construction in Theory and Practice, Richard L. Schleicher

Engines

Shaft Drives for Airship and Airplane Propellers, J. L. Goldthwaithe
Torsional Vibration of Aircraft Engine Crankshafts, W. G. Lundquist
Air Compression With Temperatures Above Adiabatic—With Special Reference to Airplane Superchargers, Sanford A. Moss

Monday Evening, June 6

Airship and Airplane Carriers

(Joint auspices Aero Club of Buffalo and Aeronautic Division)
Airplane Carriers, H. B. Miller
Mechanical Equipment for Handling Large Rigid Airships, C. M. Bolster
Artificial Payload for Coming Commercial Airships, T. L. Blakemore

Maintenance

Aviation Maintenance Manual, Jerome Lederer
Relation of Maintenance to Design, R. G. Lockwood
Effect of Plane Impact on Airport Surfacing, C. N. Conner
Report on Wage Incentives in Aeronautic Industry, W. T. Tiffin

Tuesday Afternoon, June 7

Design

Cost of Air-Line Operation, W. Irving Glover
The Ideal Transport Airplane, Ernest W. Dichman
Standardizing Location and Direction of Movement of Stabilizer Control, Clifford Swartz
Heating and Ventilating of Cabin Airplanes, M. Gould Beard
The Possibilities of Cabin Type Autogiros, A. E. Larsen
Aeronautical Research in Canada, J. J. Green, George J. Klein, and K. F. Tupper

Fuels and Engines

Aircraft Engine Steels, N. L. Deuble
Combustion Processes in Aircraft Engines, H. K. Cummings
Recent Developments in Grading of Fuels for Aeronautic Use, W. W. White
Relation of Quality to Economies in Manufacture of Aviation Gasoline, G. G. Oberfell

Applied Mechanics Division

NEW HAVEN, CONN., JUNE 23–25, 1932

The Second National Meeting of the Applied Mechanics Division was coordinated with the summer meeting of the American Physical Society at Yale University, under the auspices of the New Haven Section, with a combined attendance of nearly three hundred. The meeting was reported in the *A.S.M.E. News* of July 22, 1932.

The Applied Mechanics Division held five sessions of its own and one jointly with the American Physical Society. The program for these sessions follows.

Thursday Morning, June 23

Hydro- and Aerodynamics

Resistance of Slender Bodies Moving With Supersonic Velocities, Th. von Karman and N. B. Moore
On the Life Distribution for a Wing of Arbitrary Plan Form in a Circular Wind Tunnel, C. B. Millikan
On the Buckling Strength of Columns With Elastic Intermediate Supports, W. Klemperer (presented by title)
A New Kind of High-Speed Water Craft (Film), O. Tietjens

Thursday Afternoon, June 23

Vibration

Vibration During Acceleration Through a Critical Speed, F. M. Lewis
Self-Induced Vibrations, J. G. Baker
Critical Torsional Oscillations of a Rotating Accelerating Shaft, M. Biot
Vibration With Velocity Damping, M. Stone
Vibrations of a System With Two Degrees of Freedom Analyzed by Vector Diagrams, J. L. Mansa (presented by title)
Calculation of the Stresses Occurring in a Building During an Earthquake, M. Biot (presented by title)

Friday Morning, June 24

Bending of Long Rectangular Plates With Lateral Loading, S. WAY
Strength of Semi-Circular Plates and Rings Under Uniform External Pressure, A. M. WAHL
Shearing Stresses in Torsion and Bending by Membrane Analogy, P. ALLERTON CUSHMAN
Concentration of Stress Around Spherical and Cylindrical Inclusions and Flaws, N. GOODIER
The Design of Columns of Varying Cross-Sections, A. N. DINNIK (presented by title)

Friday Afternoon, June 24

ELASTICITY AND PLASTICITY

Creep of Metals, A. NADAI
The Elastic Behavior of Vulcanized Rubber, H. HENCKY
Creep in Bending, G. MACCULLOUGH
Stress Distribution in a Re-entrant Corner, J. H. A. BRAHTZ
Distribution of Stress Due to a Single Force Acting on the Edge of a Circular Hole, etc., W. O. RICHMOND (presented by title)
The Distribution of Pressure Concentrated on a Small Surface, M. A. SADOWSKY (presented by title)
Solution of Problem of Plane Strain in Bending, J. M. KLITCHIEFF (presented by title)

Saturday Morning, June 25

JOINT SESSION WITH AMERICAN PHYSICAL SOCIETY

Mosaic Crystals Structure, F. ZWICKY
Plasticity of Metals, F. BITTER
Dissipational Resistance to Distortion in Solid Bodies and Its Correlation With Other Physical Properties, R. L. WEGEL and H. WALTHER

Saturday Afternoon, June 25

THERMAL STRESSES

Thermal Stresses in Spheres and Cylinders Produced by Temperatures Varying With Time, C. H. KENT
Some Changes of Shape Characteristics of a Smooth, a Corrugated, and a Creased Pipe Bend Under Load, E. T. COPE and E. A. WERT

The entertainment features included an inspection of the Sterling Memorial Library, where tea was served on Thursday afternoon, a dinner at the Lawn Club that evening, followed by a performance at the University Theater by the Yale Dramatic Society, and a joint outing of the Applied Mechanics Division and American Physical Society on Friday afternoon. Another feature of the meeting was an exhibit of special testing devices arranged by the local committee.

Iron and Steel Division

PITTSBURGH, PA., APRIL 28, 1932

The Iron and Steel Division, in cooperation with the Pittsburgh Section of the Society and the Engineer's Society of Western Pennsylvania, held a joint meeting on Thursday afternoon, April 28, 1932. Arthur G. McKee, Chairman of the Division, presided. The meeting was held at the William Penn Hotel in Pittsburgh, and was preceded by a luncheon program.

Machine Shop Practice Division

BUFFALO, N. Y., OCTOBER 3, 1932

As part of the National Metal Congress held in Buffalo the week of October 3, 1932, the Buffalo Section and Machine Shop Practice Division of the Society held two technical sessions on Monday, October 3, at the Hotel Statler. The Society of Automotive Engineers also held a session on the same day, and both societies joined in a luncheon meeting at which Kenneth Condit, editor, *American Machinist*, discussed "Equipment Policies."

The following papers were presented at the A.S.M.E. sessions:

Monday Afternoon, October 3

The Influence of Oil Compressibility on Speed Characteristics of Hydraulic High-Speed Presses, WALTER ERNST
The Torque Required to Tap Cast Iron Using National Coarse-Thread Series and National Fine-Thread Series Taps, J. E. MILLER
Recent Trends in Machine-Tool Design, GUY HUBBARD

Monday Evening, October 3

Technique of Size Control in Precision Grinding, R. E. W. HARRISON
Design of Products to Utilize Die Castings of Machine Parts, L. H. MORIN
Materials for Modern Cutting Tools, J. V. EMMONS

As part of the Congress there was the annual exhibit of metal-treating equipment.

During the week the American Society for Steel Treating presented a program of thirty papers, the American Welding Society held its semi-annual meeting, and the American Institute of Mining and Metallurgical Engineers, through its Iron and Steel and Institute of Metals Divisions, sponsored five sessions.

A somewhat more complete report of this meeting was published in the *A.S.M.E. News* for October 22, 1932.

M-M-M Congress

DETROIT, MICH., MAY 4–5, 1932

The Detroit Section of the Society was host to the Management, Maintenance, and Materials Handling Congress held on May 4 and 5 in connection with the annual meeting of the Ameri-Foundrymen's Association.

The attendance at the M-M-M Congress was more than two hundred. The meeting was recorded in the *A.S.M.E. News* of June 7, 1932.

The Management Division and its Subcommittee on the Elimination of Waste and the Materials Handling Division and its Manufacturers' Committee joined in the following technical program, with the Materials Handling Institute cooperating in one of the sessions.

Wednesday Morning, May 4

Maintenance of Materials-Handling Foundry Equipment, THOS. A. BISSELL
Relative Wear of Metals by Abrasion, C. R. WEISS
Management Policies and Practices in a Continuous Production Gray-Iron Foundry, W. G. REICHERT

Thursday Morning, May 5

MANAGEMENT

Waste Elimination Symposium

Elimination of Waste in Industry, E. S. CARMAN
Savings by Substitution of Other Materials, GEO. BANGS
Common Savings in Shop Wastes, C. B. HALL
Weekly Accounting of Waste, S. K. COOPER (presented by title)
Maintaining Interest in Suggestion Systems, W. E. FISHER (presented by title)

MATERIALS HANDLING

(Auspices of Manufacturer's Committee, Materials Handling Division, Materials Handling Institute cooperating)

Report on Performance Standards of Locomotive and Crawler Type Cranes and Shovels, F. A. SMYTHE
Report on Capacity of Containers, W. E. FARRELL
Report on Nomenclature and Classification of Materials-Handling Equipment, GEO. L. MOREHEAD
Report on Materials-Handling Lectures and Meetings in Colleges, MATTHEW W. POTTS
Report on Standardization of Materials-Handling Equipment, J. M. ENDERS

Thursday Afternoon, May 5

Management

Knowledge of Markets and Its Effect on Product Design, R. F. Elder

International Trade of the United States, George Quisenberry

Materials Handling

(Auspices American Foundrymen's Association, Materials Handling Division cooperating)

Tramrail for Materials Handling in the Foundry

Materials-Handling Problems in the Foundry Department of the Western Electric Company

Materials Handling as Related to Miscellaneous Jobbing Foundries

The program also included an inspection trip to the plant of the Ford Motor Company and a dinner at which the speakers were R. L. Lockwood, of the U. S. Department of Commerce; John Van Deventer, editor of *Iron Age;* and representatives of the Divisions.

Oil and Gas Power Division

STATE COLLEGE, PA., JUNE 8–11, 1932

The Fifth National Meeting of the Oil and Gas Power Division was held at Pennsylvania State College concurrent with the Fifth Oil Power Conference of the college. As in previous years there was an interesting exhibit of Diesel engine parts and accessories. The program of technical papers was as follows:

Wednesday Morning, June 8

Heating Fuels for Injection Engines, Edward Adams Richardson

Spray Characteristics of a Jerk-Pump Injection System, O. F. Zahn, Jr.

Wednesday Afternoon, June 8

Surface-Volume Ratio as a Critical Factor in Automotive Diesel Combustion Chambers, Julius Kuttner, with discussion of Fuel Injection Engines With Subdivided Combustion Chamber and Heat Accumulator, by Kurt Neumann

Fuel Spray Formation, Dana W. Lee

Combustion Knock in Diesel Engines, P. H. Schweitzer

Thursday Morning, June 9

Metallurgical Problems of Diesel Engines, Russell J. Allen

Fuel Injection in Gas Engines, E. G. Beardsley and J. N. MacKendrick

Friday Morning, June 10

Diesel Power Cost Committee Report, presented by M. J. Reed

Burning Heavy Oil in Diesel Engines, H. W. Stalnaker

Saturday Morning, June 11

Inertia Supercharging of Engine Cylinders, E. S. Dennison

Ignition Quality of Diesel Fuels; Cetane Figures as Compared With Octane Figures, G. D. Boerlagd

The *A.S.M.E. News* of June 22, 1932, includes comments on the discussion of these papers.

The new Nittany Lion Inn on the campus served as headquarters and was the scene of several entertainment features, including an informal dance, card party, and banquet. Prof. C. M. Allen, vice-president of the Society, was the chief speaker at the banquet. Other events were a golf tournament, and a picnic and baseball game.

Printing Industries Division

NEW YORK, N. Y., MARCH 14–15, 1932

The Third Conference of the Technical Experts in the Printing Industry, sponsored by the Printing Industries Division, with the New York Club of Printing House Craftsmen assisting, and the McGraw-Hill Publishing Company as official host, drew an attendance of nearly one thousand. The technical sessions were held in the new building of the McGraw-Hill Publishing Company on West 42nd Street, and a considerable number of those attending the conference took advantage of the opportunity to be shown through the building.

In addition to the technical sessions there were four group conferences, dealing with the following subjects: Thickness of Curved Plates and the Depth of the Recess for Such Plates, Humidity as It Affects Printing, Standards on Paper, and Closer Cooperation Between the Different Printing Crafts.

At the opening session of the meeting Calvin W. Rice, secretary of the A.S.M.E., gave a talk on "The Art of Printing as a Source of Special Satisfactions." The speaker at the banquet on the evening of March 14 was Joseph F. Gillick, president of the American Type Founders Company, whose subject was "What Is Ahead of the Printing Industry?" Arthur C. Jewett, director of the College of Industries of the Carnegie Institute of Technology, was toastmaster, and Hon. George H. Carter, Public Printer of the United States, gave a brief talk. The telephotograph service was demonstrated at the banquet by Dr. J. O. Perrine, and the Walter Howey photoelectric engraver process by B. W. Woodward. There was also a cabinet exhibit, "Edison as a Printer." Following the morning session on Monday Dr. Perrine demonstrated television, and after Tuesday's morning session Robert E. Naumburg demonstrated the automatic printing visagraph.

The program of technical papers for the conference, which was reported in the *A.S.M.E. News* of April 7, 1932, follows. The papers presented at the conference were published with discussion in a special pamphlet form.

Monday Morning, March 14

Application of Engineering to the Printing Industry, George C. Van Vechten

Developments in New Printing Processes, Clarence L. Johnston

Monday Afternoon, March 14

Advanced Stereotype Methods, Arnold A. Schwartz

Advanced Electrotype Methods, John H. Davis

Premakeready Developments, George F. Bryant

Tuesday Morning, March 15

Newspaper Multi-Color Printing, George E. Pancoast

Progress in Offset Printing, Otto R. Trampusch

What Can Science Do for Practical Determination of Color Standards for Printing, Loyd A. Jones

Tuesday Afternoon, March 15

Relation of Press Speeds to Production, John J. Maloney

Condition of Paper as It Affects Printing, William G. MacNaughton

Printing Rollers, Arthur H. Burns

Process Industries Committee

BUFFALO, N. Y., JUNE 6–7, 1932

As already noted in the report of the Aeronautic Meeting at Buffalo, the Process Industries Committee held its First National Process Meeting on the same dates, the two groups having joint entertainment features. The meetings were reported in the *A.S.M.E. News* of June 22, 1932.

The plants visited by the process group on the morning of June 7 were those of Pratt & Lambert, Inc., the Buffalo Foundry & Machine Co., and the Buffalo Pottery Company (Larkin Company), the last-named being luncheon hosts.

An exhibit of process equipment arranged by the Buffalo Committee attracted considerable interest. Four technical sessions were held as follows:

Monday Morning, June 6

Grinding Symposium

An Analysis of Crushing and Pulverizing Processes as Related to Industrial Operation, Lincoln T. Work

Monday Afternoon, June 6

Heat Transmission

The Flow of Fluids in Closed Conduits, R. J. S. Pigott
Design Alignment Charts, T. H. Chilton, A. P. Colburn, R. P. Generaux, and H. C. Vernon
Fluid Friction at Parallel and Right Angles to Tubes and Tube Bundles, E. N. Seider and N. A. Scott, Jr.

Dust Problems

Silicosis, A. E. Russell
Dust Determinations, J. J. Bloomfield
Improved Methods of Dust Collecting, George Kelley
Shop Methods of Controlling Dust Hazards, F. Willson

Tuesday Afternoon, June 7

General Process

The Manufacture of Rubber-Covered Wire for Telephone Installations, S. E. Brillhart
Industrial Air Conditioning, Geo. B. Bailey
Developments in Cotton-Seed-Oil Processing, W. R. Woolrich

Textile Division

BOSTON, MASS., OCTOBER 27, 1932

A New England Textile Meeting was held on October 27, 1932, at the Massachusetts Institute of Technology under the auspices of the Boston Section and the Textile Division. After a morning inspection trip through the Boston Woven Hose & Rubber Co. and the laboratories of the Institute, luncheon was served in the Walker Memorial Building of the Institute.

At an afternoon session four papers were presented, as follows:

Textiles as They Are, E. R. Schwarz
Recent Developments in Spinning, James L. Truslow
The All-Electric Dye Jig, C. E. Robinson
Variable Speed Spinning, C. L. Irwin.

Wood Industries Division

JAMESTOWN, N. Y., NOVEMBER 15–16, 1932

The Seventh National Meeting of the Wood Industries Division, with the National Association of Furniture Manufacturers cooperating, was held at Jamestown, N. Y., on November 15 and 16, 1932, with two hundred in attendance. The Jamestown Hotel was headquarters for the meeting.

The meeting was opened at a luncheon with a talk by Dr. A. P. Haake, secretary of the National Association of Furniture Manufacturers, in which he outlined the economic problems facing the furniture industry and the need for engineering in their solution.

There were four technical sessions at which papers were presented as follows:

Tuesday Afternoon, November 15

Research

Timber Research and Wood Industries, W. Kynoch
Faith in Research, Arthur Koehler
Why Research in Furniture Manufacturing, G. R. Petrie and A. C. Saunders
Furniture Distribution, D. D. Fennell

Tuesday Evening, November 15

Machinery

Different Methods of Taking Lumber Out of Wind, A. S. Kurkjian
Different Methods of Making Glue Joints, G. M. Diehl
The Electric Moulder and Its Efficiency, Anton Vonnegut

Wednesday Afternoon, November 16

Manufacturing

Door Construction, Design, and Manufacture, Sern Madsen
Modern Developments in Wood Finishing Materials, M. J. Pearce
Accelerated Varnish Drying, R. H. McCarthy and L. A. Lefcort

Wednesday Evening, November 16

Veneer and Plywood

Fundamentals of Knife Cut Veneers, J. R. and J. N. Roberts
Manufacture of Custom-Built Plywood, E. R. Morrison and E. J. Maroney
Some Practical and Theoretical Considerations Involved in Laminating With Phenolic Resin, E. H. Merritt
The Moisture Content, Specific Gravity, and Air Space in Woods, J. D. MacLean

Tuesday, Wednesday, and Thursday mornings were devoted to inspection trips to plants in Jamestown and vicinity manufacturing furniture and wooden toys and novelties, plywood, and woodworking equipment. Among the plants open for inspection were those of the Jamestown Lounge Company, Maddox Table Company, Union Furniture Company, Jamestown Panel Company, Curtis Machine Company, and Merritt Engineering & Sales Co. Considerable interest was displayed in the Jamestown Furniture Market during which the meeting was held. A more detailed report will be found in the *A.S.M.E. News* for December 7, 1932.

Necrology

WILLIAM AHLÉN (1857–1932)

William Ahlén, whose death occurred on July 17, 1932, was born at Arla, Sköllersta, Sweden, on April 7, 1857. He was graduated from the technical school at Örebro, Sweden, at the age of 21 and served a two-year apprenticeship at the Söderbloms Foundry & Machine Works, Eskilstuna, Sweden, following his graduation. He then came to the United States, where he was employed until 1887 by the Pennsylvania Railroad Company, at Altoona, Pa., being promoted from the position of machinist and draftsman to that of assistant chief draftsman.

After leaving the Pennsylvania he spent three years with the Norfolk & Western R.R. at Roanoke, Va., as draftsman for locomotives, cars, and machinery. From that time until his retirement in 1919 he was connected with the Carnegie Steel Company. He was located at the Homestead Steel Works of the company from 1890 to 1894 as assistant civil engineer, working on the construction of a pumping station, electric power station, armor plate plant, and cogging and beam mills. During the remainder of the time he was stationed at the Duquesne Steel Works and Blast Furnaces, for four years as civil engineer and thereafter as chief engineer. A large number of furnaces and mills were designed and built under his supervision, many novel features being introduced.

Mr. Ahlén became a member of the A.S.M.E. in 1912. Since his retirement he had made his home in Stockholm.

HARRY ALEXANDER (1871–1932)

Harry Alexander, who retired from active business in 1929, died in New York, N.Y., on October 18, 1932. He was born in that city on August 6, 1871, and after leaving school served an apprenticeship in shop work and machine construction with the Daft Electric Light Company, Greenville and Marion, N.J., from 1886 to 1888. Subsequently he worked as draftsman for that company and the Thomson-Houston Electric Company, Lynn, Mass. He was superintendent of construction for the Thomson-Van Depoele Mining Company from 1889 to 1891, and supervised the building of special and mining machinery for the company at the Somersworth Machine Shops at Dover, N.H.

During the latter part of 1891 Mr. Alexander organized the Alexander-Chamberlain Electric Company, Inc., New York, N.Y., and became its vice-president and general manager, in charge of electrical and mechanical engineering work. He designed and installed power and electric plants for factories, hotels, and other buildings. The firm was reorganized in 1899 as Harry Alexander and was incorporated as Harry Alexander, Inc., in 1914, and he continued general mechanical and electrical engineering contracting, testing, and consulting work until his retirement in 1929.

Mr. Alexander became a junior member of the A.S.M.E. in 1895, an associate four years later, and a member in 1901.

MAGNUS WASHINGTON ALEXANDER (1870–1932)

Magnus Washington Alexander, a founder and president of the National Industrial Conference Board, Inc., died suddenly of heart disease at his apartment in New York, N.Y., on September 10, 1932.

Mr. Alexander was a native of New York, having been born there on February 17, 1870, the son of Alexander M. Alexander and the former M. Jelenkiewicz. He was educated abroad, studying mechanical, metallurgical, and electrical engineering at Vienna, Leoben, and Gratz in Austria. Trinity College later gave him an honorary M.S. degree.

After a few years in iron and steel work with the Oesterr. Alpine Montan. Gesellschaft, Mr. Alexander returned to the United States, in 1893, and entered the employ of the Weston Electrical Instrument Company as a designer. The following year he took a position with the Westinghouse Electric & Manufacturing Co., with which he remained until 1899. He then spent several months as chief designer for the Siemens & Halske Electric Co. of America, after which, in 1900, he became associated with the General Electric Company at Lynn, Mass. For 18 years he was engineer in charge of design for that company and then was made "consulting engineer on economic issues."

In 1916 Mr. Alexander helped to organize the National Industrial Conference Board, a body devoted to industrial planning and research, and since 1919 he had given the greater part of his time to its work. The offices of the board were moved from Boston to New York in 1920. Mr. Alexander was intensely interested in the industrial and economic problems of the country and each year made one or more trips to Europe to study conditions there. He was the author of many magazine articles and monographs upon economic subjects and an ardent spokesman in support of the policies of the board. He published a book on "Safety in the Foundry" and in other ways aided in the movement to further safety in industry. He was chairman from 1908 to 1910 of the Massachusetts Commission on Old Age Pensions, Annuities, and Insurance, a member from 1910 to 1912 of the Massachusetts Commission on Industrial Accidents, and chairman of the 1914 Commission on Pensions.

Mr. Alexander became a member of the A.S.M.E. in 1906 and also belonged to the American Institute of Electrical Engineers, the Verein deutscher Ingenieure, and the American Academy of Political and Social Science. His only club affiliation was the Engineers' Club, New York.

Surviving Mr. Alexander are his widow, the former Baroness Irmgard von Rothenthal, whom he married in 1927, and a son, Herbert.

SAMUEL SAUL AMDURSKY (1892–1932)

Samuel Saul Amdursky, consulting engineer and head of the mechanical department of the Taylor Instrument Companies, Rochester, N.Y., died on October 6, 1932, after a short illness.

Mr. Amdursky was born in Rochester on August 15, 1892. He prepared for college at the Rochester Athenium and Mechanics Institute, and received an M.E. degree from Syracuse University in 1916. During his college years he had considerable practical experience at the Rochester Municipal Laboratory, testing building materials such as cement, asphalt, and paving brick, and with the Rochester Gas & Elec. Corp., for which he designed gas distribution lines, made efficiency studies, and supervised construction work. He continued to work for this company for about two years after his graduation, designing and installing industrial gas furnaces and ovens.

During part of 1918 Mr. Amdursky was in the Mechanical Research Division of the Chemical Warfare Service, designing and perfecting various devices. In January, 1919, he entered the sales engineering department of the Taylor Instrument Companies, his work having to do with the design and application of temperature and pressure indicating, recording, and controlling devices. In this connection he also assisted in the layout of plants and equipment and in the design of heating systems required by various industrial processes.

Mr. Amdursky became a member of the A.S.M.E. in 1928 and belonged also to the Rochester Engineering Society and Society of American Military Engineers.

CARL ANGSTRÖM (1856–1932)

Carl Angström, a leading figure in the development of mechanical engineering in Sweden, died at his home in Stockholm on September 18, 1932. Mr. Angström was born in Taberg, Sweden, on April 22, 1856, the son of Carl Arendt Angström, a professor at the Technological Institute in Stockholm. After his graduation from the Institute Mr. Angström came to the United States. He was employed by the Pennsylvania Railroad as machinist and draftsman in 1877 and 1878 and subsequently by the Washburn & Moen Mfg. Co., Worcester, Mass., on the design of rolling mills and wire machinery.

He returned to Sweden in 1884, taking a position as mechanical engineer at the iron and steel works in Domnarfvet, where he remained until 1890. During the next two years he was government inspector of factories in the Southern District, Jonköping, Sweden. He then became managing director of the Motala Works, a position he retained until 1910. Since then he had engaged in consulting work in Stockholm.

Mr. Angström was a member of the Swedish Society of Engineers, which in 1882 awarded him the Polhem medal for his treatise on hydraulic turbines. He was a well known contributor to the technical press. He had been a member of the Swedish Society of Inventors since 1893 and held patents on a slide valve control for double cylinder or compound engines, an arrangement with two-cycle explosion or internal-combustion engines, and a device for control of water injection in explosion or internal-combustion engines. He was a director of the association of industrial owners in Sweden (Verkstadsföreningens överstyrelse) and had served as a judge at several industrial exhibitions in that country. He belonged to several other Swedish technical organizations and was a Knight of the Royal Order of Wasa and the Order of the North Star. He had been a member of the A.S.M.E. since 1883 and also belonged to the Iron and Steel Institute (London).

WILLIAM HOGG BAKER (1879–1932)

William Hogg Baker, whose death occurred on May 13, 1932, at his home in Montclair, N.J., was born in Philadelphia, Pa., on July 25, 1879, the son of Franklin and Sarah J. (Hogg) Baker. After securing his M.E. degree from Cornell University in 1901 Mr. Baker worked as draftsman for a year each with the Pencoyd Iron Works, Philadelphia, and the Atlas Portland Cement Company, New York, N.Y. He then went to Louisville, Ky., as chief engineer on the construction of the Kosmos Portland Cement Company plant, where he remained for two years. From 1905 to 1907 he served as manager of the Colorado Consolidated Mining & Electric Co., Breckenridge, Colo., and during the next four years engaged in private practice in engineering and construction work with headquarters in New York. In 1911 he returned to the employ of the Atlas Portland Cement Company, being assistant general superintendent for a time and later manager of the Western Manufacturing Department, at Hannibal, Mo.

About 1920 Mr. Baker accepted the vice-presidency of the Hardinge Conical Mill Company, New York. After several years in that office he was manager for a short time of the Fuller-Lehigh Company, New York, and president of the Quigley Fuel Systems, Inc. He became president in 1925 of the Acme Cement Corporation, Catskill, N.Y. He returned to private engineering practice in 1927 as president of Baker and Spencer, Inc., New York. Since 1928 he had been president of the Merritt-Chapman & Scott Corporation, New York. He was also director of the North America Cement Corporation and United Dry Docks, Inc., New York.

Mr. Baker became a member of the A.S.M.E. in 1915. His clubs included the Engineers', Whitehall, Down Town Athletic, and Cornell, in New York, and several other social and athletic clubs, among them being the Montclair Golf, The Knoll, Seaview Golf, and Boca Raton, Florida. He is survived by his widow, formerly Miss Catherine E. Brady of Denver, Colo., whom he married in 1906, and by four children, William H., Jr., Charles E., Edith L., and Sarah J. (Mrs. David Lindsay III).

THURMAN HARRISON BANE (1884–1932)

Colonel Thurman H. Bane, executive vice-president of the American Airways, Inc., New York, N.Y., a subsidiary of the Aviation Corporation, died on February 22, 1932, at the Neurological Institute of New York. Surviving him are his widow, Bessie Louise (Dichman) Bane, whom he married in 1909, and one daughter, Louise Bane.

Colonel Bane was born at San Jose, Calif., on June 12, 1884, the son of the Rev. Adam C. and Florence C. (Harrison) Bane. He was graduated from the United States Military Academy at West Point with the class of 1907, of which he was president. He served as a lieutenant of cavalry in the United States and the Philippines until 1912, when he was transferred to the Ordnance Department as first lieutenant. He was stationed at the Sandy Hook Proving Ground, New Jersey, for two years, first as a student officer in the School of Application and then as a proof officer, testing ordnance materiel. For a year, beginning in June, 1914, he was located at the Rock Island Arsenal, as assistant to the officer in charge of the armory and the harness shop.

In July, 1915, he returned to duty with his regiment, the 6th Cavalry, on the Mexican Border and with Pershing in Mexico. During the year spent there he became interested in aviation, and was transferred to the Signal Corps Aviation School, at San Diego, toward the end of 1916. He completed his training in May of the following year and was appointed secretary of the school and officer in charge of the experimental and repair shops. As a student flyer he worked out a course in aerodynamics and design which was accepted as standard.

In October, 1917, he was promoted to lieutenant-colonel, Air Service, and transferred to Washington, D.C. He was made chief of the technical section of the Bureau of Military Aeronautics early the following year, and advanced to the rank of colonel later in 1918. Following the Armistice he was appointed chief of the Engineering Division and commanding officer of the Aeronautical Experimental and Research Station of the Air Service at McCook Field, Dayton, Ohio, where he was stationed until being retired, at his request, at the end of 1922. He also served on the National Advisory Committee for Aeronautics from 1918 to 1922. While he was at McCook Field a parachute which is now standard equipment was developed by him. He also was a leader in aerial photography, and designed air-cooled engines and earth-induction compasses.

After his retirement in 1922 Colonel Bane spent six years in California. He turned his attention to commercial aviation in 1928, when he became chief of the technical section of the Aviation Corporation of Delaware, and was active in laying out some nine thousand miles of airways, which were lighted for night flying and equipped with landing fields and ground facilities under his direction. Colonel Bane also assisted in the development of a scientific staff for forecasting weather conditions for pilots which was complementary to the Government system. Radio telephony as adapted to airplanes occupied his attention and it was due to his efforts that the planes of the American Airways were equipped with telephones.

The King of Italy appointed Colonel Bane Commander of the Order of the Crown of Italy for technical service during the World War. He had been an associate member of the A.S.M.E. since 1918 and also belonged to the Society of Automotive Engineers and the Army and Navy clubs in New York and Washington, D.C.

LOUIS BARBER (1870–1932)

Louis Barber, mechanical engineer for The National Screw & Mfg. Co., Cleveland, Ohio, died of heart failure at his home in that city on July 9, 1932.

Mr. Barber was born at Ottawa, Canada, on June 17, 1870, the son of Alfred and Caroline (Cooper) Barber. He was educated by a private tutor and courses of the International Correspondence Schools. After about ten years in wood and metal pattern making he took a position as draftsman with The National Screw & Tack Co., which later became The National Screw & Mfg. Co. He was connected with this company during the remainder of his life, except from 1902 to 1904, when he was draftsman for the Brown Hoisting Machinery Company and the Royal Motor Car Company. He served the company for many years as machine designer and assigned to it two patents for improvements in a nut castellating machine.

Mr. Barber became a member of the A.S.M.E. in 1920 and was also a member of the Masonic fraternity. Surviving him are his widow, formerly Miss Eleanor Galloway, and two children, Mrs. C. G. Fox, Hudson, Ohio, and W. Donald Barber, of Cleveland.

FRANK GEORGE BAUM (1870–1932)

Frank George Baum, internationally known hydroelectric engineer, died at Redding, Calif., where he made his home, on March 14, 1932. As an inventor, writer, and consultant he made many notable contributions to the development of hydroelectric engineering.

Mr. Baum was born at Sainte Genevieve, Mo., on July 18, 1870, the son of Christen and Caroline Klein Baum. He was graduated from Stanford University with an A.B. degree in electrical engineering in 1898 and was an assistant instructor in that subject at the University during the following year, while working for his E.E. degree, which he received in 1899.

It is interesting to note that Mr. Baum's first position after leaving the University, with the Standard Electric Company of California, San Francisco, involved high-tension transmission work, for it was the transmission phase of the industry which he furthered to the greatest extent. After a few months in San Francisco he went to Pittsfield, Mass., where for about a year he was employed at the works of the Stanley Electric Company. He returned to Stanford University in 1900 as an instructor in electrical engineering, and during two years so spent also did special work in electrical transmission for the Bay Counties Power Company and others.

In March, 1902, Mr. Baum entered the employ of the California Gas & Electric Corp., remaining with this company and its successor, the Pacific Gas & Electric Co., for five years, in charge of hydraulic and electrical construction and operation. His work as a consultant was begun in 1907 and in this capacity and later as its chief engineer he continued for many years to assist the Pacific Gas & Electric Co. in the development of its system, and as consultant for many other companies played a large part in building up hydroelectric power on the Pacific Coast.

In the Piedmont, California, station he originated a method of compounding synchronous motor-generator sets, whereby the compounding of the exciters was taken from the shunt on the busbar of the railway load, changing the power factor of the motors and keeping the potential of the substation nearly normal. This was in line with his much later invention, the synchronizing condenser and regulator, announced in 1927, a device which solved the problem of economical transmission of large quantities of electrical power over distances of several hundred miles, dividing the lines into sections of from 100 to 200 miles linked by rotary regulators or condensers, each transmitting the current onward with small losses. By means of this device it became possible to materially increase the capacity of a line at a comparatively low cost, thus bringing about the economical transmission of power from distant points and permitting sparsely settled districts and farms to be supplied with electric power at a reasonable price.

The conception as well as the plans for the Pit River, California, project of the Pacific Gas & Electric Co. may be traced to Mr. Baum's appreciation of the possibilities of the basin. He designed the Hat Creek stations Nos. 1 and 2, Pit River No. 1, the 220,000-volt Pit transmission line, and the great Vaca substation at the receiving end.

He also put into practical form a type of high-tension switch and invented an outdoor high-tension switch which were quite generally introduced in western transmission systems.

In 1900, in conjunction with Dr. F. A. C. Perrine, Mr. Baum presented the first paper published on the calculation of the charging current in three-phase transmission lines, and developed his method of calculating the regulation of transmission systems, which forms the basis for his "Alternating-Current Calculating Device," published in 1902. His paper on "Surges in Transmission Systems," presented in 1902 before the Pacific Coast Transmission Association, first pointed out in a practical way a simple method of calculating the rise in pressure due to surges in transmission systems. In 1904 he presented a notable paper before the International Electric Congress, St. Louis, on high-tension, long-distance transmission and control. He was the author of a book entitled "The Alternating-Current Transformer," and in 1923 published an "Atlas of U.S.A. Electric Power Industry," outlining a plan for nation-wide electric service. His paper on "Voltage Regulation and Insulation of Large-Power Long-Distance Transmission System," won for him the annual transmission prize of the American Institute of Electrical Engineers in 1921 and was the basis for later work on the development of insulation and regulation systems. Many other articles dealing with different phases of hydroelectric power development and transmission were contributed to the technical press by Mr. Baum.

His work as a consultant took Mr. Baum to France and Germany, and he spent several years studying the European electrical power industry and compiled a voluminous report on the enlargement and extension of one of Germany's largest electric utilities. He had recently established extensive laboratories in the mountains in Northern California where he planned further study of hydroelectric problems.

Mr. Baum became a member of the A.S.M.E. in 1906. He served as vice-president of the American Institute of Electrical Engineers from 1906 to 1908 and was also a member of the American Society of Civil Engineers, several clubs in New York and San Francisco, and the Sigma Xi fraternity.

Surviving Mr. Baum are his widow, Mary Elizabeth (Dawson) Baum, formerly of Butte, Mont., whom he married in 1900, and three daughters.

BERNARD ARTHUR BEHREND (1875–1932)

Bernard Arthur Behrend, widely known as a consulting engineer in the electrical field and who had recently been in ill health, died on March 25, 1932, at his home in Wellesley Hills, Mass. Mrs. Behrend, formerly Miss Margaret Chase, of Boston, Mass., whom he married in 1926, survives her husband.

Dr. Behrend was an authority on the design of heavy alternating-current machinery, and his long and distinguished career placed him in the front rank of contributors to theory and practice. In recognition of his achievements, the honorary degree of doctor of engineering was conferred upon him in 1931 by the University of Darmstadt, Germany. The John Scott Medal was awarded him by the City of Philadelphia in 1912, upon the recommendation of The Franklin Institute.

He was born at Villeneuve, Switzerland, on May 9, 1875, the son of Moritz and Rebecca (Wolf) Behrend. His early education was secured by private tutelage in Switzerland, Paris, and in England, where part of his boyhood was spent. He studied civil and mechanical engineering at the Polytechnic Institute of Charlottenburg, Germany, and at the University of Berlin, from which he was graduated in 1894 with a C.E. degree. During the year following he was assistant to Gisbert Kapp as designer of power plants, and for the next three years assistant to the chief engineer of the Oerlikon Company, Switzerland, in charge of the Experimental and Testing Departments, working on the development and design of electrical machinery and the design of the Jungfrau Railway.

Dr. Behrend came to the United States in 1899, applied for citizenship at once, and was granted naturalization in 1903. After some consulting work and the delivery of a course of lectures at the University of Wisconsin on the theory and design of induction motors, he became connected in 1900 with the Bullock Electric Manufacturing Company, Cincinnati, Ohio, not long afterward being appointed its chief engineer. In 1904 this company was absorbed by the Allis-Chalmers Manufacturing Company, Dr. Behrend continuing in the office of chief engineer of the electrical departments in the United States and serving as consulting engineer to Allis-Chalmers Bullock, Ltd., Montreal, until 1908, with headquarters at the main plant at West Allis, near Milwaukee, Wis., during the latter part of the time. In 1908 he was invited to join the engineering force of the Westinghouse Electric & Manufacturing Co. at East Pittsburgh, Pa., and assumed his duties early the following year, shortly afterward taking charge of the Power Division. About two years later he opened an office in Boston as consulting engineer and was retained in that capacity by the Westinghouse company for many years. He gave up the Boston office in 1926 and since then had continued his practice at Wellesley Hills.

Dr. Behrend was a frequent contributor to technical literature. An early article of first-rate importance, written in the summer of 1895 and published in *Elektrotechnische Zeitschrift* in February, 1896, dealt with the theory of the circle diagram which he had originated for calculating the performance of induction motors in a simple and direct manner. The substance of his lectures at the University of Wisconsin in 1899, covering single-phase as well as polyphase motors, was published in 1901 under the title, "The Induction Motor, Its Theory and Design," translations appearing in French in 1902, German, 1903, and some sections later even in Japanese. A new edition, considerably enlarged and revised, appeared under the title, "The Induction Motor and Other Alternating-Current Motors," in 1921.

Another of Dr. Behrend's early achievements was the successful design of alternating-current machinery, including a.-c. generators and induction motors, many of them of difficult ratings for those days. In a paper which he presented before the American Institute of Electrical Engineers in 1903, entitled "The Experimental Basis for the Theory of the Regulation of Alternators," he suggested improved methods for determining regulation which were later made the basis of the rule adopted by the Standards Committee of the Institute.

The following year he presented a paper on "The Testing of Alternating-Current Generators" at the International Electrical Congress in St. Louis, Mo., dealing with his "split-field" method. This method enabled him to test alternators at nearly zero power factor, adequate load being obtained by one part of the machine having lagging, and the other leading, current.

The first turbo-alternator built by the Bullock Electric Manufacturing Company, jointly with Hoovens, Owen & Rentschler under Dr. Behrend's supervision, was exhibited at the Louisiana Purchase Exposition at St. Louis, in 1904. This unit demonstrated the radial-slot cylindrical turbo-rotor with chrome-nickel-steel end rings now generally standard construction with all manufacturers of turbo-generators. It received a grand prize at the exposition and Dr. Behrend was awarded a gold medal for its design. The largest power unit of the exposition, a 3500-kw. generator driven by an Allis-Chalmers engine, was also designed by him and secured for itself the name of "Old Reliable," as it was always functioning when other units were out of commission.

While Dr. Behrend was still with the Bullock company he made a study of the distribution of stresses in rotating disks and tested the permanent deformation of lead disks driven at high speed. Some of his results were published in a paper entitled "A New Large Generator for Niagara Falls," presented to the A.I.E.E. in 1908, in which he showed how stresses are distributed, both radially and tangentially, in a high-speed disk.

Among many other technical papers contributed to the A.I.E.E. by him were those dealing with the mechanical forces in dynamos caused by magnetic attraction, the elementary theory of surges on long lines, the winding of electric generators for 22,000 or more volts, and the feasibility of this voltage, even for small outputs. He was also the author of miscellaneous publications, including papers on the achievements of Oliver Heaviside and C. E. L. Brown, engineering education, and machine tools.

As an educator he had been non-resident lecturer at Leland Stanford, Jr., University, McGill University, and the Massachusetts Institute of Technology, in addition to the University of Wisconsin. In 1901 he organized the first engineering training classes at Cincinnati, Ohio, under A. G. Wessling.

His work between 1900 and 1908 included several other achievements of particular note. In collaboration with Ralph D. Mershon he brought about the first successful paralleling of several large power stations connected through transmission systems and synchronous frequency changers. This was the linkage, at Montreal, of power from the Lachine Rapids, the Montreal Light, Heat & Power Co., and Shawinigan Falls, 80 miles distant.

In an important instance of the parallel operation of large gas-engine-driven alternators dealt with by him and his assistant, Mr. A. B. Field, the somewhat bold course was successfully adopted of using very light flywheels, with the natural frequency between two forced frequencies, rather than lower than the lowest frequency; the fifteen 3000-kva sets of the Indiana Steel Company, at Gary, were so designed. Other groups of large gas-engine-driven alternators were built for the power houses of the United States Steel Corporation at Rankin, Pa., the Illinois Steel Company, South Chicago, Ill., and the American Steel & Wire Co., Cleveland, Ohio. Dr. Behrend also designed the electric generating units for the Kern River Power Company, the Pacific Electric Company, the Denver Gas & Electric Co., a large group of units for Niagara Falls, and the steam-turbine units of the Brooklyn Edison Company and Brooklyn Rapid Transit Company, at that time the largest and fastest of their type.

The plate-rotor construction which the Westinghouse Company has used for many years in its large turbine generators of more than two poles was another product of Dr. Behrend's inventive ability. It overcame the danger of failure occurring in high-speed turbine-generator rotors from lack of homogeneity, from internal shrinkage stresses, or from pipes, cracks, etc., which are liable to appear in large steel castings or forgings. In all, he took out more than 80 patents, the most of which were assigned to the Allis-Chalmers or Westinghouse companies.

Dr. Behrend was a senior vice-president of the American Institute of Electrical Engineers, which he had also served as manager. He was a Fellow of the Institute and had been particularly active in its committee work. He had served as chairman of its Electrical Machinery Committee and Committee on Professional Conduct and had represented the Institute on the Edison Medal Committee, Standards Committee, U.S. National Committee of the International Electrotechnical Commission, and Engineering Societies Library Board. He was the first chairman of the Cincinnati Section of the Institute.

He was also a Fellow of the American Physical Society, the American Association for the Advancement of Science, and the American Academy of Arts and Sciences. He had been a member of the A.S.M.E. since 1909 and also belonged to the American Society of Civil Engineers, The Franklin Institute, the Institution of Electrical Engineers (Great Britain), and the Society for the Preservation of New England Antiquities, as well as the Engineers' Clubs in New York and Boston and the Pittsburgh Athletic Club.

WILLIAM DIETRICH BERGMANN (1892–1932)

William Dietrich Bergmann, who died on December 15, 1932, was born on March 20, 1892, in Schenectady, N.Y., the son of William Dietrich and Henrietta (Fischer) Bergmann. He attended the New York State Institute for the Deaf until he was fourteen and then the Barnard School for Boys of Columbia University for several years. From 1916 to 1922 he had a varied experience in designing, making detailed drawings and layouts for different companies and individuals in New York and vicinity. He worked on engines for the Aeronautical Motor Corporation, Long Island City, N.Y., and the Duesenburg Motor Corporation, Elizabeth, N.J.; a motorcycle and light automobile for the Militor Corporation, Jersey City, N.J.; and an electric furnace for a foundry in Brazil, an asphalt plant in Japan, and a U.S. Army tank tractor, as draftsman for consulting engineers. For a time he was assistant in charge of a film laboratory in the New York district for Movette, Inc., of Rochester, N.Y., and had made a special study of moving picture photography and also of television. He also was employed by the Electric Car & Locomotive Corp., Petroleum Power Devices Corporation, and Dickinson Cord Tire Corporation. Subsequently he was on the staff of the Borough president of Queens, in Long Island City, as mechanical designer and engineer for some years.

Mr. Bergmann became a junior member of the Society in 1920 and an associate member six years later. He is survived by his widow, Lillian (Berg) Bergmann and two daughters, Etta L. and Marie E. Bergmann, and by his mother.

JAMES LORD BERNARD (1870–1932)

James Lord Bernard, who died of pneumonia at Beaver, Pa., on August 20, 1932, was born on November 10, 1870, in Philadelphia. His parents were William and Sarah (Lord) Bernard.

After completing his public school work Mr. Bernard attended the Episcopal Academy in Philadelphia and was graduated from the University of Pennsylvania in 1892 with a B.S. degree. From then until 1901 he was connected with the A. & P. Roberts Co., Pencoyd, Pa., for three years in the office of the superintendent of motive power, as draftsman, for about five years in the repairs department, working on engines, boilers, etc., and the remainder of the time as inspector and engineer of tests.

Mr. Bernard became assistant mechanical engineer of the American Bridge Company in Philadelphia in 1901 and three years later was made chief mechanical engineer, with office at Ambridge, Pa., the position which he held at the time of his death. He held a number of patents in the United States and Canada relating to power house, rolling mill, and bridge shop operations. He was an authority on matters pertaining to power generation and utilization and outstanding in machinery invention and design.

Mr. Bernard became a member of the A.S.M.E. in 1902. He is survived by his widow, Sophia (Lehman) Bernard, whom he married in 1894.

CHARLES HAROLD BEST (1898–1932)

Charles Harold Best, technical engineer of the Marysville Power House of The Detroit Edison Company, Port Huron, Mich., died on March 28, 1932, in Detroit. He was born at St. Helens, Lancashire, England, on August 2, 1898, the son of Thomas Thompson and Ada (Fisk) Best. He was educated in England, receiving a Bachelor of Engineering degree from Liverpool University in 1922.

Mr. Best worked in the shops of the Metropolitan Vickers Company in Manchester during his university vacations. His first position following his graduation was in Canada, for the Canadian Salt Co., Ltd., Windsor, Ontario. He came to the United States late in 1922 and had since been connected with The Detroit Edison Company, first as a student engineer and since 1925 as technical engineer at the Marysville plant.

Mr. Best became a junior member of the A.S.M.E. in 1927 and belonged to the Congregational Church and several local clubs. He is survived by his widow, Elsie (Degen) Best, whom he married in 1930.

HUGO BILGRAM (1847–1932)

Hugo Bilgram, inventor of the bevel gear generator and an economist of note, died at his home in Moylan, Pa., on August 27, 1932, at the age of 85. Until two years before his death he had been active in the Bilgram Machine Works, Inc., of Philadelphia, of which he was president and owner.

Mr. Bilgram was born in Memmingen, Bavaria, on January 13, 1847, the son of George David and Rosina (Wiedemann) Bilgram. He was graduated from the Augsburg Maschinenbau Schule, where he studied mechanical engineering, in 1865, and worked as a draftsman and machinist for several firms in Germany before coming to the United States four years later.

His first business connections in this country were with the L. B. Flanders Company and the Southwark Foundry & Machine Co., in Philadelphia, for which he designed instruments and machines. During this period, in 1876, he also assisted in an evening class in drawing at The Franklin Institute. In connection with the drawing of accurate outlines of the teeth of gear wheels, he developed a method which led to the design in 1883 of a machine for cutting the teeth of gear wheels, particularly of bevel wheels. Later it was improved and adapted to production work, especially in the automotive industry, greatly facilitating the manufacture of bevel gears.

The Bilgram Machine Works grew out of the Brehmer Brothers Company, for which Mr. Bilgram first worked as a machinist. In 1879 the main works were transferred to Germany, and Mr. Bilgram was put in charge of the branch in this country. He became sole owner in 1884 and later incorporated the company under his own name.

Mr. Bilgram is also credited with several other inventions in connection with gear manufacturing, and wrote several books on mechanical engineering and on economics, including "Slide Valve Gears," "The Remedy for Overproduction and Unemployment," "Involuntary Idleness," and "The Cause of Business Depressions." His achievements won him a number of medals, including the Elliott Cresson Gold Medal of The Franklin Institute, the John Scott Medal of the City of Philadelphia, and awards of various world expositions. He was also an amateur botanist and was keenly interested in microscopic work.

Mr. Bilgram's was the oldest membership in The Franklin Institute and he was one of the early members of the A.S.M.E., which he joined in 1885. He also belonged to the American Academy of Political and Social Science, the Philadelphia Technische Verein, and the Engineer's Club of that city.

Surviving Mr. Bilgram are a son, Oscar Bilgram, and a daughter, Miss Bertha Bilgram, both of Moylan. His wife was Mary Fisher, of Philadelphia, whom he married in 1872.

GEORGE HUTCHINSON BLACK (1872–1932)

George Hutchinson Black, mechanical superintendent of the Berkshire Fine Spinning Associates, Adams, Mass., died on November 9, 1932, after a few weeks' illness. He was an associate member of the A.S.M.E., which he joined in 1919, and belonged to the Masonic fraternity.

Mr. Black was born in Dunfermline, Fifeshire, Scotland, on March 26, 1872, the son of David and Janet (Hutchinson) Black. He was educated in Scotland and served a four-year apprenticeship as draftsman, patternmaker, erecting engineer, and lathe hand at the foundry of Messrs. Bennett & Sons, Dunfermline.

During the next two years, 1891–1893, he was erecting and repair engineer for Hendersons Anchor Line, Govan, Glasgow. He then went to Hyde, near Manchester, England, where he was connected for about seven years with Messrs. G. B. Goodfellows & Sons, stationary engineers, experimenting on and building cold-air refrigerating machines for ship cargoes. After two more years in Hyde as mechanical engineer for the Newton Bank Calico Printing Company, he came to the United States.

Mr. Black's first position here was with the American & British Mfg. Co., Providence, R.I., as erecting engineer and on general work in connection with oil and steam engines. He was also employed for a time by the George H. Corliss Co. in Providence. In 1908 he became mechanical superintendent at the Kilburn Mills, New Bedford, Mass., with which he was connected until the latter part of 1917. After about six months with the Acushnett & Hathaway Corp., also in New Bedford, he became mechanical superintendent for the Berkshire Cotton Manufacturing Company, Adams, Mass., which later merged into the Berkshire Fine Spinning Associates.

Surviving Mr. Black is his widow, Elizabeth (MacLaren) Black, whom he married in 1928.

HOWARD EDWARD BOARDMAN (1879–1932)

Howard Edward Boardman, recently appointed Dudley professor of railroad engineering in the Graduate School of Yale University, died of pneumonia on February 28, 1932, at his home in New Haven, Conn. Professor Boardman was the first to hold this chair, the purpose of which is to develop, in cooperation with railroads, practical and scientific research in the general field of railroad engineering, and to guide graduate students in this field. Although he had but recently begun the work, he had already achieved marked success in outlining a program of research and in interesting leading railroad executives and promising students in his plans.

Professor Boardman was born in Meriden, Conn., on March 17, 1879, the son of Edward Allen and Nellie (Savage) Boardman. His early education was secured in Meriden and he was graduated from the Civil Engineering Department of the Sheffield Scientific School of Yale with a Ph.B. degree in 1899. The honorary degree of Master of Arts was conferred upon him by Yale in 1931.

Following a year as instrumentman for the Pennsylvania Railroad making preliminary surveys for branch-line construction in Central Pennsylvania and New Jersey and another year as assistant in the Engineer Corps on lines west of Pittsburgh, during the latter part of the time in charge of construction at a large freight interchange yard at Conway, Pa., he was transferred to work on the Pennsylvania tunnels under the Hudson River. He was engaged in this work from 1902 to 1909, serving successively as chief of party, assistant engineer, and senior assistant engineer. Surveys, contract drawings and specifications, estimates, cost records, and reports were made by him, and he was in charge of the alignment of the tunnels and inspection of excavations and tunnel linings.

In 1909 Professor Boardman entered the employ of the Missouri Pacific Railway as senior assistant engineer in its Maintenance of Way Department. He had charge of the construction carried on by the office of the chief engineer, entailing drafting, estimating, investigations and reports, and varied construction work. Later, as division engineer for that road, he was in charge of maintenance of more than five-hundred miles of line.

Leaving the Missouri Pacific in 1912, Professor Boardman went to Buenos Aires, Argentina, taking the position of chief assistant engineer of the Buenos Aires Western Railway. He remained there for about four years, in charge of layout and construction of four miles of concrete-lined electrified railway tunnel under the city of Buenos Aires, with a joint underground passenger station.

After his return to the United States in 1916 he was appointed engineering assistant to the General Valuation Counsel, New York Central Lines, New York, N.Y. Special reports and cost analyses, the preparation of data for the Interstate Commerce Commission, and general valuation work on the several lines of the road, engaged his attention during his seven years with it.

During the latter part of 1922 Professor Boardman accepted the office of president and treasurer of the Foster Merriam & Co., Meriden, Conn., hardware and metal specialty manufacturers and gray-iron and brass founders. He entirely reorganized the financial structure of the company, greatly reduced overhead expenses, designed and brought out new products, realigned the sales policy, and increased sales about seventy-five per cent during the next four years. In 1927 and 1928 he was sales manager, in charge of sales, sales engineering, and experimental work for the Divine Brothers Company, Utica, N.Y., constructing, designing, demonstrating, and selling automatic and other machinery for the use of the metal finishing industry. Following this he was for one year manager of research and assistant to the president of the National Industrial Conference Board in charge of the organization engaged in collecting and interpreting authentic industrial economic information and statistics. From then until his appointment at Yale he had been employed as construction engineer for the Boston & Maine R.R.

Professor Boardman had been a member of the A.S.M.E. since 1927 and also belonged to the American Society of Civil Engineers. Surviving him are his widow, Enna M. (Jenkins) Boardman, whom he married in 1903, and two sons, Edward T., and Howard Foster Boardman.

FREDERICK BAYLIS BROWN (1881–1932)

Frederick Baylis Brown, consulting engineer, Montreal, Canada, was instantly killed on August 6, 1932, when struck by the propeller of a seaplane at Lac Ouareau, his summer home.

Mr. Brown was born in Montreal on December 27, 1881, the son of William Forbes and Annie C. (Baylis) Brown. He received his early training at the Montreal Collegiate Institute and the Montreal High School, and then enrolled at McGill University, from which he received the degree of Bachelor of Science in 1903, with honors in mechanical engineering. The following year he took honors in electrical engineering and in 1905 he was awarded the degree of Master of Science for research work in civil, hydraulic, and mechanical engineering subjects.

Mr. Brown's first practical experience in engineering was as an apprentice in the machine shop of the firm of Pillow and Hersey in Montreal during his college vacations. In 1904 he was employed in the locomotive shops of the Grand Trunk Railway System at Point St. Charles, and for the next five years was a member of the staff of Messrs. Ross and Holgate, consulting engineers, Montreal. He then became a partner in the consulting firm of Walter J. Francis and Company, and in 1924, upon the death of Mr. Francis, became the senior partner.

Among Dominion engineers Mr. Brown took first rank. His work embraced civil, hydraulic, mechanical, and electrical problems, and was carried on in every province of the Dominion. He had taken part in arbitration and legal cases, made appraisals and estimates, determined rates for public utilities, and designed and built hydroelectric and steam power plants, waterworks, and various other structures. Some of the outstanding accomplishments with which he was associated were the power plant for the Angus Shops of the Canadian Pacific Railway; among several assignments for the City of Westmount, the first successful installation in America of high-temperature refuse destructors and the first installation of magnetite arc lamps in Canada; a complete water supply system, costing about $600,000, for Moose Jaw, Saskatchewan; surveys and designs for the Carillon hydroelectric plant on the Ottawa River, an eighteen million dollar project covering several hundred miles; building problems in connection with the Mount Royal Tunnel; supervision, with other members of special board, of the design and construction of the Montreal Aqueduct; Gatineau River hydroelectric development for the Hull Electric Company; and hydroelectric plant and street railway for the Sherbrooke Railway, Light & Power Co., Ltd. He served as consulting engineer with the Royal Commission of Inquiry in 1922 and 1923, investigating the engineering and economic aspects of the Ontario Hydro Electric Power Commission, and was called upon in a consulting capacity to assist many municipalities and corporations in connection with engineering problems. Just before his death he had attended the official opening of a new street lighting system in the town of Mount Royal. During the World War he was engaged in munition plant work, including power plant problems and steel treatment.

The Beauharnois power development is a monument to his engineering skill, for he was associated with the enterprise from the start, was responsible for all the preliminary plans, and was a member of the board of consulting engineers at the time of his death.

Mr. Brown's investigations of industrial and manufacturing problems included shop organization and management and he had given special lectures on engineering economics at McGill University.

He was a contributor to the publications of the technical organizations to which he belonged. These included the A.S.M.E., which he joined in 1913, the American Institute of Electrical Engineers, and The Engineering Institute of Canada, of which he was a life member and past council member. He was a charter member of the Corporation of Professional Engineers of Quebec and served as honorary-secretary-treasurer of this Corporation from 1920 to 1930. He was a Graduates' Representative Fellow in Applied Science and a member of the Corporation of McGill University. For many years previous to his death he was president of his graduating class, Science '03. He was elected a life member of the University Club of Montreal in 1920, was a member of the Homeopathic Hospital Association and a director from 1914 to 1925, and belonged to a number of social and athletic organizations. In 1924 Mr. Brown was an official Canadian delegate at the First World Power Conference held in London, England. His Masonic affiliations included University Lodge at Montreal, Royal Albert Chapter of Royal Archmasons, and in the Scottish Rite the Hochelaga Grand Lodge of Perfection, the Sovereign Chapter of Rose Croix, and the Montreal Sovereign Consistory 32d degree.

Surviving Mr. Brown are his widow, Alice (Lech) Brown, whom he married in 1907, one son, Frederick William Lech Brown, two daughters, Mrs. John A. MacLennan, of McMasterville, and Alison Hamilton Brown, and a grandson, Frederick F. MacLennan.

LUTHER D. BURLINGAME (1865–1932)

Luther D. Burlingame, industrial superintendent of the Brown & Sharpe Manufacturing Co., Providence, R.I., and for many years a leading figure in Providence civic affairs, died at his home in that city on June 2, 1932, after a short illness.

Mr. Burlingame was born in Whitestown (now Whitesboro), N.Y., on January 12, 1865, the son of Luther R. and Emeline (Aldrich) Burlingame. He attended the public schools of Dover, N.H., and Providence, being graduated from the English Department of the Providence High School in 1884 as valedictorian. He entered the employ of the Brown & Sharpe Manufacturing Co., as an apprentice in the drafting department, in the fall of the same year, and had training both in that department and in the machine shop.

He was made chief draftsman in 1888, when there were 14 employees in the department, and continued in that position for more than 25 years, seeing the personnel of the department increase in number to more than 100. He then became industrial superintendent, chairman of the safety committee, and patent specialist.

For many years Mr. Burlingame had been a leader in work for the improvement of Rhode Island's park and recreational facilities and the beautification of State roads. He served as secretary and president of the League of Improvement Societies in Rhode Island, and in 1922 helped to effect the consolidation of the League with the Public Parks Association and the Citizens' City Planning Association, forming a new organization called the Civic Improvement and Park Association. He was elected the first president of the association and served continuously in that capacity until his death.

Recently he had been made chairman of the committee on subsistence gardens of the Governor's Conference on Employment and Relief and had been working tirelessly to organize the state in a program of gardening for the benefit of the unemployed. During the World War he gained much experience in this line of work by organizing and directing a large garden for employees of the Brown & Sharpe Manufacturing Co.

Mr. Burlingame had long been active in the Providence Chamber of Commerce; he was a member of its Civic Affairs Committee from 1915 to 1919, chairman of the committee from 1922 to 1927, and a member of the Chamber's Board of Directors from 1921 to 1928. He was president of the Providence Safety Council and an organizer and president, in 1897, of the Providence Association of Mechanical Engineers, later reorganized to embrace all branches of engineering and now known as the Providence Engineering Society. He was president and a director of the Pleasant Valley Land Company and a member of the corporation of the Providence Institution for Savings.

Mr. Burlingame joined the A.S.M.E. in 1903 and during his 29 years of membership was a frequent contributor to its publications and an active member of its technical committees. In 1920 when the Sectional Committee on Plain Limit Gages for General Engineering Work was organized he was recognized as a pioneer in this field and was appointed to membership on this committee as an official representative of the A.S.M.E. He made important contributions to its report. Then, when a new committee was formed to revise and amplify the report published in 1925, he was reappointed as a representative of the Drill and Reamer Society, the Tap and Die Institute, and the Milling Cutter Society.

Screw thread fits was another of his interests, so he was a member of all the committees on this subject organized since he became a member of the Society. With the reorganization of the Sectional Committee on the Standardization and Unification of Screw Threads he was appointed as one of the Society's official representatives. In 1924, as a direct result of his activities in this field, the A.S.M.E. nominated him for appointment to membership on the National Screw Thread Commission.

In addition, he has represented the Society's interests on the Technical Committees on T-slots and Machine Tapers, both subdivisions of the Sectional Committee on the Standardization of Small Tools and Machine Tool Elements.

He enjoyed traveling, so rarely missed attendance at the Spring Meetings of the Society. He and Mrs. Burlingame were always present at the Annual Meeting in New York.

Mr. Burlingame was a member of the Executive Committee of the American Institute of Weights and Measures, a member of the Board of Directors of the National Safety Council, and a member of The Franklin Institute, the National Economic League, the Economic Club of Rhode Island, the corporation of the Rhode Island School of Design, the Rhode Island Field Naturalists' Club, the Grand Central Art Galleries (New York), and a number of clubs, including the Players and Turks Head in Providence and the Engineers' in New York. He was a prominent member of the Fourth Baptist Church, Providence, for many years, serving as a leader of the Sunday School and the teacher of the Men's Burlingame Bible Class. He had been an active worker in the cause of prohibition.

Mr. Burlingame had made a noteworthy collection of mounted butterflies and moths. He used friezes of the mounted butterflies for screens and other decorations in his home.

Surviving him are his widow, formerly Miss Christine Ward, four children, Mrs. Grace C. (Ernest L.) Lockwood, Warwick, R.I., Harold Luther, residing in California, and Mrs. Ethel B. (Henry J., 3d) Spooner, and Stanley W. Burlingame, both of Providence, and 12 grandchildren.

CARLETON STRONG CAIROLI (1886–1932)

Carleton Strong Cairoli, mechanical engineer for the Western Electric Company, New York, died on June 14, 1932. He had been on the Western Electric staff since 1924, and was also connected with the company in 1918.

Mr. Cairoli was born at Milford, Conn., on February 12, 1886. He received a Ph.B. degree from the Sheffield Scientific School of Yale University in 1908. His first position was with the B. & R. Rubber Co., North Brookfield, Mass. From there he went to Stamford, Conn., where he was employed by the Yale & Towne Mfg. Co., from 1909 to 1915, as instructor and foreman in the Apprentice Department and as designing draftsman. During the next three years he was connected successively with the Remington Arms & Ammunition Co., Bridgeport, Conn., in designing and installing power transmission, heating, and other equipment; the Kathodion Bronze Works, Nyack, N.Y., since discontinued, in similar work; Wm. S. Gilbert Clock Co., Winsted, Conn., in analyzing and standardizing operation and production; and the August Buerman Manufacturing Company, Newark, N.J., in charge of the design and installation of exhaust, ventilating, and heating systems. From 1918 to 1923 Mr. Cairoli was maintenance engineer for the National Conduit & Cable Co., Inc., Hastings-on-Hudson, N.Y. Since then he had been in charge of heating and ventilating in maintenance and construction work for the Western Electric Company.

Mr. Cairoli became an associate member of the A.S.M.E. in 1919. He is survived by his widow, Florence (Maeder) Cairoli, whom he married in 1920, two daughters, Emily Maeder and Myrtis Strong Cairoli, and his mother, Susan Strong Cairoli.

ALEXANDER WINCHESTER CARROLL (1867–1931)

Alexander Winchester Carroll, consulting engineer, Elizabeth, N.J., whose death occurred on December 17, 1931, was born at Baltimore, Md., on May 31, 1867. His parents were Henry Hill and Mary (Winchester) Carroll. He attended private schools and the Baltimore Manual Training School and served an apprenticeship as a machinist with the Chesapeake Screw Company and Bartlett Haywood & Co., in Baltimore, from 1885 to 1888.

Before beginning his consulting work in 1908 Mr. Carroll was connected successively with the Maryland Steel Company, Sparrows Point, Md., the Homestead Steel Works of the Carnegie Steel Company, steel, wire, and tube works in Beaver Falls, Pa., the De Lamar Copper Refining Company, Carteret, N.J., and the Chrome Steel Works, Chrome, N.J. In 1911 he was mechanical engineer for J. G. White & Co., New York, and for the next five years held a similar position with Barclay, Parsons & Klapp, New York. For about ten years, beginning in 1916, he was assistant superintendent of the Raritan Copper Works of the Anaconda Copper Mining Company, Perth Amboy, N.J., and from 1926 to 1928 superintendent of the American Brass Company, Hastings-on-Hudson, N.Y. Since then he had devoted himself to consulting work in Elizabeth. He was a member of the Home Guard in Elizabeth during the World War.

Mr. Carroll became a member of the A.S.M.E. in 1905, and also belonged to several clubs in Elizabeth.

ROY B. CHAMPION (1881–1932)

Roy B. Champion, superintendent of Public Works at Holland, Mich., died in that city on April 21, 1932, of apoplexy. He had been in ill health for about two years.

Mr. Champion became a member of the A.S.M.E. in 1928 and was serving on the Executive Committee of the Peninsula Section at the time of his death. He also belonged to the American Water Works Association and the Michigan Engineering Society. Locally he was affiliated with the Chamber of Commerce, Knights of Pythias, Exchange and Social Progress Clubs, and Sons of the American Revolution. He was a member of the Third Reformed Church and superintendent of the church Bible School.

Mr. Champion was born at Loveland, Iowa, on October 21, 1881. His parents, James A. and Addie (Waters) Champion, removed to Cherokee, Iowa, and later to Iowa City, where he was graduated from high school. He then attended the University of Iowa, which gave him a B.S. degree in 1906 and an E.E. degree in 1907. While at the University he became major of the University Battalion of the Iowa National Guard. For a short time after graduation he was superintendent of construction with the North Shore Electric Company in Chicago (since become the Public Service Company of Northern Illinois). He then went to Holland as city electrician in charge of the electric distribution system and station switchboard. He was promoted to the office of superintendent of public works in 1910 and retained the position for eight years. He was in direct charge of the electric, water, and sanitary sewer systems, supervising both construction and operation. He rebuilt part of the electric plant, putting in new switchboard and outgoing feeders, and developed an additional well-water supply.

In 1918 Mr. Champion resigned to become superintendent of the new Chester Water Power Company, Chester, Pa., where he remained two years. He returned to his former position in 1920, since when he had designed and built a motor-operated pumping station, rebuilt the boiler plant, and made many other improvements. Under his management the city of Holland has won a national reputation as an example of the successful operation of public utilities. With rates much lower than those of near-by public utilities, the municipal plants have returned to the city nearly $300,000 during the past eight years, representing a reduction in the annual tax rate on an average of $2.28 per thousand dollars of assessed valuation. In addition a splendid new municipal hospital was opened in 1929 at a cost of $184,000, financed entirely from the earnings of the utilities.

Surviving Mr. Champion, besides his parents and two sisters, are his widow, formerly Miss Oma G. Schaeffer of Iowa City, whom he married in 1907, and one daughter, Eula.

WILLIAM BREWSTER CHAPMAN (1873–1931)

William Brewster Chapman, whose death occurred in Chicago, Ill., on December 17, 1931, was born at Elyria, Ohio, on October 11, 1873, the son of James W., and Margaret (Darling) Chapman. He attended Oberlin College, 1892–1895, and then engaged for several years in civil engineering for the City of Cleveland and the Big Four Railroad.

From 1899 to 1901 Mr. Chapman was secretary and treasurer of the International Chemical Company and from then until 1905 was engaged in designing and building chemical works in Michigan for the Wood Alcohol Chemical Works. Subsequently he was connected for about a year with the Gas Producer Department of the Morgan Construction Company, Worcester, Mass. He then established the Chapman Engineering Company, New York, N.Y., manufacturers of producer-gas equipment. Mr. Chapman solved a number of difficult problems involved in the mechanical handling of coal, fire, and ash in mechanically operated gas producers during his years as president of the company, and earlier invented a process for manufacturing wood alcohol.

Mr. Chapman became a member of the A.S.M.E. in 1915. His clubs included the Machinery and Columbia Yacht, of New York, and the Mt. Vernon Country Club. He was twice married. His first wife was Rose Woodallen, of Ann Arbor, Mich., whom he married in 1902. A son, Bruce Chapman, of New York, N.Y., survives. His second marriage was to Ida Bailey Allen, of New York, in 1921.

LYLE GLENTWORTH CHASE (1886–1932)

Lyle Glentworth Chase, New York district sales manager for the Yarnall-Waring Company of Philadelphia, Pa., died on June 10, 1932, at Ithaca, N.Y., as the result of an automobile accident.

Mr. Chase was born at Chadron, Neb., on May 8, 1886, the son of Charles G. and Belle (Whitehill) Chase. His early education was secured at Kings Ferry and Union Springs, N.Y., and he was graduated from Cornell University with an M.E. degree in 1908. In the fall of that year he took a position as draftsman and designer in the Engineering Department of Thos. A. Edison, Inc., in Orange, N.J. After a year and a half there he became test engineer for the Parson Manufacturing Company, Elizabeth, N.J., later being advanced to the position of assistant superintendent. He remained there for about four years, working on forced-draft systems, vacuum ash ejectors, and fuel distributors. His next connection was with the Eastern Coal & Export Corp., Richmond, Va., first as assistant engineer and later as an expert on fuel economy and general power-plant consulting work.

Mr. Chase did some special work for the Yarnall-Waring Company in the summer of 1918, and in 1919, after serving for a few months as efficiency engineer for the Rosemary (N.C.) Manufacturing Company, in charge of power plants, he returned to the employ of the former company. He engaged in experimental and service work for about three years and then was transferred to New York as sales manager for that district.

Mr. Chase became a member of the A.S.M.E. in 1921. He was an executive member of the Watchung (N.J.) Council of the Boy Scouts of America. He belonged to the First Presbyterian Church and the Cornell Club in Plainfield, N.J., where he made his home, and was a Mason. Surviving him are his widow, Alice (Miller) Chase, whom he married in 1909, and three children, Nancy G., Margaret C., and Glentworth C. Chase.

ROBERT INGHAM CLEGG (1866–1931)

Robert Ingham Clegg, who died at Cleveland, Ohio, on December 3, 1931, was born at Acerington, Lancashire, England, on May 13, 1866. He secured his early education and served an apprenticeship as a machinist in Acerington. After coming to the United States in 1886 he worked in the shops of several Rhode Island companies, and was for some time associated with A. J. Cross, of Providence, in handling Shipman engines and as consultant to inventors.

Mr. Clegg entered the publishing field in 1898 as mechanical editor of *Horseless Age*, New York. From there he went to Cleveland as editor of the Machinery Department of the *Iron Trade Review* and subsequently was editor of *Woodcraft and Castings*, managing editor, *Blast Furnace and Steel Plant* and *Automobile Builder*, and vice-president of the Gardner Printing Company, Cleveland. He was a regular contributor of articles to many scientific publications, as well as to Masonic publications.

Mr. Clegg, a 33d degree Mason, had been a member of the fraternity since 1905 and for some years had been vice-president and editor-in-chief of The Masonic History Company, Chicago, Ill. He had received the most of the degrees conferred by Freemasons in Europe and the United States. For a number of years he was president of the Masonic Temple Association of Cleveland and had served on building committees for various masonic structures. Perhaps his greatest work for the Order was the revision of Mackey's History, Encyclopedia, Symbolism, and Jurisprudence of Freemasonry.

He was active in civic affairs, having served as a member and president of the Cleveland School Board and given both time and money to the development of the Cleveland Public Library. He had belonged to the A.S.M.E. since 1902 and continued to have a keen interest in its activities after entering upon the work of the Masonic fraternity. He served on the Constitution and By-Laws Committee from 1921 to 1923, as chairman during 1923. He was also a member of the Cleveland Engineering Society and had served a term as its vice-president.

Surviving Mr. Clegg are three children, Mrs. Ruth C. Hahn, and Norman V. and Lee M. Clegg. Mrs. Clegg, formerly Miss Emma Poole, of Providence, R.I., whom he married in 1892, died in 1914.

WILLIAM FLORENCE COCHRANE (1886–1932)

William Florence Cochrane, whose death occurred on January 5, 1932, was born at Steele, N.D., on May 5, 1886, the son of William Florence and Alma (Fridley) Cochrane. He was graduated from the United States Naval Academy at Annapolis in 1907 and spent seven years in the Navy, serving as chief engineer on several ships until 1913, when he was appointed assistant inspection machinist, U.S.N., at the Wm. Cramp & Sons Ship & Engine Bldg. Co., Philadelphia, Pa.

Following his resignation from the Navy in 1914, Mr. Cochrane became chief engineer for the U.S. Industrial Alcohol Company and its subsidiaries, the U.S. Industrial Chemical Co., Cuba Distilling Company, and Curtis Bay Copper & Iron Works, South Baltimore, Md.

During the World War he served as a lieutenant in the Ordnance Department, working on airplane fuel development. He was a director of the Cochrane Sales Company, Industrial Bank (Baltimore), and National Safety Fenders Corporation. He became a member of the A.S.M.E. in 1920 and also belonged to the Society of Automotive Engineers, American Society of Naval Engineers, the Army and Navy Club, Washington, D.C., Chemists Club, New York, and several other clubs.

Mr. Cochrane was married in Troy, N.Y., in 1909, to Gretchen Schneider, who, together with a son, William Henry Cochrane, survive him.

EUGENE LAMBERT COOKE (1894–1932)

Eugene Lambert Cooke, treasurer and general manager of the Cooke Boiler Works, Inc., New Haven, Conn., died of pneumonia at his home in that city on January 6, 1932.

Mr. Cooke was born in Philadelphia, Pa., on April 17, 1894, the son of John and Anna L. (Blakely) Cooke. He had two years' of study at the Erasmus Hall High School and a year at the Mechanics Institute. He then entered the employ of the Babcock & Wilcox Boiler Co., New York, working for two years on the erection of boilers in the field. From 1914 to 1916 he was assistant to the engineer of tests of the New York Edison Company at the Waterside Station. During the next two years he engaged in sales engineering work for the Elliott Company, New York, handling boiler equipment such as oil and water filtration systems, steam specialties and mechanical cleaners, and for the Vincent-Gilson Engineering Company, New York, selling and servicing combustion recorders and other instruments for controlling and regulating combustion in boiler furnaces. He returned to the employ of this company early in 1919, after several months in the Coast Artillery School for Enlisted Specialists, at Fort Monroe, Va., where he was enrolled in the electrical course.

Mr. Cooke went to New Haven in 1922 and spent two years with the New Haven Boiler Works before forming his own company. He enjoyed trap-shooting, hunted big game in Maine every fall, and was an excellent pianist. He is survived by his widow, Pauline (Berk) Cooke, whom he married in 1923, and by one son, Eugene L. Cooke, Jr.

Mr. Cooke became a junior member of the A.S.M.E. in 1917 and an associate member four years later.

RICHARD TELLER CRANE, JR. (1873–1931)

Richard Teller Crane, Jr., was born in Chicago, Ill., on November 7, 1873, fourth son of Richard Teller Crane, founder in 1855 of the Crane Co., manufacturers of valves, fittings, fabricated piping, plumbing, heating, and air-conditioning equipment. His mother was Mary Josephine (Prentice) Crane.

His early education was received at the Tilden School in Chicago, where his father organized and supported at his own expense the first public grade manual training school in Chicago. Later he attended Hill School, and in 1895 was graduated from Yale University with the degree of Bachelor of Science in the Sheffield Scientific School. Shortly thereafter he entered actively into the affairs of the rapidly growing business his father had founded. He held various official positions with the company until August 1, 1914, when, upon the retirement of his elder brother, Charles R. Crane, from the presidency, he was elected to that office, retaining it actively until the time of his death.

During the 17 years that Mr. Crane was president, Crane Co. saw the greatest expansion in its 76 years of growth. Under his leadership it developed into an organization with factories, branch houses, sales offices, and exhibit rooms in 200 cities throughout the world and with more than 20,000 employees. In administering its affairs Mr. Crane continued the traditions and policies of his father, which included a deep concern for the welfare of the personnel. The Crane Veteran League, which he organized in 1915 as a memorial to his father, is supported by an endowment fund provided by Mr. Cran and, at the time of his death, had a membership of 1401. Membership in the League is based on a minimum continuous service with the company of 25 years. During his presidency Mr. Crane distributed from his private fortune more than $13,000,000 worth of common stock in the company, and in his will supplemented this with a further large allotment of stock to those workers who had been with the company ten years and longer.

Mr. Crane's philanthropies were not confined to the company. To the City of Chicago he contributed the major portion of the cost of Iroquois Memorial Hospital, as a memorial to those who perished in the Iroquois Theatre fire in 1903. He also presented a hospital to the town of Ipswich, Mass., in memory of his friend, Benjamin Stickney Cable, and, jointly with Mrs. Crane, the completely equipped eye, ear, nose, and throat Florence Crane Hospital to the Hartford (Conn.) Hospital group and $100,000 toward the endowment of the Department of Therapeutics of New York University and Bellevue Hospital Medical College. He memorialized his parents in the gift of a carillon of 43 bells and the tower to house them, to St. Chrysostom's Episcopal Church, in Chicago, together with an endowment fund for maintenance. Buffalo Rock, a picturesque 50-acre spot on the Illinois River, which previously had served as a recreational and recuperative place for Crane employees and their families, was presented in 1928 to the State of Illinois, to be maintained perpetually by the State as a public park. "Crane Farms," near Lake Geneva, Wis., is now used by Crane employees. Among other donations are a valuable collection of Washingtoniana to the United States Naval Academy, the Library Building to Morristown (N.J.) School, and an aquamarine gem weighing 34.5 carats, said to be the largest perfect gem of its kind in the United States, to the Field Museum of Natural History in Chicago.

In addition to the manifold responsibilities shouldered by Mr. Crane as executive head of a large corporation, he found time to devote to public activities. From 1901 to 1912 he was consul general of Persia in Chicago; he served on the Yale Committee for Participation in the Restoration of the Library of the University of Louvain; he was a life member of the Art Institute, Chicago; life member and director of the Field Museum of Natural History, Chicago; and vice-president (1921–1923) of the Civic Opera Association of Chicago and a guarantor for ten years. On several occasions he joined in syndicates of members of the New York Yacht Club, of which he was a life member, to finance the construction and operation of defenders of the America's Cup, the last time in 1917, when he participated in building the yacht *Wetamoe*, one of the candidates against Sir Thomas Lipton's challenger.

Mr. Crane became a member of the A.S.M.E. in 1916. Among the clubs to which he belonged were the Chicago Club, New York Yacht Club, The Brook (New York), Jekyll Island Club (Brunswick, Ga.), Old Elm (Chicago), Piping Rock Club, and Mount Royal Club (Montreal).

The honorary degree of Doctor of Laws was conferred upon Mr. Crane by Hobart College, Geneva, N.Y., in 1931. The following citation accompanied the degree:

"Richard Teller Crane, Jr., promotor of human relationships in American industry, philanthropist, worthy citizen of a great city, Bachelor of Philosophy of Yale University. A loyal and devoted son of his Alma Mater, he has translated its ideal of 'Light and Truth' into the complex mechanism of a great industrial organization, ever emphasizing men rather than things, so that it stands as a conspicuous example of mutual and cooperative work and benefit. Recognizing his wide interest in educational and social welfare, Hobart is glad to welcome him to fellowship with her sons."

Mr. Crane died of heart disease on his fifty-eighth birthday, November 7, 1931, at the Doctors Hospital in New York, N.Y. He is survived by his widow, Florence (Higinbotham) Crane, of Chicago, whom he married in 1904, and by a son, Cornelius, and a daughter, Florence.

ROBERT EDWARD CRANSTON (1873–1932)

Robert Edward Cranston, who died in San Francisco, Calif., on July 30, 1932, was one of the outstanding authorities on gold and platinum dredging. He was known to the mining profession chiefly through his activities in gold dredge design and operation and his sampling and valuation of alluvial deposits, but he also had had extensive experience in the sampling and operation of lode properties in Colorado, California, Montana, and others of the western states. His work on alluvial properties took him to Brazil, Colombia, New Zealand, Australia, and other parts of the world.

Mr. Cranston was born at St. Johns, Mich., on June 14, 1873. He prepared for college at the Michigan Military Academy, Orchard Lake, and then attended the Michigan College of Mines for four years. During the early years of his career, from 1893 to 1898, Mr. Cranston was associated with mining and consulting engineers in several states, assisting in placer and lode examinations and operations, patent and underground surveying, assaying and sampling. He served in 1895 and 1896 as U.S. Deputy Mineral Surveyor in the Cripple Creek District in Colorado and later examined and acted as consulting engineer for several mines, notably the Smuggler Union at Telluride, Colo. He also was active in the Leadville, Colo., district.

In 1898 Mr. Cranston took charge of the Pacific Coast examinations of the New England Exploration Company, Boston, and also became connected with the Ashburton Mining Company; he developed the property of this company on the American River near Folsom, Calif., and operated the mine for many years, as manager of the company. He also organized the Marysville Dredging Company, which began operations in 1905 on the Yuba River. Both these companies were supplied with gold dredges designed by Mr. Cranston. From 1907 to 1910 he was secretary and consulting engineer to the Greater Nevada Mining Company, Rhyolite, Nev., and did other consulting work. Subsequently he devoted himself largely to consulting practice, which included the investigation, equipment, and operation of many mining properties, both placer and lode, in nearly every mining state in the United States and in Canada, Mexico, Brazil, and Colombia.

During the World War Mr. Cranston was Chief of Division of Collateral Commodities, U.S. Food Administration, Washington, D.C. After his return to private life he developed a gold dredging property in New Zealand and formed the Rimu Gold Dredging Company, Ltd., Hokitika, to operate it. He was still serving as managing director of this company and was also director and general manager of the South American Gold & Platinum Co., New York, at the time of his death, and held similar positions with various companies related to these organizations.

Mr. Cranston became a member of the A.S.M.E. in 1907 and belonged to several other societies, including the American Institute of Mining and Metallurgical Engineers, the Mining and Metallurgical Society of America, and the Engineer's Club of San Francisco. Other club memberships included the Olympic and Bohemian, San Francisco, Marin Golf and Country Club, New Rochelle (N.Y.) Yacht, and Lawyers' (N.Y.).

Surviving Mr. Cranston are his widow, Mrs. Mary P. Cranston, and one son, Graham.

JOHN C. CROMWELL (1866–1932)

John C. Cromwell, whose death occurred on May 31, 1932, at Columbus, Ohio, was born on September 26, 1866, in Frankfort, Ky., the son of Alvin W. and Sidney A. (Jett) Cromwell. He secured his early education in Frankfort and was graduated from the University of Illinois in 1886 with a B.S. degree in mechanical engineering, receiving his M.E. degree in 1911.

During the ten years following his graduation Mr. Cromwell did drafting for the Ellithorpe Air-Brake Company, Chicago, on steam and hydraulic elevators, the Bates Machine Company, Joliet, Ill., on Corliss engines and wire machinery, and the Joliet Works of the Illinois Steel Company, as chief draftsman.

For a period of twenty years, beginning in 1897, Mr. Cromwell was associated with the Garrett-Cromwell Engineering Company, of Cleveland, designing and constructing rolling mills.

During the early days of the World War Mr. Cromwell purchased some 80,000 tons of steel car axles, for the Allies, for the manufacture of shrapnel. The Cromwell Steel Company, which he organized at Cleveland in 1917, was discontinued after the close of the War. Since 1921 he had been connected with the Groeniger Associates, consulting engineers, Columbus. In 1927 he organized the Steel Sanitary Company, at Alliance, Ohio, and served as its general manager for three years. He was also a former president of the Alliance Machine Company.

Among a number of inventions patented by Mr. Cromwell were processes for rolling steel, pressing steel into bathtubs, etc.

Mr. Cromwell is survived by a sister, Florence (Cromwell) Denton, of Columbus. His wife died in 1909.

EDWARD HARRIS CROSBY (1868–1932)

Edward Harris Crosby, vice-president of Veeder-Root, Inc., Hartford, Conn., died at his home in that city on April 30, 1932, after a short illness. Mr. Crosby was born at Hebron, in Yarmouth County, Nova Scotia, on February 23, 1868. After leaving school he served an apprenticeship with the Hinkley Locomotive Works, Boston, Mass., and worked for the American Watch & Tool Co. and American Waltham Watch Company in Waltham, Mass., as machinist and toolmaker, and the E. W. Bliss Co., Brooklyn, N.Y., as a model maker for several years before going to Hartford.

Mr. Crosby's first position in Hartford was with the Pope Manufacturing Company, as toolmaker. He was also employed for a time by the Pratt & Whitney Co. as a model maker.

The Veeder Manufacturing Company was organized by Curtis H. Veeder in 1895 to manufacture a cyclometer invented by him. Mr. Crosby entered the employ of the company shortly after its organization and later was made superintendent and had a large part in the development of Mr. Veeder's many inventions in counting and registering machines. When the company was merged with the Root Company of Bristol in 1928 Mr. Crosby was made factory manager. He was elected vice-president and made consulting engineer in 1931.

Mr. Crosby became a member of the A.S.M.E. in 1913. He belonged to the Hartford Get-Together Club and the Masonic fraternity and was active in the Central Baptist Church. He is survived by his widow, Mrs. Belle (Backadar) Crosby, a son, Dr. Edward H. Crosby, of Cleveland, Ohio, and two daughters, Miss Martha B. Crosby, of Hartford, and Mrs. A. E. Anderson, of Jamestown, N.Y.

CHARLES NORMAN CROSS (1879–1932)

Charles Norman Cross, a member of the faculty of the Mechanical Engineering Department of Stanford University since 1906, died on January 9, 1932, of heart trouble. He was honorary chairman of the A.S.M.E. Student Branch at the University, and had been a member of the Society since 1911.

Professor Cross was born on April 9, 1879, at Warsaw, Wyoming County, N.Y., the son of Norman D. and Harriet (Beckwith) Cross. He prepared for college at the Pike (N.Y.) Seminary, and then worked for about three years in his father's machine shop before entering Cornell University. During one vacation he was employed as machinist's helper by the Lake Shore & Michigan Southern Railroad at Collinwood, Ohio, and Elkhart, Ind., and from February 1, 1905, to February 1, 1906, worked at the Long Island State Hospital as assistant electrical engineer and at the Waterside Station No. 1 of the New York Edison Company. He received his M.E. degree at Cornell in June, 1906, and during the intervening time between then and the beginning of his work at Stanford was electrician for the Lackawanna Steel Company at Buffalo, N.Y.

In addition to his duties on the staff of instruction in the Department of Mechanical Engineering at Stanford, he was frequently called in as a consultant for the study of various problems in the domains of construction, power, and oil-well engineering. Thus he acted as engineering expert for the Kern Trading & Oil Co. on special testing and investigations of power used in the drilling and pumping of oil wells. At different periods he served as consultant for several construction companies in California and for the Pacific Gas & Electric Co. of San Francisco and the Palo Alto Municipal Gas Service. During 1914–1915 he spent a sabbatical year in the Research Department of the General Electric Company at Lynn, Mass. He had been, for some time, conducting research work on the viscosity of steam at high pressures and temperatures. He held a number of patents on gas burners and a gas furnace. He was the author of a textbook on Heat Engines, published in 1930.

During the World War, Professor Cross was efficiency engineer for the Federal Fuel Administration in California, and in 1921 and 1922 he was a member of the Committee on the Revision of Boiler Safety Orders of the Industrial Accident Commission of California. He was a member of the Pacific Coast Gas Association, American Association of University Professors, honorary engineering fraternity, Sigma Xi, Stanford Faculty Club, and Engineers' Club of San Francisco.

Professor Cross is survived by his widow, Laura Parke (Mumaw) Cross, whom he married at Scottdale, Pa., in 1908, and by two children, Charles Mumaw and Eleanor Parke Cross.

EDWARD NEWTON CUNNINGHAM (1878–1932)

Edward Newton Cunningham, of Birmingham, Ala., representative of the Kewanee & Fitzgibbons Boiler Company in that district, was fatally injured in an automobile accident near Selma, Ala., on February 15, 1932. Driving with him was Raymond Newcomb, vice-president of the company and likewise a member of the A.S.M.E., who also died as the result of injuries.

Mr. Cunningham was born at Pinckneyville, Ill., on February 23, 1878, the son of William T. and Martha A. Cunningham. After completing his high-school education he became an apprentice in the Pinckneyville Electric Company. During the ten years from 1896 to 1906 he was employed in Brookhaven, Poplarville, and Hattiesburg, Miss., handling operations, repairs, new installations, and improvements in electric light and power plants and advancing to the position of superintendent. The next two years were spent as designing, contracting, and supervising engineer with the Orleans Engineering Company, New Orleans, La. In 1909 and 1910 he was associated with R. C. Houston, of Memphis, Tenn., in contracting work, making estimates and serving as field engineer on several projthe United States Naval Academy at Annapolis in 1907 and spent seven years in the Navy, serving as chief engineer on several ships until 1913, when he was appointed assistant inspection machinist, U.S.N., at the Wm. Cramp & Sons Ship & Engine Bldg. Co., Philadelphia, Pa.

Following his resignation from the Navy in 1914, Mr. Cochrane became chief engineer for the U.S. Industrial Alcohol Company and its subsidiaries, the U.S. Industrial Chemical Co., Cuba Distilling Company, and Curtis Bay Copper & Iron Works, South Baltimore, Md.

During the World War he served as a lieutenant in the Ordnance Department, working on airplane fuel development. He was a director of the Cochrane Sales Company, Industrial Bank (Baltimore), and National Safety Fenders Corporation. He became a member of the A.S.M.E. in 1920 and also belonged to the Society of Automotive Engineers, American Society of Naval Engineers, the Army and Navy Club, Washington, D.C., Chemists Club, New York, and several other clubs.

Mr. Cochrane was married in Troy, N.Y., in 1909, to Gretchen Schneider, who, together with a son, William Henry Cochrane, survive him.

EUGENE LAMBERT COOKE (1894–1932)

Eugene Lambert Cooke, treasurer and general manager of the Cooke Boiler Works, Inc., New Haven, Conn., died of pneumonia at his home in that city on January 6, 1932.

Mr. Cooke was born in Philadelphia, Pa., on April 17, 1894, the son of John and Anna L. (Blakely) Cooke. He had two years' of study at the Erasmus Hall High School and a year at the Mechanics Institute. He then entered the employ of the Babcock & Wilcox Boiler Co., New York, working for two years on the erection of boilers in the field. From 1914 to 1916 he was assistant to the engineer of tests of the New York Edison Company at the Waterside Station. During the next two years he engaged in sales engineering work for the Elliott Company, New York, handling boiler equipment such as oil and water filtration systems, steam specialties and mechanical cleaners, and for the Vincent-Gilson Engineering Company, New York, selling and servicing combustion recorders and other instruments for controlling and regulating combustion in boiler furnaces. He returned to the employ of this company early in 1919, after several months in the Coast Artillery School for Enlisted Specialists, at Fort Monroe, Va., where he was enrolled in the electrical course.

Mr. Cooke went to New Haven in 1922 and spent two years with the New Haven Boiler Works before forming his own company. He enjoyed trap-shooting, hunted big game in Maine every fall, and was an excellent pianist. He is survived by his widow, Pauline (Berk) Cooke, whom he married in 1923, and by one son, Eugene L. Cooke, Jr.

Mr. Cooke became a junior member of the A.S.M.E. in 1917 and an associate member four years later.

RICHARD TELLER CRANE, JR. (1873–1931)

Richard Teller Crane, Jr., was born in Chicago, Ill., on November 7, 1873, fourth son of Richard Teller Crane, founder in 1855 of the Crane Co., manufacturers of valves, fittings, fabricated piping, plumbing, heating, and air-conditioning equipment. His mother was Mary Josephine (Prentice) Crane.

His early education was received at the Tilden School in Chicago, where his father organized and supported at his own expense the first public grade manual training school in Chicago. Later he attended Hill School, and in 1895 was graduated from Yale University with the degree of Bachelor of Science in the Sheffield Scientific School. Shortly thereafter he entered actively into the affairs of the rapidly growing business his father had founded. He held various official positions with the company until August 1, 1914, when, upon the retirement of his elder brother, Charles R. Crane, from the presidency, he was elected to that office, retaining it actively until the time of his death.

During the 17 years that Mr. Crane was president, Crane Co. saw the greatest expansion in its 76 years of growth. Under his leadership it developed into an organization with factories, branch houses, sales offices, and exhibit rooms in 200 cities throughout the world and with more than 20,000 employees. In administering its affairs Mr. Crane continued the traditions and policies of his father, which included a deep concern for the welfare of the personnel. The Crane Veteran League, which he organized in 1915 as a memorial to his father, is supported by an endowment fund provided by Mr. Cran and, at the time of his death, had a membership of 1401. Membership in the League is based on a minimum continuous service with the company of 25 years. During his presidency Mr. Crane distributed from his private fortune more than $13,000,000 worth of common stock in the company, and in his will supplemented this with a further large allotment of stock to those workers who had been with the company ten years and longer.

Mr. Crane's philanthropies were not confined to the company. To the City of Chicago he contributed the major portion of the cost of Iroquois Memorial Hospital, as a memorial to those who perished in the Iroquois Theatre fire in 1903. He also presented a hospital to the town of Ipswich, Mass., in memory of his friend, Benjamin Stickney Cable, and, jointly with Mrs. Crane, the completely equipped eye, ear, nose, and throat Florence Crane Hospital to the Hartford (Conn.) Hospital group and $100,000 toward the endowment of the Department of Therapeutics of New York University and Bellevue Hospital Medical College. He memorialized his parents in the gift of a carillon of 43 bells and the tower to house them, to St. Chrysostom's Episcopal Church, in Chicago, together with an endowment fund for maintenance. Buffalo Rock, a picturesque 50-acre spot on the Illinois River, which previously had served as a recreational and recuperative place for Crane employees and their families, was presented in 1928 to the State of Illinois, to be maintained perpetually by the State as a public park. "Crane Farms," near Lake Geneva, Wis., is now used by Crane employees. Among other donations are a valuable collection of Washingtoniana to the United States Naval Academy, the Library Building to Morristown (N.J.) School, and an aquamarine gem weighing 34.5 carats, said to be the largest perfect gem of its kind in the United States, to the Field Museum of Natural History in Chicago.

In addition to the manifold responsibilities shouldered by Mr. Crane as executive head of a large corporation, he found time to devote to public activities. From 1901 to 1912 he was consul general of Persia in Chicago; he served on the Yale Committee for Participation in the Restoration of the Library of the University of Louvain; he was a life member of the Art Institute, Chicago; life member and director of the Field Museum of Natural History, Chicago; and vice-president (1921–1923) of the Civic Opera Association of Chicago and a guarantor for ten years. On several occasions he joined in syndicates of members of the New York Yacht Club, of which he was a life member, to finance the construction and operation of defenders of the America's Cup, the last time in 1917, when he participated in building the yacht *Weetamoe*, one of the candidates against Sir Thomas Lipton's challenger.

Mr. Crane became a member of the A.S.M.E. in 1916. Among the clubs to which he belonged were the Chicago Club, New York Yacht Club, The Brook (New York), Jekyll Island Club (Brunswick, Ga.), Old Elm (Chicago), Piping Rock Club, and Mount Royal Club (Montreal).

The honorary degree of Doctor of Laws was conferred upon Mr. Crane by Hobart College, Geneva, N.Y., in 1931. The following citation accompanied the degree:

"Richard Teller Crane, Jr., promotor of human relationships in American industry, philanthropist, worthy citizen of a great city, Bachelor of Philosophy of Yale University. A loyal and devoted son of his Alma Mater, he has translated its ideal of 'Light and Truth' into the complex mechanism of a great industrial organization, ever emphasizing men rather than things, so that it stands as a conspicuous example of mutual and cooperative work and benefit. Recognizing his wide interest in educational and social welfare, Hobart is glad to welcome him to fellowship with her sons."

Mr. Crane died of heart disease on his fifty-eighth birthday, November 7, 1931, at the Doctors Hospital in New York, N.Y. He is survived by his widow, Florence (Higinbotham) Crane, of Chicago, whom he married in 1904, and by a son, Cornelius, and a daughter, Florence.

ROBERT EDWARD CRANSTON (1873–1932)

Robert Edward Cranston, who died in San Francisco, Calif., on July 30, 1932, was one of the outstanding authorities on gold and platinum dredging. He was known to the mining profession chiefly through his activities in gold dredge design and operation and his sampling and valuation of alluvial deposits, but he also had had extensive experience in the sampling and operation of lode properties in Colorado, California, Montana, and others of the western states. His work on alluvial properties took him to Brazil, Colombia, New Zealand, Australia, and other parts of the world.

Mr. Cranston was born at St. Johns, Mich., on June 14, 1873. He prepared for college at the Michigan Military Academy, Orchard Lake, and then attended the Michigan College of Mines for four years. During the early years of his career, from 1893 to 1898, Mr. Cranston was associated with mining and consulting engineers in several states, assisting in placer and lode examinations and operations, patent and underground surveying, assaying and sampling. He served in 1895 and 1896 as U.S. Deputy Mineral Surveyor in the Cripple Creek District in Colorado and later examined and acted as consulting engineer for several mines, notably the Smuggler Union at Telluride, Colo. He also was active in the Leadville, Colo., district.

In 1898 Mr. Cranston took charge of the Pacific Coast examinations of the New England Exploration Company, Boston, and also became connected with the Ashburton Mining Company; he developed the property of this company on the American River near Folsom, Calif., and operated the mine for many years, as manager of the company. He also organized the Marysville Dredging Company, which began operations in 1905 on the Yuba River. Both these companies were supplied with gold dredges designed by Mr. Cranston. From 1907 to 1910 he was secretary and consulting engineer to the Greater Nevada Mining Company, Rhyolite, Nev., and did other consulting work. Subsequently he devoted himself largely to consulting practice, which included the investigation, equipment, and operation of many mining properties, both placer and lode, in nearly every mining state in the United States and in Canada, Mexico, Brazil, and Colombia.

During the World War Mr. Cranston was Chief of Division of Collateral Commodities, U.S. Food Administration, Washington, D.C. After his return to private life he developed a gold dredging property in New Zealand and formed the Rimu Gold Dredging Company, Ltd., Hokitika, to operate it. He was still serving as managing director of this company and was also director and general manager of the South American Gold & Platinum Co., New York, at the time of his death, and held similar positions with various companies related to these organizations.

Mr. Cranston became a member of the A.S.M.E. in 1907 and belonged to several other societies, including the American Institute of Mining and Metallurgical Engineers, the Mining and Metallurgical Society of America, and the Engineer's Club of San Francisco. Other club memberships included the Olympic and Bohemian, San Francisco, Marin Golf and Country Club, New Rochelle (N.Y.) Yacht, and Lawyers' (N.Y.).

Surviving Mr. Cranston are his widow, Mrs. Mary P. Cranston, and one son, Graham.

JOHN C. CROMWELL (1866–1932)

John C. Cromwell, whose death occurred on May 31, 1932, at Columbus, Ohio, was born on September 26, 1866, in Frankfort, Ky., the son of Alvin W. and Sidney A. (Jett) Cromwell. He secured his early education in Frankfort and was graduated from the University of Illinois in 1886 with a B.S. degree in mechanical engineering, receiving his M.E. degree in 1911.

During the ten years following his graduation Mr. Cromwell did drafting for the Ellithorpe Air-Brake Company, Chicago, on steam and hydraulic elevators, the Bates Machine Company, Joliet, Ill., on Corliss engines and wire machinery, and the Joliet Works of the Illinois Steel Company, as chief draftsman.

For a period of twenty years, beginning in 1897, Mr. Cromwell was associated with the Garrett-Cromwell Engineering Company, of Cleveland, designing and constructing rolling mills.

During the early days of the World War Mr. Cromwell purchased some 80,000 tons of steel car axles, for the Allies, for the manufacture of shrapnel. The Cromwell Steel Company, which he organized at Cleveland in 1917, was discontinued after the close of the War. Since 1921 he had been connected with the Groeniger Associates, consulting engineers, Columbus. In 1927 he organized the Steel Sanitary Company, at Alliance, Ohio, and served as its general manager for three years. He was also a former president of the Alliance Machine Company.

Among a number of inventions patented by Mr. Cromwell were processes for rolling steel, pressing steel into bathtubs, etc.

Mr. Cromwell is survived by a sister, Florence (Cromwell) Denton, of Columbus. His wife died in 1909.

EDWARD HARRIS CROSBY (1868–1932)

Edward Harris Crosby, vice-president of Veeder-Root, Inc., Hartford, Conn., died at his home in that city on April 30, 1932, after a short illness. Mr. Crosby was born at Hebron, in Yarmouth County, Nova Scotia, on February 23, 1868. After leaving school he served an apprenticeship with the Hinkley Locomotive Works, Boston, Mass., and worked for the American Watch & Tool Co. and American Waltham Watch Company in Waltham, Mass., as machinist and toolmaker, and the E. W. Bliss Co., Brooklyn, N.Y., as a model maker for several years before going to Hartford.

Mr. Crosby's first position in Hartford was with the Pope Manufacturing Company, as toolmaker. He was also employed for a time by the Pratt & Whitney Co. as a model maker.

The Veeder Manufacturing Company was organized by Curtis H. Veeder in 1895 to manufacture a cyclometer invented by him. Mr. Crosby entered the employ of the company shortly after its organization and later was made superintendent and had a large part in the development of Mr. Veeder's many inventions in counting and registering machines. When the company was merged with the Root Company of Bristol in 1928 Mr. Crosby was made factory manager. He was elected vice-president and made consulting engineer in 1931.

Mr. Crosby became a member of the A.S.M.E. in 1913. He belonged to the Hartford Get-Together Club and the Masonic fraternity and was active in the Central Baptist Church. He is survived by his widow, Mrs. Belle (Backadar) Crosby, a son, Dr. Edward H. Crosby, of Cleveland, Ohio, and two daughters, Miss Martha B. Crosby, of Hartford, and Mrs. A. E. Anderson, of Jamestown, N.Y.

CHARLES NORMAN CROSS (1879–1932)

Charles Norman Cross, a member of the faculty of the Mechanical Engineering Department of Stanford University since 1906, died on January 9, 1932, of heart trouble. He was honorary chairman of the A.S.M.E. Student Branch at the University, and had been a member of the Society since 1911.

Professor Cross was born on April 9, 1879, at Warsaw, Wyoming County, N.Y., the son of Norman D. and Harriet (Beckwith) Cross. He prepared for college at the Pike (N.Y.) Seminary, and then worked for about three years in his father's machine shop before entering Cornell University. During one vacation he was employed as machinist's helper by the Lake Shore & Michigan Southern Railroad at Collinwood, Ohio, and Elkhart, Ind., and from February 1, 1905, to February 1, 1906, worked at the Long Island State Hospital as assistant electrical engineer and at the Waterside Station No. 1 of the New York Edison Company. He received his M.E. degree at Cornell in June, 1906, and during the intervening time between then and the beginning of his work at Stanford was electrician for the Lackawanna Steel Company at Buffalo, N.Y.

In addition to his duties on the staff of instruction in the Department of Mechanical Engineering at Stanford, he was frequently called in as a consultant for the study of various problems in the domains of construction, power, and oil-well engineering. Thus he acted as engineering expert for the Kern Trading & Oil Co. on special testing and investigations of power used in the drilling and pumping of oil wells. At different periods he served as consultant for several construction companies in California and for the Pacific Gas & Electric Co. of San Francisco and the Palo Alto Municipal Gas Service. During 1914–1915 he spent a sabbatical year in the Research Department of the General Electric Company at Lynn, Mass. He had been, for some time, conducting research work on the viscosity of steam at high pressures and temperatures. He held a number of patents on gas burners and a gas furnace. He was the author of a textbook on Heat Engines, published in 1930.

During the World War, Professor Cross was efficiency engineer for the Federal Fuel Administration in California, and in 1921 and 1922 he was a member of the Committee on the Revision of Boiler Safety Orders of the Industrial Accident Commission of California. He was a member of the Pacific Coast Gas Association, American Association of University Professors, honorary engineering fraternity, Sigma Xi, Stanford Faculty Club, and Engineers' Club of San Francisco.

Professor Cross is survived by his widow, Laura Parke (Mumaw) Cross, whom he married at Scottdale, Pa., in 1908, and by two children, Charles Mumaw and Eleanor Parke Cross.

EDWARD NEWTON CUNNINGHAM (1878–1932)

Edward Newton Cunningham, of Birmingham, Ala., representative of the Kewanee & Fitzgibbons Boiler Company in that district, was fatally injured in an automobile accident near Selma, Ala., on February 15, 1932. Driving with him was Raymond Newcomb, vice-president of the company and likewise a member of the A.S.M.E., who also died as the result of injuries.

Mr. Cunningham was born at Pinckneyville, Ill., on February 23, 1878, the son of William T. and Martha A. Cunningham. After completing his high-school education he became an apprentice in the Pinckneyville Electric Company. During the ten years from 1896 to 1906 he was employed in Brookhaven, Poplarville, and Hattiesburg, Miss., handling operations, repairs, new installations, and improvements in electric light and power plants and advancing to the position of superintendent. The next two years were spent as designing, contracting, and supervising engineer with the Orleans Engineering Company, New Orleans, La. In 1909 and 1910 he was associated with R. C. Houston, of Memphis, Tenn., in contracting work, making estimates and serving as field engineer on several projects, and in 1912 and 1913 he was operating engineer for the R. C. Houston Co. The intervening period was spent as salesman for the Gulf Refining Company.

Mr. Cunningham leased the Mt. Pleasant (Tenn.) Electric Company in 1913 and devoted three years to rebuilding the system and operating it on a profit-sharing basis. The Greensboro (Ala.) Light & Water Plant was operated by him in 1916 on the same basis.

In 1917 and 1918 and also in 1920 Mr. Cunningham was associated as a steam power engineer with Howard M. Gassman of Birmingham, consulting engineer for mining and industrial plants. During the interim he was superintendent of operations at the Alabama Power Company's Warrior Steam Plant at Gorgas, Ala.

Since 1921 Mr. Cunningham had been engaged in sales and consulting work for different companies, chiefly in Birmingham. He became a member of the A.S.M.E. in 1926. His mother and a brother, Eugene R. Cunningham, of Pensacola, Fla., survive him.

LOUIS CHRISTIAN DATZ (1880–1932)

Louis Christian Datz, chief engineer of the St. Louis Public Service Co., died as the result of a cerebral hemorrhage on May 20, 1932. Mr. Datz went to St. Louis in 1925 as advisory engineer in connection with the reorganization of the United Railways Company of St. Louis. Two years later, when the Public Service Company took over the street railways, he became chief engineer.

Mr. Datz was born in New Orleans, La., on April 27, 1880, the son of Henry and Charlotte (Caesar) Datz. At the age of 21 he secured his B.E. degree in mechanical and electrical engineering from Tulane University. He remained in New Orleans until 1914, the major portion of the time being spent with the New Orleans Railway & Light Co., which he served as assistant engineer from 1903 to 1910 and later as engineer of maintenance of way and superintendent of track and overhead. His first position after graduation was with a New Orleans contractor in charge of designing and constructing dredges, derricks, etc. He was also secretary for a time at Tulane University, and spent a year as engineer with Ford, Bacon & Davis, Inc.

After leaving New Orleans in 1914 Mr. Datz spent three years in Birmingham, Ala., with the Southern Properties, United Gas & Electric Engineering Corp. Subsequently he was connected for three years with the American Cities Company, Birmingham, as chief engineer, and from 1922 to 1924 he held a similar position with the Memphis Power & Light Co., Memphis, Tenn.

Mr. Datz became a member of the A.S.M.E. in 1916. He was president in 1915 and again in 1922–1923 of the Louisiana Engineering Society and was also a member of the American Electric Railway Engineering Association and the American Society of Civil Engineers. He was a member of the St. Louis Electric Board of Trade, the Missouri Athletic Association, and the Engineers and Rotary Clubs in St. Louis and chairman of the Finance Committee of the Westminster Presbyterian Church there.

Surviving Mr. Datz are his widow, formerly Miss May C. Eblen, whom he married in 1905, and three children, Warren E., Elsie C., and Rosemary Datz.

EDWIN KENT DAVIS (1893–1931)

Edwin Kent Davis, chief engineer of the Fulton Bag & Cotton Mills, Atlanta, Ga., was born in Baltimore, Md., on June 17, 1893, the son of Edwin and Mary Register (Pope) Davis. He was graduated from the Technological High School, Atlanta, in 1911, and for the next two years was employed by the Mackler-Crawford Construction Company (later known as the Mackler Construction Company). He was successively draftsman, timekeeper, carpenter-foreman, and building superintendent for the company, working on business and public buildings in different parts of the South.

With the exception of about fifteen months during the World War Mr. Davis had been connected with the Fulton Bag & Cotton Mills since September, 1913. From that date until his enlistment in the Aviation Section of the Signal Corps, U.S.A., in November, 1917, he held different positions in the purchasing and mechanical departments of the company. When he returned in March, 1919, he was made assistant purchasing agent and mechanical engineer, and six years later chief engineer of the company. He was in charge of power plants both at Atlanta and at the branch factories, and of the maintenance of equipment and buildings. Machine design and development work was carried on under his direction, and bag-cleaning machinery and salvage systems, as well as fire protection and insurance programs, were introduced by him.

Mr. Davis trained as a pilot and was commissioned a second lieutenant in May, 1918. After flying at different fields and serving as commanding officer of the Student Officers Squadron at Love Field, Dallas, he was sent to France, in August, 1918, and given further training in testing combat planes. He was discharged in February, 1919, with a citation for excellent service as a test pilot. He retained his interest in aviation, serving as a first lieutenant in the Reserve Air Corps, and was second in command of the unit at Candler Field.

Mr. Davis became a junior member of the A.S.M.E. in 1919, an associate-member three years later, and a full member in 1926. He had served as chairman of the Atlanta Section. He also belonged to the Aero Club of America and held its regular and expert pilot's licenses.

Mr. Davis died at Atlanta on November 18, 1931. He is survived by his widow, Katherine (Du Bose) Davis, whom he married in 1925, and by two daughters, Katherine and Mary Pope Davis.

WILLIAM L. DEMPSEY (1866–1932)

William L. Dempsey, patent attorney and consulting engineer, St. Louis, Mo., died on May 17, 1932. He was born at Louisville, Ky., on October 7, 1866. He attended the Burnett Academy, Auburn, Ky., and Beck's College, Smith Grove, Ky., before entering Vanderbilt University, Nashville, Tenn., from which he was graduated in 1888. During the next year he was president of Beech Grove College, Beech Grove, Ky., and then he opened a law office in Fayette, Mo.

In 1897 Mr. Dempsey closed his Fayette office and took a position in the Law, Engineering, and Sales Departments of the International Harvester Company, Chicago, where he remained for twenty years. In 1917 he became president of the Dempsey Cycle Company, Inc., of Philadelphia, Pa., a company organized to handle the Dempsey cycle supercharger, which greatly increases brake horsepower and torque, especially at low speeds. Mr. Dempsey established his St. Louis office in 1923.

Mr. Dempsey was a fellow of the Royal Society of Great Britain, and a member of the Engineers' Club of St. Louis and The Franklin Institute. He became a member of the A.S.M.E. in 1928.

JOHN DEVRIES (1853–1932)

John DeVries, retired mechanical engineer and manufacturer, died at his home in Clifton, N.J., on April 4, 1932. He was born in the Netherlands on November 30, 1853, emigrating to the United States with his parents in 1865. He supplemented his early education in the Netherlands with courses in mechanical drawing in evening school in Newark, N.J., and by private tuition.

At the age of nineteen Mr. DeVries began a three-year apprenticeship in the manufacture of machine tools with the New York Steam Engine works, Passaic, N.J. He then spent a year in repair work in the bleaching and printing business at the Rockland Print Works, Haverstraw, N.Y. From that time until 1892 he was connected with the Hewes & Phillips Iron Works at Newark, N.J., in the capacity of erecting and testing engineer. For several years he erected and tested refrigerating plants and during the remainder of the time he erected and ran tests on various types of engines, particularly Corliss cross compound condensing and non-condensing and Boyden automatic cut-off engines. He designed and applied the first adjustable cut-off for low and intermediate pressure cylinders on compound and triple expansion engines, and also designed an adjusting screw for taking up lateral motion on the valves of both high and low pressure cylinders which was adopted as universal equipment.

In 1892 Mr. DeVries and his brother founded The Novelty Iron Works in Passaic, for general machine and engineering work. The company built and tested both steam and belt driven condensers and repaired all classes of steam and gas engines. It also built the DeVries patent feedwater heater and purifier, a continuous circulation feedwater heater, and various devices used in manufacturing textiles, artificial leather, chemicals, rubber goods, matches, tin cans, and other products. In addition to the feedwater heater Mr. DeVries devised and patented an all-metal device for feeding the uncombed wool to the points of a comber, replacing the so-called dabbing brushes and greatly increasing the operating speed of the combs. Mr. DeVries retired from active business in 1925.

Mr. DeVries became a member of the A.S.M.E. in 1921. He was a charter member of the Passaic Branch No. 11 of the National Association of Power Engineers. He was also active in the civic life of Passaic, having served for two terms as a member of the Board of Education. He was one of the founders and a director of the Merchants Bank, Passaic, and a director in the Service Trust Company, Hobart Trust Company, and The Peoples Bank & Trust Co. until illness necessitated his retirement about a year before his death. He was also vice-president of the Mutual Loan & Building Association, an auditor of the Home Loan & Building Association, and treasurer of the Lodi Cemetery Company. He belonged to the Clifton Reformed Church.

Surviving Mr. DeVries are his widow, Mrs. Jemima (Lokker) DeVries, four sons, and one daughter.

ROBERT CONRAD DOERR (1883–1932)

Robert Conrad Doerr, sales and consulting engineer and power plant analyst for the Sarco Company, New York, N.Y., since 1925, died at St. Mary's Hospital in Hoboken, N.J., following an operation, on November 6, 1932.

Mr. Doerr was born in Chicago, Ill., on September 26, 1883, the son of Adam and Elizabeth (Becker) Doerr. He attended Lewis Institute, Chicago, for two years and in 1901 entered the employ of the Daimler Manufacturing Company, Steinway, L.I., N.Y. After two years there he went to Coronado Beach, Calif., where he was superintendent of construction of the Dupee estate until 1909.

In 1909 Mr. Doerr went into business for himself in the hydraulic engineering field. Later he designed and developed a portable coal elevator for bunkering express passenger ships and a system for cleaning condenser tubes and express type boilers, called bullet tube cleaners. He was commissioned a lieutenant in the U.S. Naval Reserve in 1918 and placed in charge of all bunkering equipment of the Navy transport force. Subsequently he was appointed director of fuel in the Fifth Naval District. He was made a lieutenant-commander in the U.S. Naval Reserve in 1928.

After the World War Mr. Doerr became sales engineer for the M. K. Bowman-Edson Company, New York, with which he was connected until he joined the Sarco Company. He became a member of the A.S.M.E. in 1921. He was a Royal Arch Mason and Knight Templar and a member of the Elks organization and several military groups. His wife died in 1927.

Early in 1932 Mr. Doerr was granted a patent for chemically treated felt pads for use on windshields to repel rain and snow.

CHARLES VINCENT EYRE DOVE (1868–1932)

Charles Vincent Eyre Dove, whose death occurred in Chicago, Ill., on March 26, 1932, was born in London, England, on March 10, 1868. His early education was obtained in London and at schools in Germany and Switzerland. He was graduated from the Hammond Technical College in London in 1886 with an E.E. degree, and qualified as a civil engineer in Australia during the next four years.

Between 1890 and 1908 Mr. Dove practiced as a consulting engineer, maintaining an office in Honolulu, Hawaii. In 1908 he took charge of the development of the University Park Addition in Seattle, Wash. Not long after entering upon this work he was appointed Park Engineer for the City of Seattle, and later opened offices as consulting engineer in that city. Since 1926 he had been located in Chicago and vicinity, where for five years he was associated with James Walker in consulting work.

Mr. Dove became a member of the A.S.M.E. in 1921. He also belonged to the Pacific Northwest Society of Engineers.

Surviving Mr. Dove are his widow, formerly Miss Kathleen Monsarrot, whom he married in 1908, and a son, John Forbes Dove.

HAROLD GEORGE DRYSDALE (1891–1932)

Harold George Drysdale, consulting engineer, Brooklyn, N.Y., who died on March 12, 1932, was born in Birmingham, England, on March 18, 1891, the son of Robert and Ruth (Butler) Drysdale. He studied engineering at the Lowell Institute, securing M.E. and E.E. degrees, and served a four-year apprenticeship as machinist and tool and die maker at the General Electric Company, West Lynn, Mass. He remained with this company until October, 1915, working as a journeyman for the first year and subsequently on the design of tools and dies for railway motors, steam turbines, and special automatic devices. He supplemented his experience during the next two years as tool and machine designer for the United Shoe Machinery Company, Beverly, Mass., the Hamel Machinery Company, Lynn, and E. B. Badger & Sons Co., Gray & Davis, and the National Packaging Machinery Company, all of Boston.

In the fall of 1917 Mr. Drysdale entered the employ of the Curtiss Aeroplane & Motor Corp., Buffalo, N.Y., soon becoming chief of the tool design section and later assistant aeronautical mechanical engineer. He left this post in November, 1918, to sell a mechanical device for the New Era Manufacturing Company of New York, for about a year. Next, he directed the design and construction of a special automatic machine for the Pull-Man Engineering Service, Brooklyn. When this was completed, in May, 1920, he took a position as tool and die designer with the Automatic Straight Air Brake Company, New York, later becoming production engineer. For a short time he was connected with the Safeguard Sales Company, selling mechanical devices, and then spent a few months on the design of a special automatic machine for the Lancaster Engineering Corporation. Early in 1922 he became factory manager and chief engineer of the Twisted Wire & Steel Co., New York, his duties including the supervision of manufacturing, inspection, personnel, and purchasing.

From 1923 to 1925 and from 1926 to 1928 Mr. Drysdale was connected with the American Machine & Foundry Co., Brooklyn, working on the design of cigar and cigarette machines and other machinery, in the capacity of assistant to the chief of the cigarette machine design department during the second period. A brief intervening period was spent as chief draftsman for the F. L. Smith Machine Co., New York. He engaged again in airplane manufacture in 1929 as assistant to the production chief of the Fairchild Airplane Company, Farmingdale, L.I. During the next two years he was consulting engineer for Gibson Arnoldi & Co., New York, in charge of all mechanical work as well as plant surveys, estimates, and valuations. Since late in 1931 he had been on the engineering staff of the Hoffman Beverage Company, Newark, N.J.

Two of Mr. Drysdale's many designs were patented by him, one a guard for circular saws and the other an automatic egg boiler.

Mr. Drysdale became an associate member of the A.S.M.E. in 1923. He belonged to the Masonic fraternity, Odd Fellows, and the Sheepshead Bay Yacht Club. He is survived by a brother, Leslie W. Drysdale, Brooklyn, N.Y., and four sisters, Mrs. A. J. Summers, Mrs. H. D. Ricker, Mrs. Prescott W. Whittier, and Mrs. E. V. Holmes, all of Lynn, Mass.

FRANCIS HOSKINS EASBY (1861–1932)

Francis Hoskins Easby, a member of the A.S.M.E. since 1888, died at his residence in Philadelphia, Pa., his birthplace, on March 1, 1932. Mr. Easby was born on August 18, 1861, the son of William and Mary Anne (Hoskins) Easby. He attended the public school in Media, Pa., and the Episcopal Academy and Lauderbach's Preparatory School in Philadelphia before taking a four-year course in mechanical engineering at the University of Pennsylvania, with the class of 1881. He had some early experience in the repair shop of his father's sugar refinery and after completing his work at the university took a position as draftsman for the Baldwin Locomotive Works. After a year there he was similarly employed at the machine tool works of F. B. Miles for a year and by the Pratt & Whitney Co., Hartford, Conn., for two years.

In 1885 Mr. Easby opened a machine shop in Philadelphia, later moving to Bristol, Pa. He gave this up the following year and went to Johnstown, Pa., where he was engaged for a time in designing a cold saw for the Johnson Steel Street Railway Company. When that piece of work was done he returned to Philadelphia as draftsman and designer for Bement, Miles & Co., with which he was connected for two years. He next spent four years with the Betts Machine Company, of Wilmington, Del., as designer and superintendent. For 17 years, beginning in 1891, he was superintendent for the Detrick & Harvey Co., Baltimore, Md., then for three years engineer for Ladd & Baker, Philadelphia, and from 1913 to 1917 engineer for the Richard DeCou Company.

Mr. Easby entered the United States Navy as senior inspector of engineering materials in 1917 and continued in that work until illness necessitated his retirement in 1930.

Mr. Easby was also a member of the Academy of Natural Sciences in Philadelphia and of Alpha Tau Omega fraternity. He had patented an open-side planer feed device of his invention. He was a student of American political history. Surviving him are his widow, Gertrude K. (Peirce) Easby, whom he married in 1884, and two children, Mrs. Charlotte Easby (William C.) Grave of Philadelphia, and John Peirce Easby, of Merion, Pa.

CHARLES LEAVITT EDGAR (1860–1932)

Charles Leavitt Edgar, president of The Edison Electric Illuminating Company of Boston, with which he had been associated for nearly forty-five years, died of pneumonia on April 14, 1932, at Atlantic City, N.J., where he had gone for a brief relaxation. The tremendous growth of the company which he headed from the small beginnings of a pioneer time to the all-inclusive service now given reflects his courage to try new things, his thorough study of conditions to be met, his perseverance in the face of difficulties, and his grasp of administrative, legal, and engineering problems.

Charles Leavitt Edgar was born on December 23, 1860, at Griggstown, near Princeton, N.J., the son of Thomas and Annie (Veghte)

Edgar. He attended the Rutgers Preparatory School, New Brunswick, N.J., for three years and received an A.B. degree from Rutgers College in 1882. He then took up post-graduate work there in electricity and for this and subsequent practical experience he received from Rutgers an A.M. degree in 1885 and an E.E. degree two years later. In 1927, at the 161st Commencement of Rutgers, he was awarded the honorary degree of Doctor of Science, and in the same year Tufts College conferred upon him the honorary degree of Doctor of Laws. The words of the president of the latter institution upon that occasion were particularly well chosen:

"In this age of science it is natural that every result of research in the realm of pure science should be hailed with acclamation. He who reveals new truth deserves and receives the plaudits of his fellows. But the history of human achievements indicates very clearly that in general, before any scientific discovery may be turned to the advantage of mankind, genius of a special kind must be brought to bear upon it. There must be imagination which visualizes human needs. There must be idealism which transcends mere venture for gain. There must be practical sense of values which avoids the shallows of romantic optimism, there must be skilfulness to manage men and manipulate materials, there must be steadfastness of purpose which never falters. Mr. Edgar, you share with the inventor credit for the development of the electric light. Your years of service to the community demonstrate of what I say."

Mr. Edgar's decision to enter the field of electricity came from his interest in the work of Edison at Menlo Park. He sought employment of Mr. Edison in January, 1883, and was sent to the old Edison Machine Works in New York, where he remained for about a year. He was next sent to the factory of the Bergmann Company, manufacturers of central-station equipment. Subsequently he was located at the original New York factory of the Edison Electric Light Company, where he stayed until 1887, rising to the position of chief engineer. His work there was of a general engineering character, particularly relating to the installation of small central stations in New York and neighboring states.

Mr. Edgar was transferred to Boston in 1887 to serve as superintendent of The Edison Electric Illuminating Company of Boston, which had recently been organized. Two years later he was made general manager, in 1894 advanced to the post of vice-president, and in 1900, upon the death of Mr. Jacob C. Rogers, elected president of the company.

Mr. Edgar was a pioneer in the electrical industry and he advanced with it, and while he advanced with the industry the industry advanced because of his initiative and progressiveness. He studied closely the practice of the principal stations both in the United States and abroad and adopted the most up-to-date equipment and methods adaptable to the needs of the territory served by his company. He also originated engineering practices and operations which later were adopted by the industry. Ideas which he gathered during several weeks spent abroad in 1890 were incorporated in the Atlantic Avenue generating station. The first storage battery used in this country as a central-station auxiliary was a Tudor battery which he imported from Germany. The first vertical engines used in America for central-station work were installed by him. Following a study of its use in England in 1898 he introduced the Wright demand system of charging in the Boston Edison service. The adoption of the steam turbine as a prime mover of large capacity, undertaken by the company under his direction in 1904, was the outstanding event of that year in the electrical industry. And his introduction of the 1200-lb boiler and turbine in the Edgar Station was an innovation in engineering practice which created wide interest.

Under such leadership the district supplied by the company increased from eleven-hundredths of a square mile, serving only 260 customers in the downtown district, in 1887, to an area of nearly 600 square miles, serving some 43,000 customers, twenty-five years later. The first notable expansion of the company was in 1902, when the Boston Electric Light Company and the Suburban Light & Power Company became part of the Edison system. Two years later the service began to spread into the cities and towns of Greater Boston. The system today supplies more than 400,000 customers. The development of district steam-heating service and the interconnection of New England central-station companies were among the many results of his endeavors. The Charles Leavitt Edgar generating station in Weymouth, Mass., one of the largest and most modern electric steam-generating plants in the United States, is a monument to his achievements.

Mr. Edgar was equally progressive in regard to the welfare of the employees of the company. The Edison Employes' Club, which he helped to form, served as a model for similar clubs in other cities. He provided comfortable, attractive, and healthy working conditions for the employees of the company, with very many of whom he was personally acquainted. The company also has established recreational and educational facilities, liberal sickness, accident, and death benefits, and a generous pension system. In 1912, on the 25th anniversary of his connection with the company, the employees presented him a loving cup in appreciation of his personal interest in their behalf. A message from Thomas Alva Edison on that occasion read as follows:

"When you took hold of the Boston Edison Company a quarter of a century ago, I expected you would give a good account of yourself, but I must confess I did not anticipate the magnificent showing that has been made by you and your company in these later days.

"Allow me to compliment and congratulate you on your success and to wish you many more years of useful endeavor."

On his 40th anniversary with the company, Owen D. Young, who wrote a testimonial article, spoke particularly of his service to his fellowmen. "Edison Service," in Boston, stood for what Mr. Edgar stood.

The electrical industry through several associations in that field also knew Mr. Edgar as a leader. He was president of the Association of Edison Illuminating Companies from 1893 to 1895; chairman of the board of directors of the New England Power Association; and three times vice-president and in 1903 president of the National Electric Light Association. He had served as president of the Massachusetts Gas and Electric Association and as chairman of the Boston Section of the American Institute of Electrical Engineers, of which he was a Fellow. He had also served the Institute as a member of the Edison Medal Committee. He was a past-president of the Edison Pioneers and a director and member of the executive committee of the Employers' Liability Assurance Corporation, Ltd.; director of the Employers' Fire Insurance Company, American Employers' Insurance Company of Boston, and the Electrical Testing Laboratories, New York; and a trustee of the Massachusetts Utilities Associates and of Rutgers College.

Mr. Edgar became a member of the A.S.M.E. in 1910. He also belonged to the Illuminating Engineering Society, the Society for Electrical Development, the Institution of Electrical Engineers (Great Britain), the Boston Society of Civil Engineers, the National Geographic Society, and the American Academy of Political and Social Science.

When the United States entered the World War Mr. Edgar was appointed an associate member of the Naval Consulting Board. He was chairman of the board of directors for the State of Massachusetts Organization for Industrial Preparedness, served on the national committee on gas and electric service, and was also connected with the fuel administration work.

During recent years Mr. Edgar had devoted much of his time to the affairs of the National Civic Federation, serving as a member of its committee of twenty-four, investigating the question of municipal ownership of public utilities in other countries. He also was chairman of the industrial welfare department of the federation for several years, in which work he made several surveys of the problem of old-age dependency and pensions.

Mr. Edgar lived quietly at his home in Brookline, Mass. He liked to attend first nights at the theater and was a prolific reader, finding relaxation in fiction. He was a member of the Brookline Country Club and played golf frequently when business permitted. His other clubs included the Engineers' and University in New York and Boston; Exchange and Algonquin in Boston; and Kingswood and Bald Peak in Wolfeboro, N.H., where he had a country home.

He is survived by his widow, Annette (Duclos) Edgar, whom he married in 1896, a son, Leavitt L. Edgar, vice-president and director of the Boston Edison Company, one brother, and two grandchildren.

JOHN EDGAR ELDER (1873–1932)

John Edgar Elder, building manager for the N.Y. Stock Exchange Building Co., New York, since 1922, died in that city on October 16, 1932.

Mr. Elder was born at Bells Valley, Va., on October 30, 1873, the son of Robert C. and Nancy Jane Elder. He worked as fireman, oiler, and assistant engineer for the Virginia Iron & Railway Co., and for several hotels in that state before going to New York in 1898.

During the remainder of his life he had charge of power plants and other equipment in a number of hotels and other buildings in New York. He was assistant engineer at the Mills Hotel for five years, in full charge of operation and maintenance. From 1903 to 1910 he was located at power stations, first the 74th Street Station of the Interborough Rapid Transit Company and then at the Port Morris Station of the New York Central Railroad. Since then he had been chief engineer for Saks & Company and the Washington Life Building (1910–1912), assistant chief engineer, Hotel McAlpin (1912–1917), chief engineer, American Express Building (1917–1918), and chief engineer and superintendent of building, in full charge of the mechanical, electrical, and building equipment, Hotel Pennsylvania (1918–1922). He also acted in an advisory capacity in Statler plants in Buffalo, Detroit, Cleveland, and St. Louis, in connection with changes and new work. The N.Y. Stock Exchange Building Co., with which he had been associated since 1922, controls four buildings.

Mr. Elder became a member of the A.S.M.E. in 1920. He had belonged to the National Association of Power Engineers for 25 years and was its president in 1913. He was a 32d degree Mason. Mr. Elder was predeceased by his wife, Emma L. (Clark) Elder.

IRVING STANILAUS FELLNER (1891–1932)

Irving Stanilaus Fellner, who had been connected with the McGraw-Hill Publishing Company for some years, died suddenly at his home in Chappaqua, N.Y., on October 30, 1932.

Mr. Fellner was born at Ft. Smith, Ark., on March 5, 1891, the son of Samuel and Lena (Berck) Fellner. Before going to New York he spent six years with the Kawneer Manufacturing Company, in charge of the sales staff and construction in Southern and Central California. During his last two years there he also was assistant sales manager for the entire United States.

In 1919 Mr. Fellner became business manager for *Chemical and Metallurgical Engineering*, in charge of the sales staff and marketing counselor for the McGraw-Hill Publishing Company. Later he was also made publishing director of *Power* and at the time of his death was with *Management Methods*.

Mr. Fellner was the author of many articles on design and construction and a lecturer before the architectural departments of eastern universities. He was active in the evolution of the philosophy of the sales of materials in industries and closely identified with the design and sales departments of many large industrial organizations.

During the World War Mr. Fellner served overseas as first lieutenant of infantry with the 26th and later the 30th Division. He became an associate of the A.S.M.E. in 1927.

CHARLES H. FISH (1861–1932)

Charles Henry Fish died on December 20, 1932, at the home of his niece, Miss Margaret Fish, in Brookline, Mass.

Mr. Fish was born in Taunton, Mass., on April 4, 1861, one of four sons of Captain Frederick and Mary Jarvis (Perry) Fish. He secured his first engineering experience with the Amoskeag Manufacturing Company, Manchester, N.H., working in the various shops and mills for four years and serving as assistant superintendent for two years. The next two years (1886–1888) were spent as agent for the Chicopee Manufacturing Company, Chicopee Falls, Mass. He then became treasurer and constructing engineer for the P. C. Cheney Paper Co., Manchester, N.H., and Excelsior Paper Stock Company, Goffstown Centre, N.H.

From 1895 to 1909 Mr. Fish was agent of the Cocheco Manufacturing & Print Works, Dover, N.H., the following year general manager and construction engineer for B.B. & R. Knight, Providence, R.I., and from then until 1913 general manager at the Garner Print Works & Bleachery in Garnerville and Wappingers Falls, N.Y. Since then he had engaged in consulting work as a textile engineer in Boston.

Mr. Fish became a member of the A.S.M.E. in 1891. He was a past-president of the National Association of Cotton Manufacturers, a member of the Engineers Clubs of Boston and New York and the California Club of Los Angeles, and belonged to several local clubs, including the Union Club in Boston. He enjoyed sailing and had a collection of old prints of ships. He also made sketches and water colors.

Mr. Fish is survived by his widow, Agnes (Cheney) Fish, whom he married in 1888, and three daughters, Mrs. Charles P. Woodworth of Weston, Mass., Mrs. Clarence F. Graham of Albany, N.Y., and Mrs. Philip F. Broughton of Brooklyn Heights, N.Y.

WALTER EVERETT FOSTER (1877–1932)

Walter Everett Foster, district sales manager for Reading-Pratt & Cady Co., Inc., Chicago, Ill., died suddenly at Decatur, Ill., on December 22, 1932.

Mr. Foster was born at Harvard, Mass., on January 29, 1877, the son of Joseph Ansil and Angelia B. (Hatch) Foster. He attended public school in Rochester, N.Y., and studied at St. Lawrence University before entering Worcester Polytechnic Institute. After his graduation in 1899 with a B.S. degree in the electrical engineering course, he worked for a short time as factory superintendent for the Sargent Automatic Railway Signal Company, Rochester. From 1900 to 1904 he was signal inspector for the Pennsylvania lines west of Pittsburgh, in full charge of all new signal work. During the next six years he advanced from construction engineer to western manager for the Union Switch & Signal Co., Swissvale, Pa. He directed the design and installation of signal apparatus aggregating several million dollars and patented several devices in the field. From 1908 to 1910 he was also president and treasurer of the Signal Supply Company, Chicago, Ill.

In 1910 Mr. Foster became sales engineer for the Ingalls-Shepbard Forging Company, Harvey, Ill., with which he remained until 1918. He was next associated with the Pfaudler Company, Rochester, N.Y., as manager of the Eastern District for three years, and subsequently became sales engineer for The Superheater Company, New York. In 1925 he took a position as sales engineer for the Reading Steel Casting Company, Bridgeport, Conn., now known as Reading-Pratt & Cady Co., Inc. He was transferred to Chicago as district sales manager in 1927.

Mr. Foster was technical secretary of the Western Division for the Naval Consulting Board in 1917 and 1918 and also technical secretary to the Committee on Engineering of the Illinois Council of Defense. He was in charge of an industrial inventory survey for Illinois and a member of the Illinois Home Guard at Oak Park, Ill.

Mr. Foster became a member of the A.S.M.E. in 1919 and also belonged to the Railway Signal Association, the Western Society of Engineers, and the Chicago and New York Engineers Clubs.

Surviving Mr. Foster are his widow, Harriett Combs Foster, whom he married in 1906, and two children, Josephine C. and Robert C. Foster.

CHARLES COLMAN FREDERICKS (1882–1932)

Charles Colman Fredericks, president of the St. Louis Meter & Pump Co., St. Louis, Mo., died on June 15, 1932. Mr. Fredericks became a member of the A.S.M.E. in 1921. At that time the following statement concerning him was submitted by the St. Louis Pump & Equipment Co.

"Mr. Fredericks has devoted practically his entire life to liquid handling engineering, giving special attention to the problems involving the safe and economical storage, distribution, and reclamation of oils and similar liquids.

"At the present time he is vice-president and general manager of the St. Louis Pump & Equipment Co., engineers and manufacturers of oil-handling equipment. Prior to this association he was connected with S. F. Bowser & Co., Ft. Wayne, Ind., in both executive and engineering capacities. He gave particular attention to liquid handling problems in connection with railroads, and has made personal surveys of oil and similar liquid handling facilities at practically every important railway terminal in the United States.

"During the past year he has been in close collaboration with his associated engineers perfecting, and is now manufacturing, the 'St. Louis' rotary piston pump, and is giving special attention to the improvement in design and construction of pumps, both hand and power, measuring and non-measuring."

Mr. Fredericks was born in Richmond, Va., on August 18, 1882, and held an LL.B. degree from Valparaiso University.

JOHN RIPLEY FREEMAN (1855–1932)

John Ripley Freeman was born on a farm at West Bridgton, Me., July 27, 1855. Early education in the public schools of Portland, Me., and Lawrence, Mass., led to studies in science and engineering at the Massachusetts Institute of Technology, from which he was graduated in 1876, with the degree of bachelor of science from the department of civil engineering.

In accordance with a custom which is as sound today as it was then, Mr. Freeman spent his summer vacations in gaining profitable experience in industry, working as assistant engineer with the water-power company at Lawrence, Mass. Returning to this work after graduation, he soon became principal assistant engineer to the company and to its chief engineer, Mr. Hiram F. Mills, in whose extensive consulting practice in water power, foundations, and factory construction he participated. It was here also that he came in contact with James B. Francis, of Lowell, Mass., recognized as the foremost hydraulic engineer of his day in this country, with John C. Hoadley, the eminent mechanical engineer, and with Charles S. Storrow, one of the best educated engineers of his day, who planned the new city of Lawrence, designed and developed its water-power plant, and wrote the earliest treatise on hydraulics of water supply in the English language.

Ten years of this valuable apprenticeship led, in 1886, to Mr. Freeman's resignation to become engineer and special inspector for the Associated Factory Mutual Fire Insurance Companies of Boston, Mass. These companies were associations of manufacturers established for the double purpose of insurance and the development of means for preventing diastrous fires. Because of Freeman's ability and technical training, he was soon asked to undertake the reorganization of the corps of inspectors maintained by the fire-insurance companies. This work he supervised for about ten years, conducting also many researches on the improvement and standardization of fire-prevention apparatus, including automatic sprinklers, fire pumps, fire hose, and the causes of fire. It was during this period that he presented to the A.S.C.E. his well-known papers, "Experiments Relating to the Hydraulics of Fire Streams," which received that society's gold medal in 1889, and "The Nozzle as an Accurate Water Meter," the gold-medal paper in 1891.

While carrying on the work of supervising the inspectors of the insurance companies, Mr. Freeman engaged also in consulting practice in Boston, Mass. This twofold interest was maintained throughout the remainder of his active life. Or perhaps it would be better to say threefold—or many fold, for the researches in which he was constantly engaged, or in which he displayed a lively personal interest, also persisted throughout his entire career. During recent years he was engaged in preparing a book on researches on the flow of water in pipes, elbows, and tees.

In 1896 Mr. Freeman was called to Providence, R.I., to become president and treasurer of what is now the Manufacturers Mutual Fire Insurance Company, the position which he held at the time of his death.

Space will not permit a complete recital of Mr. Freeman's achievements in the many fields in which he worked. While a definite chronology pertains to each, his work lay in several of them simultaneously. For convenience, therefore, a general classification of them has been attempted.

Of his business and insurance interests mention has already been made, and the success of the company he served seems adequately to express Mr. Freeman's competence and accomplishments in its non-engineering aspects. Its principal success lying in adequate fire prevention, it is only natural that a great many of Mr. Freeman's engineering achievements were also in this field. To it he brought a technical training and a valuable knowledge of hydraulics, the subject in which most of his engineering practice lay. He wrote on hydraulic and piping arrangements for the protection of cities in 1892, and of the protection of cities from fire in 1915. In 1905 he presented to the A.S.M.E. in his presidential address a comprehensive study of theater fires, their causes and means of prevention, and in 1923 this Society awarded him its gold medal "for eminent service rendered to industry in fire prevention."

In his consulting practice, as has already been indicated, Mr. Freeman made a speciality of hydraulics. It is possible to mention only briefly the principal projects that engaged his attention.

In 1895 to 1896 he was engineer-member of the Massachusetts Metropolitan Water Board.

In 1903–1909 he was chief engineer in charge of investigations for damming the Charles River between Boston and Cambridge, Mass., creating a fresh-water "basin." The project and its result is well known to all visitors to these cities.

He served, at various times, the Metropolitan Park Commission of Massachusetts on matters of river improvements and drainage.

In 1899 he was engaged by the Finance Department of the City of New York to investigate additional sources of water supply—the first step in works since built. Noteworthy researches on water waste in municipalities were conducted as part of this work.

Later, in 1904, he again served the New York Metropolitan District as a member of the Burr-Hering-Freeman Commission for further study of additional water supply, and, in 1905, became consulting engineer to the New York Board of Water Supply (a post which he filled for the remainder of his life) after having refused, because of his consulting practice and insurance business, to become its chief engineer.

Other communities came to him for advice on their waterworks problems. In 1907–1908 it was the New York State Water Supply Commission, later known as the State Water Conservation Commission, on studies for conserving water resources. He was one of the engineering commission of three reporting on the feasibility and location of the Los Angeles aqueduct, 240 miles long, from the Owens River (1906). Baltimore, Md., secured from him in 1909 designs for a new source of water supply. San Francisco employed his services from 1909 to 1912 in planning the Hetch Hetchy water-supply system substantially as it is now being constructed. He made electric-power development an important feature of this project, greatly adding to the income of the city. Nashua, N.H., Denver, Colo., Seattle, Wash., San Diego, Calif., and Mexico City also sought out his services.

In the field of water-power development he was employed by the Aluminum Company of America at Massena, N.Y., at the Long Sault, Niagara, and on several southern rivers. He planned power developments on the Feather River in California for the Great Western Power Company; made investigations for the Canadian Government on water-power development in the provinces of Alberta, Manitoba, and British Columbia; designed high masonry dams for the Mexican Northern Power Company at La Boquilla de Conchos, for the Medina Irrigation Works in Texas, the Pacific Gas & Electric Company at Lake Spaulding, the Spring Valley Water Company at Calaveras, the Great Western Power Company at Big Bend, Calif., the Aluminum Co. at Badin, N.C., etc.; and assisted engineers of the U.S. Reclamation Service on construction methods for the Arrow Rock Dam near Boise, Idaho. He also designed and supervised the construction of a high masonry dam on peculiarly difficult foundations on the Missouri River at Holter, Mont.; prepared designs (not executed) for developing the Great Falls of the Potomac with a great reservoir by a single dam 200 feet high; designed extensions and to some extent supervised construction of high earth dams by hydraulic fill at Coquitlam, British Columbia, and San Pablo, Calif.; and made outline plans (not executed) for a new subterranean power development for the Ontario Power Company at Niagara and for the development of 800,000 continuous horsepower on the St. Lawrence River, near Montreal, from the Lachine Rapids, with its backwater raising Lake St. Louis nearly to its flood level.

In the field of drainage and flood control Mr. Freeman acted as consulting engineer, 1917 to 1920, to the Chinese Government on the improvement of the Grand Canal, including preliminary studies of flood prevention on the Yellow River and the Hwai River. In 1922 he prepared designs for a large railroad bridge across the Yellow River. In his plan the bridge was reduced to about one-fifth of its previous length by training and confining the river to a narrow channel. From 1924 to 1926 he served on the Engineering Board of Review of the Sanitary District of Chicago on the controversy over the lowering of the level of the Great Lakes.

Space will permit only the bare mention of his services to the United States during the World War on the National Advisory Committee for Aeronautics, his report on the Hog Island Shipyard, his studies, in 1905, 1908, and 1915, of various special problems of the Panama Canal; of his connection with the Providence, Rhode Island, gas company, and his studies in city planning, highways, and parks for the City of Providence.

One of Mr. Freeman's most patriotic services was his untiring efforts to secure for the United States a National Hydraulic Laboratory. The bill authorizing the laboratory was passed by the Congress under the leadership of Senators Ransdell and Hebert, and the laboratory, constructed largely in conformity to designs supervised by Mr. Freeman, was dedicated in the spring of 1932. A description of it will be found in *Mechanical Engineering*, May, 1932. Many hydraulic laboratories exist abroad, and in a book, "Hydraulic Laboratory Practice," published by the A.S.M.E. in 1929 but financed and edited by Mr. Freeman, these laboratories and their work are described.

Geologists and seismologists have felt the stimulus of Mr. Freeman's enthusiasm and breadth of interest. Studies in water supply and flood control naturally presupposed a comprehension of geological formations. He was a pioneer in calling upon geologists and seismologists to aid in clearing up questions that arise in engineering works. He studied the continental depression of the New England shore line in his investigation for the Charles River Basin, and summarized new and old data and drew valuable conclusions as to continental movement in connection with his report on the regulation of the Great Lakes.

In the words of the Reverend John Joseph Lynch, S. J., representing the Seismological Society of America at a testimonial dinner to Mr. Freeman in Providence in April, 1931, "Divine Providence has decreed that there will be earthquakes, but the City of Providence through one of its honored sons and engineers has arranged that the effects of these earthquakes shall not be so disastrous." Presenting a paper before this society in 1930, Mr. Freeman was (quoting Father Lynch again) "embarrassingly insistent with the seismologists that we must make better measurements regarding the basic facts of earth motion and seismology before we can put up buildings that are going to withstand earthquake shock, and he was so insistent that one felt one had to go out and find these data." To the work of this society Mr. Freeman made financial contributions; and within the past year he brought out his 600-page book on a "Study of a Rational Basis for Earthquake Insurance."

Not only in science, in engineering, and in business did Mr. Freeman's talents exercise themselves, but in the field of education and engineering societies as well. A graduate of Massachusetts Institute of Technology, twice president of its Alumni Association, and life member of its corporation, on which he served for more than forty years, he was offered the presidency of the institution when Dr. Pritchett resigned. Twice President Eliot offered him the chair of Civil Engineering at Harvard University. These honors he declined, feeling that his services to mankind were better engaged in the practice of his profession. He spoke and wrote on educational matters. He held honorary degrees from Brown, Tufts, University of Pennsylvania, Yale, and the Sächsische Technische Hochschule, Dresden.

In 1923 Mr. Freeman gave $25,000 each to the American Society of Civil Engineers, The American Society of Mechanical Engineers, and the Boston Society of Civil Engineers to provide for traveling scholarships in hydraulics. The first Freeman Traveling Scholarships were awarded in 1927. They enable young engineers or junior professors between the ages of 25 and 35 years to profit by a year or more of study in the best engineering laboratories of Europe.

Mr. Freeman was a loyal and active member of many engineering societies. He was an honorary member of the Providence Engineering Society, the Boston Society of Civil Engineers, the American Society of Civil Engineers, and the American Water Works Association. He was elected to honorary membership in the A.S.M.E. in 1932. He was president of the Boston Society of Civil Engineers in 1893, of The American Society of Mechanical Engineers (of which he became a member in 1887) in 1905, and of the American Society of Civil Engineers in 1922.

He was a member of the National Academy of Arts and Sciences, the Visiting Committee of the Bureau of Standards, honorary member of the Badische Technische Hochschule, Karlsruhe, and Mitgleid des Wissenschaftlichen Beirats des Forschungsinstituts in Munich and Walchensee, Bavaria.

Mr. Freeman died in his sleep on the night of October 6, 1932, following a brief illness of two days. He is survived by his widow; four sons, Clarke F., Hovey T., John R., Jr., and Evert W. Freeman; and a daughter, Miss Mary Elizabeth Freeman.

JOENS ELIAS FRIES (1876–1932)

Joens Elias Fries, chief engineer of the Tennessee Coal, Iron & Railroad Co., Birmingham, Ala., died at the Fairfield Hospital in that city on January 23, 1932, after a long illness.

Mr. Fries was born in Frinnaryd, Sweden, on April 6, 1876, the son of Andreas Peter and Maria (Castenson) Fries. He was graduated from the College of Uppsala in 1894 and from the Royal Technical Academy (Kongl. Tekniska Hogskolan), Stockholm, in 1898, with degrees in electrical and mechanical engineering.

Mr. Fries worked in Sweden until 1903. For the first two years following his graduation he was employed by a Stockholm firm manufacturing telephone apparatus. During the remainder of the time he was connected with the General Swedish Electric Company (Allmanna Svenska Electriska A.B.) as estimator for plants of every kind, and with the Holmia Electric Company, Stockholm, as superintendent.

In 1903 Mr. Fries came to the United States, his first position in this country being with the New York Edison Company. After a short time in that connection, he was employed by the Westinghouse, Church, Kerr & Co. for drafting work for the electrification of the Long Island Railroad. He next took a position, in 1905, with the Allis-Chalmers Company, Milwaukee, Wis., as engineer in the contract department, where he remained for two years. He then went to Toronto in the capacity of engineer of power plants and power transmission for the Canadian General Electric Company, but returned to the United States in 1908. From then until 1916 he was identified with the Crocker-Wheeler Company, spending a year and a half in charge of the estimating department, a like period as industrial engineer, two years as Pacific Coast engineer, and the remainder of the time as assistant chief engineer. His work for that company included the construction of the 6000-kw power plant on Bishops Creek for the Southern Sierras Power Company, and the electrification of a large sugar mill in Cuba. He was responsible for new designs entailed in all this work.

Mr. Fries had been connected with the Tennessee Coal, Iron & Railroad Co., a subsidiary of the United States Steel Corporation, since September, 1916. At first he was in charge of the Electrical Department, as chief electrical engineer. About 1920 he succeeded Mr. R. E. Brakeman, who resigned to enter the employ of the Otis Steel Company, as chief engineer. At that time the blooming mill, structural mill, and plate mill for the company's fabricating shop at Fairfield and the assembling plant at Mobile had been completed, and the Engineering and Drafting Departments of the company were consolidated and Mr. Fries placed in charge of the Ensley and Fairfield Works. He designed the power-house equipment and crane equipment for the Mobile plant of the Chickasaw Shipbuilding & Car Co. This plant was dismantled not long afterward, but freight cars continued to be manufactured at the Fairfield Steel Works, for which Mr. Fries had designed much of the equipment.

Mr. Fries was a past director of the Association of Iron and Steel Electrical Engineers and a Fellow of the American Institute of Electrical Engineers. He became a member of the A.S.M.E. in 1921 and also belonged to the Svenska Teknologforeningen, American Iron and Steel Institute, American Association for the Advancement of Science, American Society for Steel Treating, the Engineers' Club of New York, Engineers' Club of San Francisco, and Birmingham Country Club.

Since 1908 Mr. Fries had frequently presented technical papers before different organizations and contributed articles to the technical press. Among the subjects with which he dealt were distribution voltage for central stations, electric drive of turbine pumps, power for steel mills, current surge in an inductive circuit, influence of gear ratio on speed of operation, motor heating and contactor wear in auxiliary steel mill drives, and parallel operation of turbine-driven central stations. He was also an expounder in lectures and articles of Einstein's theory of relativity, and made a number of translations, including "Death and Resurrection," by Bjorklund, from the Swedish, and several works by Arrhenius, from the Swedish and German. These dealt with the transmission of life through the universe, the infinity of the universe, and the destinies of the stars.

Surviving Mr. Fries are his widow, Annerika (Bjerkander) Fries, and a son, Dr. Erik F. B. Fries.

WILLIAM SPENCER GEOHEGAN (1892–1932)

William Spencer Goehegan, who since 1930 had owned and operated a garage and machine shop in Los Angeles, Calif., died of pneumonia at his home in Pasadena, Calif., on December 13, 1932. He is survived by his widow, Elsie G. (Adney) Geohegan, whom he married in 1917, and by a daughter, Elsie.

Mr. Geohegan was born in Chicago, Ill., on November 24, 1892, the son of William and Elizabeth Geohegan. He attended public school in Chicago and later took courses in management from LaSalle Extension University and studied four years at the Throop Polytechnic Institute (now California Institute of Technology), Pasadena, Calif.

He was employed by the Crown Hardware Company in Pasadena from 1912 to 1916 and during the next three years was corporation salesman for the Union Hardware & Metal Co., of Los Angeles. In 1919 he joined the staff of the Southern California Edison Company as a buyer for the Kern River No. 3 hydroelectric project, stationed at Bakersfield, Calif. In this capacity he took care of emergency orders for construction materials for both the power house and transmission lines. After two years in that work he was transferred to the main office of the company in Los Angeles, in charge of purchasing construction materials for hydroelectric and steam generating projects. He was connected with the company until 1928, when he became sales manager for the Junior-Norris Galvanizing Company, Los Angeles, with which he remained until he went into business for himself in 1930.

Mr. Geohegan became an associate of the A.S.M.E. in 1928. He also belonged to the Society of American Military Engineers, the Electric Club of Los Angeles, and the Masonic fraternity. He was an Episcopalian.

ERNEST T. P. GREENIDGE (1881–1932)

Ernest T. P. Greenidge, superintendent of the Indiana Pipe Line Company, Huntington, Ind., died at the Grant County Hospital, Marion, Ind., on October 25, 1932, from injuries sustained in an automobile accident.

Mr. Greenidge was born on Barbados Island, British West Indies, on September 12, 1881. His technical education was secured at Stevens Institute of Technology, from which he was graduated with an M.E. degree in 1910, having spent some years in travel before entering the Institute. His first position was with the Southern Pipe Line Company, Lancaster, Pa., where he was engaged in testing pumping stations for economical operation, installing pumping machinery, boilers, etc., and general plant construction work for two years following his graduation. With the exception of two years during the World War he had been associated with the Indiana Pipe Line Company since 1912, entering the employ of the company as assistant to the superintendent and being promoted to the position of division engineer in 1914 and superintendent in 1919.

Mr. Greenidge was one of the first men in Huntington to attend the first officers' training camp at Fort Benjamin Harrison. He entered army service in May, 1917, and was commissioned a first lieutenant in the Corps of Engineers in August of that year. After further training at Camp Funston, Kan., he was sent overseas and served on the administrative staff at the main engineering depot in Paris, where he was promoted to the rank of captain. He was a charter member of Huntington Post No. 7 of the American Legion.

Surviving Mr. Greenidge are four brothers, Arthur, Sydney, and Frank, of New York, N.Y., and Philip, of Barbados. He had been a member of the A.S.M.E. since 1921, and was also a member of the honorary engineering fraternity of Tau Beta Pi, the Elks, and the LaFontaine Country Club.

OLAF NICOLAUS GULDLIN (1858–1932)

Olaf Nicolaus Guldlin, one of the founders of the Western Gas Construction Company, Fort Wayne, Ind., died at his home in that city on September 6, 1932. He was born on December 6, 1858, in Christiania (now Oslo), Norway, the only son of a family of seven children of Lars O. and Maren Sander Guldlin. After he had completed his preparatory schooling at Christiania, he entered the technical college at Bergen, Norway, from which he was graduated in 1878. He then took a year of special studies at the Polytechnikum at Munich, Bavaria, and a year of practical training in the iron works of A. L. Thune, in Christiania.

He came to the United States in 1880 and found his first employment in this country in the Baldwin Locomotive Works in Philadelphia, Pa., as a draftsman. He returned to Norway in 1882 to induce his family to come with him to America.

Upon returning to the United States, he was employed by James A. Smedberg, a gas engineer of Lancaster, Pa. At a convention in Washington, D.C., in 1884, he met A. D. Cressler, of Fort Wayne, who urged him to go to Fort Wayne. He did so not long afterward and entered the employ of the Kerr Murray Manufacturing Company.

In 1888, he decided to work independently and formed a partnership with W. A. Croxton and Frank D. Moses as consulting gas engineers. Two years later, when the original partners of Mr. Guldlin withdrew, he and Gordon W. Lloyd and Ernest F. Lloyd, of Detroit, incorporated the firm under the name of the Western Gas Construction Company. Mr. Guldlin became president and general manager.

In 1902, Mr. Guldlin, Samuel M. Foster, Charles McCulloch, and J. Ross McCulloch, all of Fort Wayne, purchased the interests of the Lloyds in the Western Gas Construction Company. Mr. Guldlin continued as president and general manager.

The Koppers Company, of Pittsburgh, Pa., in 1917 took a five-year lease on the Western Gas Construction Company with the option of purchasing the company. Mr. Guldlin retired as president but continued as a member of the board of directors until the Koppers Company made the purchase in 1922.

Mr. Guldlin had designed and patented about fifty devices, including a gas condenser, coal-treating apparatus, ammonia washer, and various governors and valves for use in the gas industry.

The Western Gas Association sent Mr. Guldlin to the International Gas Congress in Paris in 1900. He visited the principal gas plants in France, Austria, Switzerland, Germany, England, and Scotland during 1900 and 1901.

He received the grand prize at the Louisiana Purchase Exposition in St. Louis, in 1904, in recognition of his inventions and developments in the gas industry, and was appointed to the International Jury of Awards in the Department of Liberal Arts and unanimously elected to honorary membership in the Indiana Commission.

Mr. Guldlin was appointed on the American Gas Institute committee in charge of the gas industries exhibits at the Panama-Pacific Exposition at San Francisco, Calif., in 1917. His company's exhibit was awarded the highest distinction, the "Medal of Honor," two gold medals, and two silver medals. Again Mr. Guldlin was personally honored with the Exposition's Gold Medal on recommendation of the American Gas Institute, which was followed by the award to him by the International Jury of the "Medal of Honor."

Mr. Guldlin was prominent in many business enterprises and civic endeavors in Fort Wayne, and was a member of fraternal and social organizations in that city and elsewhere. He was president of the old Fort Wayne Commercial Club, which became the present Chamber of Commerce. He and Mrs. Guldlin had made contributions to the equipment for playgrounds in Fort Wayne, and he helped to plan and build the Anthony Hotel and Fairfield Manor there.

He was a charter member of the Allen County-Fort Wayne Historical Society and ranked high in the Masonic fraternity. He became a member of the A.S.M.E. in 1905 and also belonged to the Society of American Military Engineers.

Previous to his retirement in 1922 he was a member of the American Gas Institute, the Pacific Gas Association and similar industrial organizations in Michigan, Indiana, Wisconsin, and Illinois, the American Academy of Political and Social Science, the American Political Science Association, and the American Economic Association.

He had also been a member of the Cosmos Club, of San Francisco, Calif., the Lions Club, of New York, and the Missouri Athletic Club at St. Louis.

He married Addie L. Bleekman at Rarden, Ohio, in 1889, and is survived by her.

Mr. and Mrs. Guldlin returned to Europe in May, 1930, where they visited the college from which he had been graduated, his birthplace, and other places in Norway and Sweden. His health failed shortly after his return to his home here.

CLARENCE SHERMAN HAMMATT (1858–1932)

Clarence Sherman Hammatt, past-president of the Florida Engineering Society, died at a hospital in Jacksonville, Fla., on December 6, 1932. He had been in failing health for some time.

Mr. Hammatt was born in Geneseo, N.Y., on November 11, 1858, the son of Edward Rumney and Eliza H. (Pheips) Hammatt. He was graduated from the Mount Pleasant Military Academy in New York in 1877 and later took courses from Johns Hopkins University and the Bryant and Stratton Business College.

From 1880 to 1883 he was employed by the Detroit Machine Screw Works. He then learned the plumbing trade and in 1886 took charge of the plumbing department of the Drew Hardware Company, Jacksonville, Fla. The following year he was connected with the Jacksonville Water Works and in 1888 became superintendent and consulting engineer for the Gas and Electric Companies of Jacksonville, which incorporated the Citizen's Gas and Electric Company, American Illuminating Company, and Jacksonville Light Company. After ten years with this organization he accepted the position of consulting engineer and manager of the Jacksonville Electric Light Company and during the years 1898–1890 was engaged in planning and building a new plant to furnish all electric current for Jacksonville. About this time he also organized and was made vice-president of the Florida Electric Company, dealers in electrical work and supplies, with which he continued to be associated until he sold out his interests in 1907.

For nearly ten years, beginning in 1901, Mr. Hammatt engaged in general contracting, covering the erection of machinery and structural iron work, under the name of the Hammatt Contracting Company. He was granted a process patent for fractional distillation of wood products in 1907. In 1910 and 1911 he was superintendent of the Ware County Gas, Electric and Ice Company, Waycross, Ga., and during the next two years part owner and operator of the Milldale Ice Works, a small ice plant in a suburb of Jacksonville. For a number of years, from 1915 on, he was president of the Consolidated Engineering Company, Jacksonville, engaging in both mechanical and electrical engineering.

From 1912 until his death Mr. Hammatt was consulting engineer to the Board of Commissioners of State Institutions in Florida and with his assistance a great many improvements in various state institutions had been made in recent years, including new buildings at the State Prison Farm. During the World War he was also a member of the Board of National Preparedness and an associate member of the Naval Consulting Board.

Mr. Hammatt was one of the organizers, in 1916, of the Florida Engineering Society and served as its fifth president. He became chairman of the society's Legislative Committee upon its formation and when the state enacted its Professional Engineering Bill, in 1917, he was appointed by the governor to the first State Board of Engineering Examiners. He served on this board continuously until his death, and had held the offices of secretary, treasurer, and president. He was also a member of the National Council of State Boards of Engineering Examiners and had been its president. In recognition of his services to the engineering profession and to the state, the C. S. Hammatt Engineering Library was established in 1926 at the University of Florida by the Florida Engineering Society.

Mr. Hammatt joined the A.S.M.E. in 1922. He was instrumental in forming the Florida Local Section in 1925, had been a member of its executive committee, and was a member of its nominating committee for 1932–1933. He also belonged to the American Institute of Electrical Engineers and the Society of American Military Engineers. He was a 33d degree Mason and a Shriner, and a member of the St. John's Episcopal Church in Jacksonville and of a number of social organizations there.

In 1885 Mr. Hammatt married Elizabeth Pratt, of Buffalo, N.Y., who survives him, as do also two sons, Sherman and Edward, and a daughter, Mrs. Gertrude Pratt, all of Jacksonville.

FRANCIS M. HARTMANN (1870–1932)

Francis M. Hartmann, professor of electrical engineering and dean of the Schools of Engineering of Cooper Union, New York, died on March 28, 1932, at his home in that city after a month's illness. A graduate of Cooper Union, Dean Hartmann had been a member of the engineering faculty for more than thirty years.

Dean Hartmann was born at Cochecton, N.Y., on August 31, 1870, the son of Franz Eugen and Paulina (Hoenninger) Hartmann. He attended Damascus Academy, in Pennsylvania, and evening high school in New York prior to entering upon his studies at Cooper Union. At the latter institution he took a five-year course in general science, a three-year course in chemistry, and post-graduate work in physics and electrical engineering, receiving an A.B. degree in 1895 and an E.E. degree eight years later. He also did graduate work in mathematics at New York University.

From 1891 to 1894 he served as city surveyor, New York, and from then until 1901 as computer of the department of public improvements. He was an instructor in physics and electrical engineering in the Cooper Union Night School of Engineering in 1899, that being the beginning of his long association with the Cooper Union day and night schools in a teaching capacity. He taught in both the day and night schools from 1901 to 1905, when he was appointed assistant professor of physics and electrical engineering. He was made a full professor two years later, and from 1908 to 1921 was professor of electrical and mechanical engineering in charge of the department. He was named dean of the Schools of Engineering in 1921.

In 1912 Dean Hartmann designed and equipped the new dynamo laboratories and thermodynamic laboratory for the Hewitt Memorial Building of Cooper Union. He also helped to develop a number of courses, including the five-year night-school course in electrical engineering, a five-year night-school course in general science, and a day-school technical science course.

Dean Hartmann also did some consulting work, in conjunction with A. G. Koenig and the E. E. Carey Company, New York, the latter relating particularly to transformer iron. He was a contributor to *Electrical Review* and was the author of "Elementary Mechanics," published in 1910, "Heat and Thermodynamics," 1911, "Biography of George W. Plympton," 1920, and "Alternating Currents and Transmission," 1923.

He had been a member of the A.S.M.E. since 1910, and also belonged to the American Institute of Electrical Engineers, the American Association for the Advancement of Science, the American Physical Society, the American Mathematical Society, and the Society for the Promotion of Engineering Education.

Surviving Dean Hartmann are his widow, Phoebe (Koenig) Hartmann, two brothers, and three sisters.

HUGO ADELBERT HECKER (1866–1932)

Hugo Adelbert Hecker, a member of the A.S.M.E. since 1906, died at his home in Norwood, Ohio, on July 24, 1932, after an illness of seven months.

Mr. Hecker was born at Stepstone, Ky., on February 10, 1866. He attended public school in Cincinnati and took night courses in engineering for three years at the Ohio Mechanics Institute there. He served a four-year apprenticeship in milling machine work and subsequently was employed by a number of Cincinnati engineers and firms, including the Lodge & Davis Machine Tool Co.; Lane & Bodley Co., working on Corliss engines; Bert L. Baldwin, as assistant draftsman on street railroad, incline planes, and power house work; F. M. Watkins Co., as chief draftsman, designing and testing gas engines; and the Watkins Laundry Machinery Company, as chief draftsman, designing and constructing both machinery and plants. For ten years, from 1891 to 1901, he was also instructor in mechanical drawing in evening classes at the Ohio Mechanics Institute.

After leaving the employ of the Watkins Laundry Machinery Company Mr. Hecker designed machinery for the American Laundry Machinery Company, Cincinnati, for a time and spent six years in similar work at the American Tool Works Company, Cincinnati, with which he was connected at the time of his death.

Mr. Hecker is survived by his widow, Nellie (Kottmyer) Hecker, whom he married in 1892, two children, Charles H. Hecker and Mrs. Dorothy E. (Hecker) Zinker, and two grandchildren, Stanley and Woodward Zinker.

JOHN BROWN FRANCIS HERRESHOFF (1850–1932)

John Brown Francis Herreshoff, first American recipient of the Perkin Gold Medal, inventor of a contact process for manufacturing sulphuric acid, died at his home in Atlanta, Ga., on January 30, 1932.

Dr. Herreshoff, the son of Charles Frederick and Julia Ann (Lewis) Herreshoff, was born on February 7, 1850, at Bristol, R.I. His father, manager of the Point Pleasant estate on Popasquash Neck, Bristol, was very fond of sailing and built a few boats for his own pleasure. His grandfather, Charles Frederick Herreshoff, came from Prussia in 1790, settling in Providence the following year and marrying Sarah Brown, the daughter of one of the largest shipowners of Rhode Island. Dr. Herreshoff's mother was the daughter of a well-known sea captain of Boston, Joseph W. Lewis.

This was the background for the Herreshoff Manufacturing Company, builders of many pleasure and commercial vessels as well as the yachts which for more than twenty years defended the United States in the international races. The business was founded in 1863 by Dr. Herreshoff's brother, John B. Herreshoff, famous blind designer, and two other brothers, Nathanael Greene, whose talents as a designer and builder are equally well known, and Charles F., Jr., joined the firm in 1878, although the latter remained with it only a year.

Dr. Herreshoff himself had comparatively little interest in the family business. He was graduated from Brown University in 1870 with the degree of Ph.B. In his sophomore year he had been appointed laboratory assistant in the department of chemistry and in his junior year was made assistant professor of analytical chemistry. He retained this post after his graduation until 1872.

After leaving Brown University Dr. Herreshoff worked as a chemist at the Silver Spring Bleachery in Providence for about a year. He then went to New York and secured employment as assistant to Professor Habirshaw, who carried on a business as general chemical expert. About 1874 he entered the chemical-metallurgical field as manager of the Laurel Hill Chemical Works, Newton Creek, L.I., then the largest concern of its kind in the United States. Out of this organization grew the Nichols Chemical Company, for which Dr. Herreshoff became designer and consulting engineer in November, 1875, and later superintendent and vice-president. In 1899 one branch of the business was organized as the Nichols Copper Company, which Dr. Herreshoff served as superintendent and vice-president, and the remaining interests, together with the business of 24 major chemical concerns in the United States, were incorporated into the General Chemical Corporation. Dr. Herreshoff was consulting engineer to the corporation. Upon his retirement in 1924 he retained the vice-presidency of the Nichols Copper Company and was made an honorary vice-president of the corporation. He was also a director of the Granby Consolidated Mining, Smelting & Power Co.

The invention of the process which revolutionized the manufacture of sulphuric acid came early in Dr. Herreshoff's career, while he was superintendent of the Laurel Hill Chemical Works.

Dr. Herreshoff was honored by Brown University in 1905 with an honorary Master of Arts degree and in 1909 the degree of Doctor of Science was conferred upon him. His contributions to the "improvement of the science and manufacture of chemical and metallurgical products" were recognized in the award of the Perkin Medal, established as a memorial to Sir William A. Perkin, English scientist.

Dr. Herreshoff was married four times. His first marriage was to Miss Grace Eugenia Dyer, of Providence, in 1876. Of this marriage a daughter, Mrs. Louis H. Eaton, of Providence, survives him. His second wife was Miss Emily Duval Lee, of Philadelphia, whom he married in 1882. They were divorced in 1919. Of their three children a son, Francis Lee Herreshoff, of New York, and a daughter, Mrs. Rudolph Borgianni, of Florence, Italy, are living. Dr. Herreshoff's third marriage was to Mrs. Carrie Ridley Enslow, who died in 1924, and his fourth to her sister, Irma Grey Ridley, who survives him.

Dr. Herreshoff became a member of the A.S.M.E. in 1894. He was past-president of the American Chemical Society and a member of the Society of Chemical Industry, the Scientific Alliance, and the Brown University Alumni Association. His clubs were the University and Chemists', of Manhattan, and the Hamilton, of Brooklyn.

F. ADOLF HEYMANN (1875–1932)

F. Adolf Heymann, machine designer for the Mergenthaler Linotype Company, Brooklyn, N.Y., died on March 25, 1932, at his home in Waterbury, Conn., after a short illness. He is survived by his widow, Mrs. Helen Heymann, and his mother, Mrs. Margaret Heymann, as well as by one brother, Otto, of Austria.

Mr. Heymann was born on September 27, 1875, at Stettin, Germany. He served a three-year apprenticeship as a machinist with Hespe & Co., manufacturers of woodworking machinery in Hamburg, and worked for a number of years as machinist, toolmaker, and shop foreman in the United States, to which he came for the first time in 1898, and in Germany. He supplemented this practical experience with courses at technical schools in Hamburg and Neustadt, securing an M.E. degree in 1903.

In 1905 Mr. Heymann was connected with the H. B. Smith Machine Co., Smithville, N.J., as designer. He left in April of the following year to take the position of chief draftsman and mechanical engineer with the Marlin Fire Arms Company, New Haven, Conn., where he remained for five years. He designed all the tools and special machines necessary for the manufacture of a new line of sporting guns. During the next two years he was located in Munich, Germany, in the position of industrial and process engineer for the Isaria Meter Works. He reorganized the manufacturing department and introduced a tool designing department for developing labor-saving devices. As the result of his efforts, production was doubled, with only about a fifty per cent increase in the working force.

Mr. Heymann returned to the United States in 1913 and took the position of tool and machine designer with the Winchester Repeating Arms Company, New Haven, subsequently being promoted to overseer and assistant foreman. After two years there he became chief draftsman and process engineer at the Marlin-Rockwell Corporation in the same city. This company was just beginning to build the Colt machine gun. Mr. Heymann supervised the design of tools and special machines for three different machine guns, being in charge of about fifty draftsmen. Later he was transferred to a branch factory and took charge of a manufacturing job until the factory was shut down in January, 1919.

From this time until 1924 Mr. Heymann was employed as process engineer and chief draftsman by the Premier & Potter Printing Press Co., Derby, Conn., for which he organized an engineering department and laid out a more economical manufacturing system.

After a short time in production and research work for the Marlin Fire Arms Company, Mr. Heymann became associated with the Sargent Company, New Haven, in similar work.

In October, 1926, Mr. Heymann took a position with the Scovill Manufacturing Company at Waterbury, Conn., where he remained until the first of April, 1931. He developed and improved various types of automatic buffing machines, continuous spray lacquer machines, automatic plating machinery, and other equipment used in the application of the results of his research on metal finishes to the fabricated products of the firm.

After leaving the Scovill Manufacturing Company Mr. Heymann engaged in special engineering work for the Mergenthaler Linotype Company until ill health necessitated his retirement.

Mr. Heymann was greatly interested in amateur photography and was also an excellent shot, winning numerous prizes in various state and local contests. He was vice-president of the Scovill Recreation Rod and Gun Club, and wore its "Monogram," which meant an average of 95 per cent or more. He was also a member of the New Haven Gun Club. He joined the A.S.M.E. with the grade of member in 1919.

MICHAEL SULLIVANT HOPKINS (1872–1931)

Michael Sullivant Hopkins, who died of pneumonia at his home in Columbus, Ohio, on November 9, 1931, was born at Henderson, Ky., on May 21, 1872, the son of William Allison and Lucy Jane (Sullivant) Hopkins. He attended high school in Henderson and served an apprenticeship in a foundry and machine shop there.

Mr. Hopkins went to Columbus in 1890 and was employed during the next two years by the Minott Elec. Machine Co. and the Thompson & Houston Elec. Co. He became foreman of shops for the Columbus Consolidated Street Railway Company, in 1892 and was connected with the railway and lighting properties of Columbus until ill health caused his retirement from business several years prior to his death. He was mechanical engineer for the Columbus Street Railway Company from 1894 to 1898; general superintendent of the Columbus Railway Company from 1899 to 1902 and of the Columbus Railway & Light Co. during the next two years; and chief engineer and subsequently vice-president of the properties operated by E. W. Clark & Co. He was also vice-president of the Portland Railway Light & Power Co., Chattanooga Railway & Light Co., East St. Louis & Suburban Railway Co., Tennessee Power Company, and Nashville Railway & Light Co.

After giving up active work Mr. Hopkins became interested in securing exact data on automobile performance and developed a system of testing for gasoline consumption, performance of spark plugs, engine compression, and all points of efficiency, etc. He had the testing apparatus built and in practical use, intending to develop it commercially, when his failing health caused him to drop this and all other commercial interests.

Mr. Hopkins was fuel administrator for Ohio during the World War. He became a member of the A.S.M.E. in 1913 and belonged to a number of clubs in Columbus and Chattanooga. He was a member of the Presbyterian Church.

Surviving Mr. Hopkins are his divorced wife, Matie Atkinson (Lockett) Hopkins, whom he married in 1899, and a married daughter, Mrs. Sidney D. L. Jackson, of Toledo, Ohio.

JAMES ARTHUR INGALLS (1889–1932)

James Arthur Ingalls, chief of the Testing Bureau of the Brooklyn-Manhattan Transit Corporation, Brooklyn, N.Y., died on March 24, 1932. Mr. Ingalls had been connected with the Bureau since 1910, with the exception of about nine months' work as instructor in drawing at the New York Vocational School.

Mr. Ingalls was a native of Brooklyn, where he was born on May 22, 1889. He became a member of the Bureau in 1910 following his graduation with a Ph.B. degree from the Sheffield Scientific School of Yale University. The Testing Bureau is connected with the Williamsburgh Power Plant Corporation, a subsidiary of the Brooklyn-Manhattan Transit Corporation, and is divided into three sections, a chemical laboratory, an electrical division, and a mechanical division.

Mr. Ingalls was appointed mechanical assistant in charge of all mechanical work in 1916 and made chief of the Bureau three years later. In addition to varied tests of fuels, equipment, and materials, the Bureau handles considerable routine work, such as the analysis of lubricants, feedwater, and boiler water, the calculation of daily water rates and efficiencies, etc., as well as analytical and consultation work for various divisions of the parent company.

Mr. Ingalls claimed credit for the design of a smoke density indicator and recorder in successful operation for several years and several remote reading level gages, designed particularly to meet special conditions in different parts of the plant, and also for the development of an indirect method of checking the accuracy of water flowmeters using a proportionate salinity method combined with electrical conductivity measurements. He collaborated in the design of a very effective type of cinder catcher used in the Williamsburgh Power Station.

Mr. Ingalls became an associate member of the A.S.M.E. in 1916 and attained full membership in 1931.

Surviving Mr. Ingalls are his widow, Lillian Grace (Williamson) Ingalls, whom he married in Brooklyn in 1914, two sons, James Arthur and George Williamson, and a daughter, Ruth Elizabeth Ingalls.

GILTNER RUSSELL INGELS (1897–1932)

Giltner Russell Ingels, whose death occurred at Cleveland, Ohio, on October 16, 1932, following an operation for appendicitis, was born at Pleasant Hill, Mo., on March 22, 1897. His parents were George and Rosa (Russell) Ingels. He prepared for college at the high school in Columbia, Mo., and was graduated from the University of Missouri in 1914. He did post-graduate work in mechanical engineering there during the next two years, and in 1917 went into the 139th Infantry of the U. S. Army with the rank of sergeant. He was commissioned a lieutenant in the Air Service after having completed a special training course and appointed an instructor in aerial navigation. He continued his studies at the University of Missouri in 1919 and obtained his M.E. degree in 1921.

Mr. Ingels spent the summer of 1921 in design work for a new power plant at the University and during the next year was an instructor in mechanical drawing and descriptive geometry there. He entered the business field at the close of the school year as chief engineer for the Peet Bros. Mfg. Co., of Kansas City, Mo., and Berkeley, Calif., and for about three years had charge of design and maintenance work at a large soap and glycerine plant.

In the fall of 1925, after a few months in mechanical design work for the California Packing Corporation, San Francisco, Calif., he went to Aurora, Ill., to become chief engineer for the Lyon Metallic Mfg. Co., in charge of all plant layout, construction, and maintenance work. Early in 1926 he began his association with the Charles E. Bedaux Co. of Illinois, Inc., in Chicago, of which he was vice-president and chief engineer until February, 1932. As field engineer during the early days of his connection with the company, he installed the Bedaux system of human power measurement for wage payment and labor control and cost purposes. Since leaving the company he had been engaged in design work for himself, and was collecting data for a book on aeronautics.

Mr. Ingels became an associate member of the A.S.M.E. in 1927. He belonged to the Masonic and several Greek letter fraternities. He is survived by his widow, Helen (Bradford) Ingels, whom he married in 1922.

GEORGE E. IRELAND (1884–1932)

George E. Ireland was asphyxiated on October 28, 1932, by carbon monoxide gas while adjusting the motor of his automobile in the garage of his home in Toledo, Ohio.

Mr. Ireland was born in Greenfield, Ohio, on February 23, 1884, the son of Mr. and Mrs. Matthew O. Ireland. He was educated in the public schools of Washington Courthouse, Ohio, later moving to Dayton, where he was first employed by the Davis Sewing Machine Company as assistant foreman of its woodworking and millwrighting departments. Later he was connected with the Recording & Computing Machines Co., for which he designed street car registers, models for naval telescopes, and special machinery for accounting and banking. He also acquired a practice as a consulting engineer and was president and general manager of the City Engineering Company in Dayton, designers and builders of tools and machinery for special requirements.

In 1917 Mr. Ireland went to Springfield, Ohio, where he became assistant manager of the Steel Products Engineering Company and the Gem City Machine Company. In 1918 he was made general manager of the former organization, with which he remained until 1925, working on special tools for quantity production and developing an aeronautical motor. During the next two years he was connected with the Michigan Stamping Company, Detroit. He had been in Toledo since then, as assistant general manager for the City Machine & Tool Co. until January 1, 1931. Mr. Ireland had designed several types of radiator shells adopted by automobile companies.

Surviving Mr. Ireland are his widow, Edith Ireland, two daughters by a former marriage, Georgie E. and Mary S. Ireland, of Detroit, and his parents. He was a member of the Presbyterian Church and the Masonic fraternity and had been an associate member of the A.S.M.E. since 1919.

GEORGE HENRY ISLEY (1882–1932)

George Henry Isley, whose death occurred on November 30, 1932, had been associated with the Morgan Construction Company since 1906. He had served as chief draftsman and designer, and at the time of his death was manager of the Combustion Control Department of the company.

Mr. Isley was born in Jersey City, N.J., on November 25, 1882. After two years at Cooper Union in New York he did drafting for a number of firms before entering the employ of the Morgan Construction Company. Among these were the A. B. See Elevator Co., Rockwell Engineering Company, M. H. Treadwell Co., Rider Conley Manufacturing Company, United Coke & Gas Co., and Power Mining Machinery Company.

Mr. Isley made important contributions to the development of the Morgan producer gas machine, and invented the Isley reversing valve, the Isley system of furnace control, and other devices. He became a member of the A.S.M.E. in 1918.

WALTER GILBERT JAMESON (1883–1931)

Walter Gilbert Jameson, district superintendent of the Philadelphia District for the Babcock & Wilcox Co. died in Philadelphia on November 12, 1931, of pneumonia. He is survived by his widow, Laura (Nesbit) Jameson, whom he married in 1916.

Mr. Jameson was born at Norwalk, Ohio, on December 2, 1883. His early engineering work was that of fireman and engineer with dredging companies in Toledo and Cleveland, Ohio, and the Wheeling & Lake Erie and Pere Marquette Railroads. In 1912 he entered the employ of the J. B. McCrory of Atlanta, Ga., in charge of sewer and water works construction in Washington, N.C., and he continued as a construction engineer for a number of years, directing the erection of a post-office at Rocky Mount, N.C., the Hopewell, Va., plant of the DuPont Companies, a temporary trestle and cofferdam for the Philadelphia & Reading R.R. at Milton, Pa., and a sand blast plant for the American Car & Foundry Co., also at Milton.

In 1916 Mr. Jameson became erection engineer on power plant work for the American Engineering Company of Philadelphia, Pa. Four years later he was made district construction engineer for the company, in charge of all work in the Philadelphia District. He was transferred to the Western Division, with office at Chicago, in 1924, and remained with the company until 1929. Between then and his connection with the Babcock & Wilcox Co. in 1930 as field engineer, stationed at Barberton, Ohio, he served as field superintendent for the Combustion Engineering Corporation, with office at Detroit, Mich., and for the Fuller-Lehigh Company, at Fullerton, Pa.

Mr. Jameson became an associate-member of the A.S.M.E. in 1924.

WILLIAM EDWARD JERAULD (1873–1931)

William Edward Jerauld, works manager of the Consolidated Ashcroft Hancock Co., Inc., Boston, Mass., died at the Newton (Mass.) Hospital on October 30, 1931.

Mr. Jerauld was born at Clinton, Mass., on July 14, 1873, the son of Albert Edward and Mary J. (Earl) Jerauld. Employment by the American Steam Gauge & Valve Mfg. Co., Boston, Mass., followed the completion of his public school education, and at the age of twenty-six he had become superintendent of works for the company. In 1923 he took a position with Manning, Maxwell & Moore, Inc., and in 1927 with its subsidiary, organized in that year, the Consolidated Ashcroft Hancock Co., Inc., which is successor to the American Steam Gauge & Valve Co. and several other organizations.

Two United States patents on safety valves were held by Mr. Jerauld. He became a member of the A.S.M.E. in 1915 and also belonged to the Boston Engineers' Club and the Masonic fraternity, in which he was a Knight Templar.

Surviving Mr. Jerauld are his widow, Beatrice C. (Silman) Jerauld, whom he married in 1899, two sons, Albert E., Waban, Mass., and Ralph E. of Newtonville, Mass., and two daughters, Mrs. Gladys M. Bruce, Newtonville, and Mrs. Doris B. Hadley, Sterling, Mass.

ARTHUR ROBERT RICHARD JOHN (1896–1932)

Arthur Robert Richard John was born at Fürstenwalde, near Berlin, Germany, on January 28, 1896. He attended the Lycee of Haguenau, France, for six years and took three years of night school work at the Arts et Metiers in Paris. In August, 1910, he entered the firm of Dietrich & Co., at Reichshoffen, Bas Rhin, France, as apprentice engineering draftsman. After the completion of his apprenticeship he remained with the company until 1925, securing practical experience in the design of machine parts, timber construction, and other work, and taking technical courses.

In 1925, Mr. John went to Paris and found work as a draftsman with the Société Rateau, where he remained for about two years, working for part of the time as detailer in the pump section and later, on the building of steam turbines. His next position was with the Constructions Électrique de France, Paris, as a designer in the construction of electric locomotives, erection of electrical apparatus, and similar work.

Mr. John came to the United States in the latter part of 1928 and was employed for nearly two years by the Carrier Engineering Corporation, Newark, N.J., in layouts for heating, ventilating, and refrigerating systems. He returned to Paris early in 1931 to assist in the design of subway cars for the firm of Berboom & Dureuchard, but was again living in the United States when his death occurred on April 30, 1932. He had been an associate member of the A.S.M.E. since 1929.

JOHN PACKARD JORDAN (1877–1932)

John Packard Jordan, a member of the firm of Stevenson, Jordan & Harrison, management engineers, New York, N.Y., died suddenly at his home in that city on July 21, 1932.

Mr. Jordan was born in Auburn, Me., on November 1, 1877, the son of the Rev. John B. and Marietta Frances Jordan. He took a high school course in Pawtucket, R.I., at the same time studying mechanical drafting in evening school classes, and in 1893 was awarded prizes for his drawings exhibited at the Chicago World Fair. Practical experience in drafting was secured during summer vacations in the office of the Pawtucket Manufacturing Company, where he worked on bolt and nut machinery. He entered Brown University, Providence, R.I., with the class of 1899 but was obliged to leave after about a year and half because of eyestrain and other reasons.

In the fall of 1901 Mr. Jordan entered the employ of the Lackawanna Steel Company, Buffalo, for which he successively inspected materials, assisted in the supervision of repair and construction shops, reported progress of work on all building operations, and directed the erection of Power House No. 1, a 725-ft. building built in a record time of 19 days. Upon the completion of this plant Mr. Jordan was appointed supervisor of buildings, in charge of all steel erection, outside the blast furnaces, but not long afterward was stricken with infantile paralysis. After an illness of eight months he returned to the company, working in the Cost Department until August, 1903. He then resigned to take up industrial engineering, studying management and manufacturing problems in different plants in a consulting capacity.

Feeling the need of a knowledge of cost accounting work, Mr. Jordan associated himself from 1905 to 1908 with Mr. W. J. Gunnell, of Buffalo, in whose employ he had practical plant experience in this field. He resumed his private practice in 1908, continuing reorganization work begun at the Waterous Engine Works, Brantford, Canada, while he was associated with Mr. Gunnell, and conducting similar work in other plants. Among these was the Gould Coupler Company, Depew, N.Y., where for two years he worked on problems of reorganization. The company then desired him to remain in its employ as assistant to the general superintendent. He greatly decreased costs through changes in methods and equipment, a particular instance being the development of a variable speed grinder for grinding steel castings which resulted in an annual saving of from $25,000 to $30,000. He terminated his connection with the company in 1917 and during the World War was associated with a friend in the organization of a small aniline plant.

In July, 1918, Mr. Jordan became vice-president and director of operation for C. E. Knoeppel & Co., New York, N.Y., with which he remained for about five years. Shortly afterward the firm of Stevenson, Jordan & Harrison was organized.

Mr. Jordan lectured on industrial engineering subjects at New York University, the Harvard Graduate School of Business Administration, The Pennsylvania State College, and Massachusetts Institute of Technology. His "Cost Accounting Principles and Practice" was published by the Jordan-Harris-Ronald Press in 1921, and articles by him on industrial management have appeared in the technical press from time to time.

Mr. Jordan became a member of the A.S.M.E. in 1920 and also belonged to the American Management Association, Society of Industrial Engineers, National Association of Cost Accountants, of which he was a past-president, as well as of the Institute of Management, and a number of clubs in New York and vicinity and in Buffalo.

Surviving Mr. Jordan are his widow, Edith (Nagel) Jordan, whom he married in 1909, a son, John Alden Jordan, and two daughters, Marietta Jordan and Mrs. Benjamin F. Cutler.

FREDERICK WILLIAMS KELLEY (1870–1932)

Frederick Williams Kelley, president of the North American Cement Corporation, died on September 19, 1932, at his summer home in Altamont, N.Y., after an illness of four years. Though confined to his home, he had been able to continue in charge of the company and only a few days before his death had presided at a meeting of its directors.

Mr. Kelley was born at Albany, N.Y., on December 15, 1870, the son of James B. and Alice (Williams) Kelley. He prepared for college at the Albany Academy and Toledo (Ohio) High School, where he studied manual training. He received an M.E. degree from Cornell University in 1893. He was elected to membership in the Sigma Xi and Psi Upsilon fraternities while in college and was a member of the crew for four years.

Following his graduation Mr. Kelley entered the employ of the Consolidated Car Heating Company, Albany, working for the first two years in the drafting room and developing and experimental department. He was made assistant to the general manager and assistant treasurer in 1895 and four years later general manager and treasurer. Prior to and during the Spanish-American War he served in the infantry and signal corps of the New York National Guard.

In 1900 Mr. Kelley became vice-president and general manager of the Helderberg Cement Company and for the next 14 years made his home at Howes Cave, N.Y., where the plant of the company was located. He returned to Albany as president of the company and retained that position until the Helderberg Cement Company and Security Cement & Lime Company of Maryland were merged into the North American Cement Corporation in 1925, with Mr. Kelley as its president.

Mr. Kelley also served as president of the Consolidated Car Heating Company from 1912 to 1915, and was later made a director of the company and continued in that capacity until he died. He was vice-president of the National Commercial Bank & Trust Co., trustee of the City Savings Bank, and a director of the Commercial Safe Deposit Corporation, all of Albany; also president of the Albany Hospital, trustee of the Albany Medical College, The Albany Academy, Albany Institute of History and Art, and Dudley Observatory, and a member of the Board of Governors of Union University. He became a member of the A.S.M.E. in 1905 and also belonged to the American Institute of Electrical Engineers, American Society for Testing Materials, American Concrete Institute, Albany Society of Engineers, Portland Cement Association of America, International Cement Manufacturers Association, and the Society of Engineers of Eastern New York, of which he was a former president, as well as of the Albany Chamber of Commerce. He belonged to the Fort Orange and Albany Country clubs, and the University Club in New York.

Besides his mother, now Mrs. Timothy S. Williams, of Huntington, L.I., N.Y., and his widow, formerly Miss Lydia L. Hun, whom he married in 1903, Mr. Kelley is survived by a daughter Alice (Mrs. Arthur Brooks Harlow, Noroton, Conn.) and a son, Frederick Williams Kelley, Jr., Albany, N.Y.

JEREMIAH JOSEPH KENNEDY (1864–1932)

Jeremiah Joseph Kennedy, who died on February 15, 1932, was born in Philadelphia, Pa., on October 22, 1864. As a child Mr. Kennedy was delicate and was unable to attend school after the age of ten years. This condition, however, did not prevent him from studying at home, and being ambitious, he embraced every opportunity to learn. He was particularly fond of mathematics and borrowed from the Apprentices' Library, in Philadelphia, all books relating to this subject. Later in life, he was instrumental in this same library in helping poor boys to further their education.

Mr. Kennedy had a wide and varied career in the engineering profession. In January, 1882, he started as a rodman with the Norfolk and Western Railroad, and after a year became principal assistant to General Russell Thayer, engaging in miscellaneous engineering activities. In 1884 and 1885, as engineer for the Grubb Iron Works, Blue Ridge Springs, Va., he constructed railway extensions, operated mines, and planned and constructed improvements for the old Lynchburg Iron Company.

Then followed varied engineering work with the Henry Disston and Sons Steel and Saw Works, with Morris Tasker & Co., and with others. From 1892 to 1894, he was engaged in designing and constructing gas works, gas holders, retorts, and accessories, and in this period he owned and operated the National Iron Works at Linwood, Pa.

In May, 1894, he became chief engineer of the White, Crosby & Company of Baltimore, which later became the J. G. White & Co. of New York. He planned, constructed, and operated, among the many engineering projects of this company under his supervision, the Atlantic Highlands, Red Bank, and Long Branch Electric Railway.

In February, 1901, Mr. Kennedy severed his connection with the J. G. White & Co., to engage in private practice as consulting engineer, in which he continued until his death.

He designed and constructed for the Whitney Reduction Company in Rowan and Stanly Counties, in North Carolina, a masonry dam 38 feet high, together with a $4\frac{1}{2}$-mile-long hydraulic canal to develop 20,000 horsepower. He designed and constructed hydroelectric developments for the Schuylkill Valley Illuminating Company at Phoenixville, Pa.; for the Lynchburg Traction & Light Company at Lynchburg, Va.; and for the American Gas Company at Winooski and Essex Junction, Vt. He also planned and constructed improvements in the power plants of the Detroit and Lake Orion Railway at Rochester, Mich., and for the Cortland County Traction Company at Cortland and Homer, N.Y. For the Baldt Steel Company he designed and constructed the buildings, furnaces, and equipment for its steel plant at New Castle, Del.

In this period, from 1901 to 1932, Mr. Kennedy was also engaged in consultations, investigations, and reorganizations of many engineering projects in various parts of the country.

From 1904 to 1907, he was in charge of all operations and extensions to the underground pneumatic-mail-tube systems in New York, Chicago, St. Louis, and Boston.

In 1908, Mr. Kennedy became financially interested in the Biograph Company, a pioneer company in the motion-picture industry. He acquired an interest in and control of a number of patents relating to the industry, and for many years helped to guide the motion-picture industry through its early difficulties and developments.

Mr. Kennedy was a member of the American Society of Civil Engineers, the American Institute of Electrical Engineers, the American Institute of Mining and Metallurgical Engineers, the New York Electrical Society, the American Society for Testing Materials, the American Association for the Advancement of Science, the Illuminating Engineering Society, and The Franklin Institute. He had been a resident of New York since 1896, and was a member of the Lotos Club, the Engineers' Club, and the Bankers Club of America. He became a member of the A.S.M.E. in 1902.—Robert H. Hammer.[1]

JULIAN KENNEDY (1852–1932)

Julian Kennedy, who for his services and contributions to the iron and steel industry was awarded the A.S.M.E. medal in 1928 and the Gary Memorial Medal at the Spring Meeting of the American Iron and Steel Institute on May 19, 1932, died suddenly of heart failure on May 28, 1932, at his home in Pittsburgh, Pa. Mr. Kennedy was also the recipient, in 1904, of the Grand Prize for blast-furnace and steel-plant construction granted by the International Jury of Awards at the St. Louis Exposition.

Mr. Kennedy was born at Poland, Ohio, on March 15, 1852, the son of Thomas Walker and Margaret (Truesdale) Kennedy. After attending public school and the Poland Union Seminary he became a draftsman, under his father's supervision, in the construction of the Struthers blast furnace at Struthers, Ohio. He entered the Sheffield Scientific School of Yale University in 1872 and was graduated three years later with a Ph.B. degree. After graduation he remained at the school for a year, giving instruction in physics and taking post-graduate work in the chemistry of iron and steel. He received the honorary degree of Master of Arts from Yale in 1900, and in 1909 the

---

[1] Assistant to Mr. Kennedy since 1899.

Stevens Institute of Technology conferred upon him the honorary degree of Doctor of Engineering.

In 1876 Mr. Kennedy became superintendent of blast furnaces of the Brier Hill Steel Company, Youngstown, Ohio. The following year he went to the Struthers Iron Company in the same capacity, and in subsequent years he served successively as superintendent of the Morse Bridge Works, Youngstown; superintendent of blast furnaces at the Edgar Thomson Works of Carnegie Steel Company, Braddock, Pa.; superintendent of the Lucy Furnaces, Pittsburgh; and general superintendent for Carnegie, Phipps & Co., with headquarters at Homestead, Pa. In all of these positions he was responsible for construction and operation.

Mr. Kennedy was appointed chief engineer of the Latrobe Steel Works, Latrobe, Pa., in 1888, and was in charge of the construction of that plant. Two years later, while continuing as chief engineer of the Latrobe Works, he opened an office in Pittsburgh for private practice as consulting engineer in blast-furnace and steel-plant construction, subsequently gaining world-wide recognition in this field. His principal projects abroad were the design and construction of the steel works and blast furnaces for both the Tata Iron and Steel Works, Sakchi, India, and the Nicopol-Maripol Mining & Metallurgical Co., Sartana, Russia.

Mr. Kennedy patented many improvements in blowing engines, reversing engines, blooming mills, hot-blast stoves, blast-furnace filling devices, and other equipment for steel works. He was president of a number of coal and coke companies, including the Ontario Gas Coal Company, Lowber Gas Coal Company, Poland Coal Company, and Orient Coke Company. He was a director of the Toledo Furnace Company.

Mr. Kennedy became a member of the A.S.M.E. in 1912. He served as vice-president of the Society during the term of 1915–1917 and was selected as the A.S.M.E. medallist in 1928. Other technical organizations to which he belonged included the Iron and Steel Institute (Great Britain), American Institute of Mining and Metallurgical Engineers, American Iron and Steel Institute, Iron and Steel Electrical Engineers, and Engineers' Society of Western Pennsylvania. He belonged to a number of social and athletic clubs in Pittsburgh and New York.

Surviving Mr. Kennedy are two sons, Julian, Jr., and Joseph Walker, both associated with their father's engineering organization, and two daughters, Mrs. Lucy Belle (J.O.) Miller and Mrs. Eliza Jane (R.T.) Smith, of Pittsburgh. Their mother was Jennie E. Brenneman, whom Mr. Kennedy married in Poland, Ohio, in 1878.

MORRIS KNOWLES (1869–1932)

Morris Knowles, sanitary engineer and city planner, died suddenly of a heart attack at his home in Pittsburgh, Pa., on November 8, 1932.

Mr. Knowles was born in Lawrence, Mass., on October 13, 1869, the son of Charles E. and Ellen B. (Richardson) Knowles. As a young man, he was a neighbor of Hiram F. Mills, who was at that time conducting the historic studies at the Lawrence Experiment Station, in the field of water and sewage treatment. In part, at least, as a result of his contacts with Mr. Mills, he elected to study engineering at the Massachusetts Institute of Technology, where he was graduated in 1891 with an S.B. degree.

From his early acquaintance and friendship with Mr. Mills and from his up-bringing in the atmosphere of sanitary engineering that prevailed in Lawrence at that time, Mr. Knowles went on to practice his profession under men who were then or later to become outstanding leaders in the field of sanitary engineering. During his student days at M.I.T., he served an apprenticeship under Richard A. Hale, then principal assistant engineer, later chief engineer of the Essex Company, Lawrence. Upon graduation from M.I.T., Mr. Knowles became assistant engineer for the East Jersey Water Company, Montclair, N.J., under Clemens Herschel, chief engineer, and J. Waldo Smith, principal assistant engineer. In 1893, he became assistant engineer on the Massachusetts State Board of Health under F. P. Stearns. Mr. Knowles was personal assistant to Mr. Stearns in the latter's investigation of a water supply for Boston and vicinity, leading to the formation of the Massachusetts Metropolitan Water Board, and the development of the Wachusett Reservoir and Aqueduct to supply Boston and 28 surrounding cities and towns.

At the same time, Mr. Knowles was a member of the Water Board at Lawrence, his home town, which marked the beginning of an intimate contact with the municipal water supply problems of Lawrence, which he always maintained, returning there many years later to build additions to the slow sand filter plant and to report on new sources of supply.

In 1897, Mr. Knowles became resident engineer of the Pittsburgh Filtration Commission, and established a laboratory and experimental filters looking to the improvement of the Pittsburgh water supply. Following completion of the report of the Pittsburgh Filtration Commission, and prior to the actual construction of the Pittsburgh filters, Mr. Knowles went to Philadelphia in 1899 to perform a similar service for that city in experimental work on filters and an investigation of a proposed new gravity water supply for Philadelphia. In 1900, Mr. Knowles became assistant engineer under John R. Freeman, aiding him in the preparation of his comprehensive report on additional water supply for the City of New York.

Mr. Knowles returned to Pittsburgh in 1901, to become chief engineer of the Pittsburgh Bureau of Filtration and to design and supervise the construction of the slow sand filters for the Pittsburgh water supply on the Allegheny River at Aspinwall.

Upon the completion of the Pittsburgh Filtration Plant, Mr. Knowles devoted himself actively to the consulting engineering practice which he had formed in partnership with L. E. Chapin in Pittsburgh a few years before, and which he continued, first as a partnership with Mr. Chapin, and later as a corporation under his own name until his death.

In private practice, Mr. Knowles designed an impounding dam for the development of an industrial water supply for the Tennessee Coal, Iron & Railroad Co., on Village Creek in the Birmingham, Ala., district. He was a member of the engineering committee of the Flood Commission of Pittsburgh, which compiled an exhaustive report upon flood protection and prevention, and following the completion of the report in 1911, Mr. Knowles continued as a member of the executive committee of the Pittsburgh Flood Commission. He was a member of the Board of Advisory Engineers of the Miami Conservancy District, 1914, and chief engineer of the Essex Border Utilities Commission, Ontario, 1916–1921.

During the World War, he was supervising engineer in charge of the construction of Camps Meade and McClellan, and in 1918 and 1919 was chief engineer of the Housing Division of the United States Shipping Board. He was a member of the Engineering Board of Review of the Chicago Sanitary District in 1924, and served this Board as chairman of its committee on construction program.

Mr. Knowles early sensed the eventual participation of the civil engineer in the field of city planning and zoning, and as a consequence of his pioneering activities in this direction, he became a member of the Advisory Committee on Zoning appointed by Herbert Hoover when Secretary of Commerce. Mr. Knowles was Chairman of the City Planning Commission of Pittsburgh from 1922 to 1929, and Chairman of the Zoning Board of Appeals of Pittsburgh from 1923 to 1927.

Mr. Knowles designed and supervised the construction of sewage disposal and harbor improvements for Lynn, Mass., costing $2,500,000. He was consulting engineer to the Attorney General of the State of Connecticut, in conducting comprehensive investigations in support of the latter's unsuccessful suit to restrain Massachusetts from the diversion of interstate waters in the extension of the Boston Metropolitan District water supply.

Mr. Knowles was director of the Department of Sanitary Engineering, University of Pittsburgh, from 1911 to 1920 and in 1929 was awarded the honorary degree of Doctor of Engineering by the University. He was vice-chairman of the Executive Committee of the Commission appointed by the Governor of Pennsylvania to study municipal consolidation in counties of the second-class in Pennsylvania, and drew up a proposed charter for a federated city to amalgamate more than 100 minor political subdivisions in Allegheny County into a Greater Pittsburgh. Mr. Knowles was chairman of the Committee on Utilities in President Hoover's Conference on Home Building and Home Ownership in 1931. He was a term member of the Corporation of the Massachusetts Institute of Technology from 1924 to 1929. He was a director in the Pittsburgh Chamber of Commerce from 1922 to 1930.

Mr. Knowles was a director in the American Society of Civil Engineers from 1928 to 1930, a former director of the National Conference on City Planning, and a member of the Institution of Civil Engineers, Great Britain, and the Verein deutscher Ingenieure, Germany. He became a member of the A.S.M.E. in 1907, was a past-president of the Engineers' Society of Western Pennsylvania, and a member of the American, New England, and Pennsylvania Water Works Association, the American Public Health Association, the American Academy of Political and Social Science, the National Institute of Social Science, the Boston Society of Civil Engineers, the National Municipal League, and the International Housing and Town-Planning Association.

He belonged to the Duquesne Club and the University Club at Pittsburgh, the Engineers' Club in New York, the Cosmos Club of Washington, D.C., and other clubs. He was the author of "Industrial Housing," 1920, and many professional papers and contributions to the technical press.

Mr. Knowles is survived by his widow, Mina (McDavitt) Knowles, whom he married in 1893, one son, Morris, Jr., of Pittsburgh, and a daughter, Helen, Mrs. H. N. Schreuder, of New York, N.Y.

WALTER CHARLES LANGE (1889–1932)

Walter Charles Lange, consulting engineer, New York, N.Y., died on February 16, 1932, in West Englewood, N.J. He was born in New York on July 24, 1889, the son of Mr. and Mrs. Gustav Lange. He attended the High School of Commerce in New York and was graduated from the Stevens Institute of Technology, Hoboken, N.J., with an M.E. degree in 1912. During the remainder of that year he worked as draftsman in the Construction Department of the Otis Elevator Company, New York, and the Engineering Department of the Nichols Copper Company, Laurel Hill, L.I., N.Y. He then became assistant engineer in the Department of Utilization of the Consolidated Gas Company of New York, where his work consisted of conducting investigations of various types of gas appliances, designing of gas burners, and other work incidental to the utilization of gas as a fuel. For part of the time he was in charge of the Hotel and Restaurant Bureau, concentrating on appliances for hotel kitchens.

Early in 1916 Mr. Lange went to Homestead, N.J., to act as superintendent of the shop of the Schmitt Manufacturing Company, manufacturers of gas-burning appliances. He spent only a few months there, returning to New York to become technical assistant to the superintendent of Duparquet, Huot & Moneuse Co. For about three years, beginning in 1917, he was in sales work for the Doehler Die Casting Company, Brooklyn, and the Hammel Oil Burning Equipment Company, New York, being in charge of the office of the latter for some months.

Mr. Lange accepted the position of combustion and sales engineer for the Uehling Instrument Company, Paterson, N.J., in September, 1920, and in January of the following year was made manager of its Chicago office. He left in November, 1922, to open an office of his own in Chicago as combustion engineer. He represented several companies as manufacturers agent, including the Uehling company and the Hammel. In 1925 he went to Memphis, Tenn., to do some work for the Southern Coal Company, upon the completion of which he opened his New York office. He specialized in fuel economy, furnace design and control, boiler-room efficiency, etc.

Mr. Lange became a junior member of the A.S.M.E. in 1914, an associate member in 1921, and a member in full in 1925. He also belonged to the American Chemical Society and the American Association for the Advancement of Science.

Surviving Mr. Lange are his widow, formerly Miss Katherine G. Clark, of Memphis, Tenn., whom he married in 1916, and four children, Clark, Katherine, Helen, and Gustav.

JAMES GAVIN LARMER (1869–1932)

James Gavin Larmer was born in Glasgow, Scotland, on September 19, 1869, the son of David and Margaret (Gavin) Larmer. He served an apprenticeship at the Dalmellington Iron Works, near Glasgow, from 1883 to 1890, and also studied at the technical college in Glasgow. During the next three years he was engaged in marine engineering with Robt. Napier & Sons, Lancefield, Glasgow, and the Fairfield Ship Building & Engineering Co., Govan, Glasgow.

Mr. Larmer came to the United States in 1893 and was employed for a year in the mechanical department of Thomas A. Edison & Co., Schenectady, N.Y., and another year in the shops of the Burlington Railroad at Havelock, Neb. He then went to Lead, S.D., where until 1915 he was assistant master mechanic for the Homestead Mining Company. His next connection was with the Standard Oil Company in Sioux City, Ia., as lubricating engineer from 1918 to 1927. Since then, until his death on April 8, 1932, in Glendale, Calif., he had engaged in consulting work in lubrication in Los Angeles.

Mr. Larmer became a member of the A.S.M.E. in 1914. He was unmarried.

WILLIAM STEVENS LECKIE (1904–1931)

William Stevens Leckie, outside plant engineer for the New Jersey Bell Telephone Company, Newark, N.J., died at his home in Elizabeth, N.J., on November 19, 1931. He was born at Lake Placid, N.Y., on August 9, 1904, the son of William John and Bernice V. (Stevens) Leckie. He attended the Battin High School in Elizabeth and took night courses in drafting at the Newark Technical School, before entering Pratt Institute, Brooklyn, N.Y., from which he was graduated in 1927. He was draftsman for the New Jersey Bell Telephone Company for a time before going to Pratt Institute, and since his graduation had been in the employ of that company.

Mr. Leckie became a junior member of the A.S.M.E. in 1928. He was secretary of the Omega Gamma Delta fraternity and a member of the Third Presbyterian Church in Elizabeth.

HENRY MARTYN LELAND (1843–1932)

Henry Martyn Leland died on March 26, 1932, in the Grace Hospital, Detroit, Mich., after a month's illness. He was 89 years old. At the age of 61 he organized the Cadillac Automobile Company; at 74 he formed the Lincoln Motor Company; at 80, when he demonstrated his vitality by walking up to his office on the 22d floor, 433 steps, he declared that he had no intention of retiring. He remained active in civic affairs until his illness in February.

Leland manufactured tools for rifle making during the Civil War and produced airplane engines for the use of the United States Government in the World War. Educated, as he said, "in the little red schoolhouses of Vermont and Massachusetts," he became an inventor and manufacturer of such ability as to win him the honorary degree of Doctor of Engineering from the University of Michigan (1920) and from the University of Vermont (1923).

Mr. Leland was born at Danville, Vt., on February 16, 1843, a son of Leander Barton and Zilpha (Tifft) Leland. He attended the public schools in Millbury, Mass., and then learned the machinist's trade at the Crompton Loom Works in Worcester, Mass. During the Civil War he worked at the United States Armory in Springfield, Mass., Colt's Armory, Hartford, Conn., and a rifle factory in Worcester.

From 1866 to 1871 Mr. Leland built card-setting machines by contract. He then began an association of nearly twenty years with the Brown & Sharpe Manufacturing Co., Providence, R.I. He was foreman for a number of years, and from 1878 to 1890, when he resigned, he was superintendent of the sewing-machine department. Two of his inventions, the barbers' hair clippers and his grinding machine, were turned over to the company. This led Mr. Leland to realize the advantages of being able to manufacture his products himself. Accordingly he went to Detroit and organized the Leland, Faulconer & Norton Co. to manufacture machine tools. This company was later reorganized as the Leland & Faulconer Manufacturing Co., of which Mr. Leland was vice-president and superintendent until it was merged into the Cadillac Automobile Company in 1905. He entered the automotive field in 1900 with the manufacture of transmission gears for the one-cylinder motors for the car designed by Ransom E. Olds. He had previously had some early experience in making engines for "naphtha" launches, and predicted an almost unlimited future for internal-combustion engines.

Mr. Leland was general manager of the Cadillac Automobile Company during the first five years of its existence and then president and advisory manager. This company developed his electric starting device, thermostatic control of engine temperatures, and other inventions, as well as the V-type engine which his son, associated with him in the company, had worked out.

In 1917, Mr. Leland and his son resigned from the Cadillac Automobile Company to organize the Lincoln Motor Company, which manufactured thousands of Liberty motors for airplanes for the United States Government during the World War. He was an ardent admirer of Lincoln and had a notable collection of Lincoln literature and relics.

Mr. Leland became a member of the A.S.M.E. in 1895 and served as manager of the Society from 1912 to 1915. He was president of the Society of Automotive Engineers from 1909 to 1914, a founder of the National Foundrymen's Association and of the National Metal Trades Association, and prominent in the work of the National Association of Manufacturers. He was also a founder of the Detroit Citizens League and for some years its president. He belonged to a number of clubs and fraternal organizations in Detroit and vicinity and to the Jefferson Avenue Presbyterian Church. Reading, in which the study of the Bible was prominent, was Mr. Leland's main recreation.

Surviving Mr. Leland are two children, Mrs. M. Gertrude (Angus C.) Woodbridge and Wilfred Chester Leland, both of Detroit. Mrs. Leland, formerly Miss Ellen R. Hull, of Millbury, Mass., whom he married in 1867, died in 1914.

WILLIAM EDWARD LINDSAY (1864–1931)

William Edward Lindsay was born at Eldersburgh, Carroll County, Md., on February 29, 1864, and died in New York, N.Y., on December 26, 1931. Mr. Lindsay was the son of William C. and Julia (Allen) Lindsay. He served an apprenticeship as a machinist with Murrill and Keizer, Baltimore, Md., from 1882 to 1885, at the same time studying at the Maryland Institute Night School of Design. He attended high school in Ithaca, N.Y., the following year and then worked as journeyman machinist for Murrill and Keizer for a year, before entering Sibley College, Cornell University, from which he received an M.E. degree in 1891.

After his graduation Mr. Lindsay took a position at the Akron Rubber Works of The B. F. Goodrich Co., in the capacity of mechanical and designing engineer. He severed the connection late in 1892 to become chief electrician at the packing-house plant of Swift & Co. at the Union Stock Yards, Chicago, and had complete charge of the electric lighting and power system of this plant until April of the following year. He was then transferred to East St. Louis to install an electric lighting plant at a new packing house there, and directed the operation of the entire mechanical and electrical equipment, including the refrigerating and ice-making departments.

From 1922 until his death Mr. Lindsay was head of the Department of Machine Design of the Mechanics Institute, New York. He also was a Y.M.C.A. home study instructor from 1921 to 1928, and an instructor in the mechanical laboratory of New York University in 1929–1930.

Mr. Lindsay became a member of the A.S.M.E. in 1895 and also belonged to the Masonic fraternity. He is survived by his widow, Emily (Schirm) Lindsay, whom he married in 1891.

OTTO LUHR (1860–1932)

Otto Luhr, a pioneer in the refrigerating industry, died on May 5, 1932, following several years' illness. He was well known both as a consulting engineer in his field and as engineering instructor at the Wahl-Henius Institute of Fermentology in Chicago and associate editor of the Wahl-Henius Mechanical and Refrigerating Engineers Handy Book. He was an early contributor to *Ice and Refrigeration* on subjects relating to practical operation of refrigerating machinery. He had designed and installed a number of successful ice making and refrigerating plants and had recently invented a mechanical refrigerator car known as the Frigicar.

Mr. Luhr was born in Magdeburg, Germany, on March 21, 1860, the son of Adolph and Augusta Rieke Luhr. His early training was secured in Germany in the Magdeburg schools and as an apprentice in general shop practice and design in Backau. Prior to his association with the Wahl-Henius Institute he had been designer for the Keystone Bridge Works, Pittsburgh, Pa., and chief engineer for the Chicago Brewery & Malting Co., Ltd.

Mr. Luhr became a member of the A.S.M.E. in 1907. He was one of the organizers of the Linde Association, a Chicago branch of the National Association of Stationary Engineers, and belonged to the American Society of Refrigerating Engineers, National Association of Practical Refrigerating Engineers, and National Association of Steam Engineers. He was examining engineer of all civil service engineers in Chicago for some time.

A son, Henry Luhr, of Chicago, survives Mr. Luhr. His wife died in 1910.

BURT MACKENZIE (1869–1930)

Burt MacKenzie, owner of the contracting firm of B. MacKenzie, Inc., Greensboro, N.C., died in that city on November 12, 1930. He is survived by his widow, Ethel (Tucker) MacKenzie, whom he married in 1920, and by a son, Burt C. MacKenzie, and two daughters, Marie and Jeannette, all of Greensboro.

Mr. MacKenzie was born at Louisville, Ky., on March 28, 1869. After finishing his high-school course he served a four-year apprenticeship and was employed for some years by Joseph McWilliams' Steam Heating Company, of Louisville. For several years he was located in Philadelphia and Atlantic City, in similar work. He moved to Greensboro about the year 1900 and opened an office as a heating, ventilating, and engineering contractor. He designed and installed some of the largest plants in the South, including the central heating plant for about eighteen buildings on the campus of the North Carolina College for Women, at Greensboro, and plants for the A. & T. College, Guilford County Court House, and O'Henry Hotel, in Greensboro, State Hospital for the Insane, Goldsboro, N.C., Sir Walter Hotel, Raleigh, N.C., Forsyth County Court House, Winston-Salem, N.C., and the Cullowhee (N.C.) Normal and Industrial School and Salisbury (N.C.) High School.

Mr. MacKenzie became a member of the A.S.M.E. in 1923. He also belonged to the American Society of Heating and Ventilating Engineers and was a Shriner, an honorary life member of the Elks, and a member of several local commercial and social organizations.

WILHELM LUDWIG FERDINAND MARTENS (1847–1931)

Wilhelm Ludwig Ferdinand Martens, generally known as Ferdinand Martens, died on September 12, 1931, at Berkeley, Calif., after a prolonged illness.

Mr. Martens was born in Germany on October 30, 1847. He served an apprenticeship in machine shop work and studied engineering in Hamburg and Karlsruhe. After some experience in drafting and erecting machinery he emigrated to America in 1871, and found employment at the Williamsburgh Gas Company in New York and subsequently at the India Rubber Comb Company in College Point, N.Y. In 1874 he established himself as a surveyor in College Point. He was appointed superintendent of water works there the following year and about five years later became drainage commissioner. He designed a number of buildings in College Point, taught freehand and mechanical drawing at the Poppenhusen Institute from 1872 to 1882, was superintendent for a time of the College Point Gas Light Company, and served as a member of the board of trustees of the College Point Savings Bank.

In 1881 Mr. Martens returned to the employ of the India Rubber Company (later known as the American Hard Rubber Company) as superintendent of its India Rubber Department. He retired from active business in 1910 and made his home in College Point until 1918, when he went to Berkeley. He had been a member of the A.S.M.E. since 1885.

JACOB C. MATTERN (1866–1932)

Jacob C. Mattern, assistant superintendent in charge of equipment at the Elizabethport, N.J., plant of The Singer Manufacturing Company since 1920, died on February 7, 1932, of injuries suffered in an automobile accident.

Mr. Mattern was born at Pomeroy, Ohio, on January 21, 1866, the son of Conrad and Elizabeth Mattern. He worked as a machinist for a number of years after finishing his high-school education. In 1889 he also took up the study of law, receiving an LL.B. degree from the University of Cincinnati Law School in 1892. He practised law in Omaha, Neb., for four years and then went back to the machine-tool industry. He was connected with the Laidlaw-Dunn-Gordon Company, Cincinnati, as machinist and later foreman, until 1900. During the next seven years he held positions with several firms, the latter part of the time that of superintendent for the National Automatic Tool Company, Dayton, Ohio.

In 1907 Mr. Mattern went East, becoming superintendent for the Cummings Machine Company, New York, N.Y. While connected with this company he designed a large number of jigs and fixtures, among which were many of those used by Sloan and Chace in building tabulating machines for the Government. The company also did considerable work for the Singer company under Mr. Mattern's supervision, and he contributed to the design of other special machinery.

Mr. Mattern had been connected with the Singer company since 1911. In addition to serving as manager of the Oil Milling Department during 1911 and 1912, he spent a large amount of time on the design of jigs, fixtures, special machines, and labor-saving devices for other departments. Later he took charge of the company's tool room, supervising the building of many very intricate automatic machines. He went to Haverhill, Mass., for a time, planning the factory of the Hamel Shoe Machinery Company, purchasing and installing the machinery, and supervising the design of jigs and fixtures for manufacturing the product. During the World War he was superintendent of the factory erected by the Singer company to manufacture the recoil mechanism for the French 75-mm gun and had a large part in the development of the special machines required. He helped to organize the manufacturing and inspection forces and supervised the final assembly of the mechanism.

Mr. Mattern became a member of the A.S.M.E. in 1920 and at the time of his death was chairman of the Sectional Committee on Standardization of Specifications for Leather Belting. He was a member of the Plainfield Engineer's Club, and had served as recorder and was otherwise active in civic affairs in Roselle, N.J., where he made his home.

In 1896 Mr. Mattern married Margaret Chashatt. He is survived by her and by two sons, Charles and Oliver, and two daughters, Mrs. Kenneth Perkins and Mrs. H. C. Beadle.

HENRY E. McGOWAN (1872–1932)

Henry E. McGowan, for nearly thirty-five years associated with the Brooklyn Union Gas Company, was born in Brooklyn on October 3, 1872. His early education was secured in private schools, Holbrook's Military Academy, and Stevens Preparatory School. He was graduated from the Stevens Institute of Technology, Hoboken, N.J., as a mechanical engineer in 1894 and spent the next three years in the employ of Church & Co., soda manufacturers, in Trenton, Mich. After he had acquired a knowledge of the processes in the laboratory he was put in charge of an eight-hour shift as process chemist, being responsible for about 100 men engaged in the manufacture of soda by an ammonia process.

In 1898 Mr. McGowan became electrical engineer for the Brooklyn Union Gas Company, being retained particularly to investigate electrolytic damage to a subsurface plant, on which subject he contributed several articles to the technical press. His work also included following up prospects for gas-engine-driven electric installations. In 1903, in addition to these duties, he was elected general manager of the Flatbush Gas Company, a subsidiary of the Brooklyn Union Gas Company, the capacity and service of which were greatly expanded under Mr. McGowan's direction. In 1914 he was elected assistant secretary of the Brooklyn Union Gas Company, retaining also his position of general manager of the Flatbush Gas Company. He had been secretary of the former since 1918.

Mr. McGowan became a member of the A.S.M.E. in 1915. He also belonged to the American Gas Association, the American Institute of Electrical Engineers, the Empire State Gas and Electric Association, the Brooklyn Chamber of Commerce, the Merchants Association of New York, and the Crescent Athletic-Hamilton Club, Brooklyn. His death occurred on May 7, 1932. He is survived by his mother, Mrs. Henry D. McGowan.

HOWARD SMITH McILVAIN (1889–1932)

Howard Smith McIlvain, who died on March 25, 1932, after a brief illness, was born in New York, N.Y., on July 10, 1889, the son of David H. and Charlotte (Hart) McIlvain. He prepared for Stevens Institute of Technology at the Montclair (N.J.) High School and Stevens Preparatory School, and received an M.E. degree in 1911. Following his graduation he spent a year each with the Western Union Telegraph Company, for which he travelled as far as the Pacific Coast as inspector of materials and construction, and with the New York Fire Insurance Exchange, New York, as inspector of automatic sprinkler equipment.

For a short time in 1914 Mr. McIlvain worked on the design and cost estimates of sprinkler equipment for the Raisler Sprinkler Company, with headquarters in New York. The following year he was inspection and production engineer for Hildreth & Co., manufacturers of aeroplane parts. He then took the position of production engineer (later being promoted to assistant chief engineer) with the Agcy Canadian Car & Foundry Co., New York and Toronto, Canada, engaging in the development of production methods and costs and the design of shells and gages in connection with the manufacture of shrapnel and high explosive ammunition.

During part of 1917 he was equipment engineer at the Watertown plant of the Maxim Munitions Corporation, supervising the design, manufacture, and installation of production equipment for small arms ammunition manufacture. He resigned this position to enter service in the Ordnance Department. He was first stationed at Frankford Arsenal with the rank of Captain, organizing and directing the manufacture and inspection of small arms ammunition, and later was made head of the Small Arms Ammunition Branch, Engineering Division, Office of the Chief Ordnance Officer, A.E.F.

In 1919 Mr. McIlvain returned to private life as engineer for the Russell Sales Company, Newark, N.J., working on the redesign and manufacture of an automobile lock. Subsequently he did similar work for the Titan Automatic Tool Company. He then entered the employ of R. H. Macy & Co., New York, in the capacity of production engineer, developing methods and cost accounting, and supervising the operation of the service and manufacturing departments. In 1924 and 1925 he was research engineer for L. Bamberger & Co., Newark, N.J., and for one year engineer with the Ware Radio Company, New York.

In 1927 he joined the pioneer solid carbon dioxide company, The Dry Ice Corporation of America, and devoted the last five years of his life to research and engineering work important in developing the manufacture and use of dry ice. He was in charge of the construction of the first large plant built exclusively for the production of dry ice, located in Elizabeth, N.J. His headquarters were in New York but he traveled considerably, spending many weeks in Europe. At the time of his death he was in charge of all research and development activities of the corporation.

Mr. McIlvain became a member of the A.S.M.E. in 1923. He is survived by his widow, Amy (Chapman) McIlvain, whom he married in 1912, and by four children, Howard Hyland, David Hart, Amy, and Marilyn McIlvain.

CHARLES JARRETT McPHERSON (1886–1932)

Charles Jarrett McPherson, sales manager, Automotive Car Division, The J. G. Brill Company, died suddenly of heart failure on June 20, 1932, while in Chicago on business.

Mr. McPherson was born on July 5, 1886, in Hopkinsville, Ky., the son of J. E. and Sarah (Glass) McPherson. He prepared for college in the schools of Hopkinsville and secured a B.S. degree in mechanical engineering from the University of Kentucky in 1906. An M.E. degree was conferred upon him by that institution three years later.

After serving a two-year apprenticeship with the Baldwin Locomotive Works Mr. McPherson spent several years as draftsman with the American Car & Foundry Co., and the National Steel Car Company, Hamilton, Ontario, before joining the Brill engineering staff in 1913, as assistant chief draftsman. During the early days of the World War he was sent abroad to represent the company's interests, and spent some time in Russia. Except for a short time in 1920 as works manager for The Hopkins Manufacturing Company, Hanover, Pa., Mr. McPherson remained with the Brill company the remainder of his life. After serving successively as assistant superintendent he was transferred to the Sales Department, in charge of sales of the Automotive Car Division, handling rail motor cars for steam railroads.

Mr. McPherson became an associate member of the A.S.M.E. in 1914 and a member in 1925. He also belonged to the American Railway Car Institute, Society of Automotive Engineers, Army Ordnance Association, Railroad Club of New York, and the Art and Penn Athletic Clubs of Philadelphia. He is survived by his widow, Mrs. Anne (Melhorn) McPherson, whom he married in 1920.

MERLE ARTHUR MESTA (1895–1932)

Merle Arthur Mesta, of Pittsburgh, Pa., died at Atlantic City, N.J., on August 28, 1932. He was born at Leechburgh, Pa., on July 6, 1895, the son of Charles J. and Hattie (Rambler) Mesta. He prepared for college at the Kiskiminitas Springs School and took a special machine design course at the Carnegie Institute of Technology. He also attended the Bordentown Military Institute for a time.

Mr. Mesta spent all of his vacations in the engineering department of the Mesta Machine Company during his school years and was subsequently connected with that and other departments, studying shop methods and practice. He also was associated for short periods with the National Tube Company, Ellwood City, Pa., working on tools, dies, and repairs on mills, and the Production Engineering Department of the Worthington Pump & Machinery Corp., Harrison, N.J.

During the World War Mr. Mesta was with the Bureau of Aircraft Production of the War Department, inspecting and directing production at different plants. After the War he was appointed assistant production engineer for the Mesta Machine Company and subsequently, until within about a year of his death, had worked on sales.

Mr. Mesta became a junior member of the A.S.M.E. in 1920. He was active in the Masonic fraternity and a member of several Pittsburgh clubs, and was also vice-president of the Bank of America Trust Company, Pittsburgh.

HENRY JOSEPH MISTELE (1865–1932)

Henry Joseph Mistele, chief engineer of the Power Department, The Falk Corporation, Milwaukee, Wis., died in that city on May 4, 1932. Surviving him are his widow, formerly Miss Nell Richards, whom he married in 1892, and four children, two sons and two daughters, all of Milwaukee.

Mr. Mistele was born at Sullivan, Wis., on January 8, 1865, and attended the Milwaukee schools. He took courses in mechanical engineering through the International Correspondence Schools and prior to his connection with The Falk Corporation in 1909 worked for the U. S. Gypsum Company as station engineer in Milwaukee and plant superintendent at Granville, Mich., and for the Maryland Casualty Company as boiler inspector. He also engaged for two years as a private consultant in steam plant efficiency.

Mr. Mistele had made a study of the causes of boiler explosions and had been called upon for civil testimony on the subject. He had also made indicator studies of Corliss engine efficiency. These studies and power plant costs were among the subjects about which he had written for the technical press.

The A.S.M.E. elected Mr. Mistele to membership in 1916 and he was also a member of the National Association of Power Engineers, which he served as national trustee from 1912 to 1930; he was a local past-president of the association.

ROBERT CHARLES MONTEAGLE (1859–1932)

Robert Charles Monteagle, secretary and treasurer of the Transportation Guarantee Company, San Francisco, Calif., died at Burlingame, Calif., on January 19, 1932. He is survived by his widow, Mariett E. (Berg) Monteagle, of Carmel by the Sea, Calif., whom he married in 1898, and by two daughters and a son, Mrs. R. Eugene

McClung, Portland, Ore., Mrs. W. F. Stearns, Jr., Carmel, Calif., and F. James Monteagle, Palo Alto, Calif.

Mr. Monteagle was born in Glasgow, Scotland, on October 14, 1859, the son of James and Jane (Findlay) Monteagle. He went from the Glasgow high school to Andersonian University, of that city. After serving an apprenticeship in the pattern shop and machine shop of William King & Co., he worked for about two years in the drafting room of the Fairfield Shipbuilding Works belonging to James and George Thomson, Glasgow.

His shop experience in the United States was secured at the Fulton Iron Works, in San Francisco, from 1882 to 1884, and he was chief draftsman for the company during the next three years. He held the position of chief draftsman successively with the Honolulu Iron Works, Honolulu, from 1889 to 1892; the Charles Hillman Ship & Engine Building Co., Philadelphia, Pa., from 1892 to 1895; and the Burke Dry Dock, New York, N.Y., from 1895 to 1898. After two years as chief engineer at the Crescent Shipyard, New Jersey, he was engaged for four years as general superintendent for the Gas Engine & Power Co. and Charles L. Seabury & Co., Morris Heights, New York, N.Y., in building launches, yachts, and other vessels and engines and boilers of all kinds, including watertube boilers.

In 1905 Mr. Monteagle went to East Boston, where he remained for ten years, the first five as chief engineer of the Atlantic Works and the remainder of the time assistant manager and engineer of the Lockwood Manufacturing Company. Since 1915 he had been located on the Pacific Coast. He was assistant to the president of the Seattle Construction & Dry Dock Co., Seattle, Wash., for two years, and then helped to found The Pacific Construction & Engineering Co., in Seattle, of which he was president and general manager. This company furnished shipyards on the Coast with heavy forgings which previously had to come from the East and cooperated in other ways to speed up construction during the War. Mr. Monteagle was a member of the American Defense Society of the U.S.A., the Aerial League of America, and other local and patriotic organizations.

Mr. Monteagle held patents on packing and piston rings and a valve and had developed a watertube boiler. He was interested in amateur photography and sketching outdoor scenes. He belonged to the Episcopal Church, the Rainier Club in Seattle, and the Masonic fraternity. The technical organizations to which he belonged were the American Society of Naval Engineers, Society of Naval Architects and Marine Engineers, and the A.S.M.E., which he joined in 1904.

ALBERT BRIDGES MOORE (1868–1932)

Albert Bridges Moore, whose death occurred in Roselle, N.J., on May 19, 1932, was born at Elizabeth, N.J., on April 4, 1868, the son of Miller F. and Helen S. (Brown) Moore. He attended the Stevens Preparatory School and was graduated from the Stevens Institute of Technology in 1890 with an M.E. degree. Following his graduation he entered the drawing room of the Samuel L. Moore & Sons Co., Elizabeth. He was made foreman iron worker in 1892 and in 1893 vice-president and assistant superintendent of the machine shop and foundries.

In 1899 Mr. Moore went to Harrison, N.J., to work as superintendent of the Marine Engine & Machine Co., where during the next three years he had charge of the design and erection of a new plant and redesigned the Alco-Vapor launch motors built by the company. He did some special engineering work with the Tirrell Gas Machine Lighting Company, of Newark, N.J., in 1903 and in that year he was also issued a patent for his internally packed plunger pump. He was also the inventor of a brush holder for electric motors and generators.

During 1904 and 1905 Mr. Moore was mechanical engineer with the Crane Company in Chicago and Bridgeport, Conn., and subsequently was connected with the Griffen Wheel Company, Chicago, as chief engineer, and the Shedd Electric Company, Roselle, as vice-president and treasurer. He retired in 1926.

Mr. Moore became a member of the A.S.M.E. in 1903 and also belonged to the Western Society of Engineers and the Roselle Golf Club. Surviving him are his widow, Ethel G. (Field) Moore, whom he married in 1896, and two daughters, Margaret and Helen.

WENSEL MORAVA (1853–1932)

Wensel Morava, consulting engineer of Chicago, Ill., who died on October 13, 1932, had been a member of the A.S.M.E. since 1886.

Mr. Morava was born in Bohemia on September 12, 1853. He entered the University of Illinois, at Champaign, in 1874 and received the degree of B.S. from the College of Engineering four years later. He ran a stationary engine for a few months following his graduation and then worked as mechanical draftsman for the U.S. Rolling Stock Co. at Urbana, Ohio, until February, 1879. He then took a position with the Excelsior Iron Works, Chicago, as chief draftsman. He designed special machinery for rolling mills and the brick industry, hoisting and stationary engines, and mining machinery. In 1880 he had charge of the machinery department of an interstate machinery exposition in Chicago. About two years later he invented and patented an improved dynamo and electric arc lamp. A plant built to manufacture these lamps was built and sold to the Excelsior Iron Works.

In the summer of 1885, after making the plans for a large stamp mill to be erected in the Black Hills, Mr. Morava secured a position as assistant to the contractor. Upon the completion of the mill he returned to Chicago and worked for several years for the Union Foundry & Pullman Car Wheel Works, developing a high-speed engine and superintending the erection of coal gas machinery. Subsequently he was employed by the Bouton Foundry Company and Link Belt Machinery Company, both of Chicago, before going into business for himself.

In 1900 he founded the Morava Construction Company, a steel fabricating and erecting concern, of which he was president until it was purchased by the McClintic-Marshall Corporation in 1924. Among the structures which were erected by this concern are the Park Row (12th St.) Railroad Station, the Boston Store, the Marshall Field Annex, all in Chicago, the Armory of the University of Illinois at Champaign, and the Mt. Wilson Observatory at Pasadena, Calif.

After his retirement from active business in 1924 he devoted himself to the development of a mechanical cotton-picking machine which he had very nearly perfected at the time of his death. He was greatly interested in travel and has written several short monographs on his travels. He was also greatly interested in assisting young engineers attain a higher education; he provided funds at the University of Illinois and at the Technical High School in Prague, Czechoslovakia, for this purpose.

RAYMOND NEWCOMB (1897–1932)

Raymond Newcomb, who, together with Edward N. Cunningham, also an A.S.M.E. member, was fatally injured in an automobile accident near Selma, Ala., on February 15, 1932, was born at Boston, Mass., on July 12, 1897. His parents were Thomas and Clara S. Newcomb. From the Boston English High School he went to Worcester Polytechnic Institute in 1914. He transferred to the Massachusetts Institute of Technology in his junior year, specializing in engineering administration.

For three months in 1917 and from June 1918, to April, 1919, he served in the United States Naval Reserve. After a time as fireman and oiler on different ships he was transferred to the U.S.N. Steam Engineering School with an ensign's commission, to train for junior engineer officer for transport service. He was graduated from M.I.T. with the class of 1919, receiving a B.S. degree in mechanical engineering.

Since leaving the Navy in 1919 Mr. Newcomb had been associated with the Kewanee Boiler Company, Inc., and its affiliated company, the Fitzgibbons Boiler Company, Inc. He spent the first six months in the engineering department at the factory at Kewanee, Ill., conducting a series of efficiency tests on tubular boilers equipped with the Hawley down-draft furnace. He was then transferred as service engineer to the New York office, where for two years his work consisted of putting new installations into operation. He had been sales engineer for the companies since 1921, representing them in Brooklyn, Long Island, and Boston, prior to his appointment in 1928 as vice-president in charge of branch sales. He assisted in the design, installation, and operation of the boilers.

Mr. Newcomb was elected to junior membership in the A.S.M.E. in 1920, promoted to the grade of associate-member in 1924, and made a member in full in 1931. He was a member of the Boiler Code Subcommittee on Heating Boilers and had served on the boiler rating committee of the American Society of Heating and Ventilating Engineers and technical committees of the Steel Heating Boiler Institute.

Mr. Newcomb is survived by his widow, Hope (Nichols) Newcomb, whom he married in 1922, and by two children, Joan and Nancy, all of White Plains, N.Y.

JOSEPH NEWMAN, JR. (1896–1932)

Joseph Newman, Jr., field supervisor of the Apparatus Repair Shops of the Air Reduction Sales Company, Philadelphia, Pa., died in that city on February 28, 1932.

Mr. Newman was born in Philadelphia on March 17, 1896, the son of Joseph and Mary (Carbaugh) Newman. He was graduated from the West Philadelphia High School and studied for a time at Temple University. He was first employed as machinist and assistant to the foreman at the Lanston Monotype Company, Philadelphia, in 1914 and in the winter of 1914–1915 assisted in Board of Health analyses at the Bryn Mawr laboratory.

During the World War Mr. Newman worked for the Remington Arms Corporation as assistant to the foreman of the manufacturing department, and at the Eddystone Ammunition Corporation, where he served successively as foreman of the repair department, foreman of the scraping department, and assistant production manager. He was assistant to the shop superintendent at the Philadelphia Navy Yard from 1917 to 1920, designing dies for structural work, making layouts and supervising construction of shops, installing toolroom operating systems, etc. During the next two years he was engaged in similar work at the League Island Navy Yard, near Philadelphia.

In 1922 Mr. Newman established the Newman Engineering Company in Philadelphia and for two years engaged in miscellaneous machine and experimental work, oxyacetylene welding and cutting, and general work for mills not large enough to maintain their own jobbing shops.

Mr. Newman had been with the Air Reduction Sales Company since 1924, working first as assistant to the manager of the Apparatus Manufacturing Plant and later being appointed to the position he held at the time of his death.

Mr. Newman joined the A.S.M.E. as a junior member in 1921 and in 1931 was promoted to the grade of member. He is survived by his widow, Marie E. (Kristel) Newman, whom he married in 1920, and by two children, Joseph and Edna M. Newman.

PAUL OEHMIG, JR. (1898–1932)

Paul Oehmig, Jr., son of the founder of Paul Oehmig & Co., Chicago, Ill., manufacturers of mixing and grinding machinery, died on September 15, 1932. He was born on March 18, 1898, in Chicago, and became associated with his father in the business immediately following his graduation from Lewis Institute in 1915.

At that time the company was making a special line of food mixing and grinding machinery, such as mustard grinders, horseradish graters, peanut butter mills, etc. During his first four years in the business Mr. Oehmig worked in the positions of machinist, shop foreman, draftsman, designer, and erection engineer, installing the company's equipment in different cities.

In 1919 he and another son formed a partnership to take over the business, Paul Oehmig becoming shop superintendent as well as erection engineer. The company purchased the paint machinery division of the Kaestner & Hecht Co., of Chicago, and Mr. Oehmig took on the responsibility of developing and producing new lines of equipment. He became sole owner in 1927 and continued to augment the business, acquiring the paint machinery division of the American Oven & Machine Co. of Chicago, and adding other special lines from time to time.

Mr. Oehmig became a junior member of the A.S.M.E. in 1923 and was transferred to the grade of a member in 1930.

HARVEY ROBINSON OGDEN (1899–1932)

Harvey Robinson Ogden, chief pilot for the Curtiss Aeroplane & Motor Co., Inc., stationed at Buffalo, N.Y., was killed on May 20, 1932, when the parachute with which he attempted to land from a disabled plane became entangled in the airplane structure and was rendered useless. Mr. Ogden attempted to jump from an Army observation plane which he was testing, when it lost a wing at an altitude of approximately 15,000 ft.

Mr. Ogden was born on January 13, 1899, in Minneapolis, Minn., the son of Ida S. and James K. Ogden. After completing his preparation for college at the Shattuck School in Faribault, Minn., he spent two years at the University of Minnesota and a year and a half at the West Point Military Academy. He entered the employ of the Curtiss company late in 1921 as draftsman. About a year later he went to Seattle, Wash., to do drafting for the American Can Company, and later was connected in a similar capacity with the Boeing Airplane Company there. For several years, beginning in 1925, he served in the United States Air Corps, successively as flying cadet, second lieutenant, flying instructor, and aide-de-camp to Brigadier-General Frank P. Lahm. He returned to the Curtiss company in 1929 and was regarded as an exceptionally able pilot.

Mr. Ogden became an associate member of the A.S.M.E. early in 1932. He is survived by his widow, Ruth (Stroud) Ogden, and by a son, Harvey Robinson Ogden, Jr.

ENOCH OHNSTRAND (1862–1932)

Enoch Ohnstrand, consulting engineer at the Tonawanda, N.Y., plant of Remington Rand, Inc., N.Y., died of heart disease at his home in Kenmore, N.Y., on September 20, 1932.

Mr. Ohnstrand was born at Norrköping, Sweden, on January 9, 1862. At the age of nineteen he entered the employ of the National Tube Company, and worked in the sheet rolling and tube mills for two years. In 1888, after several years as a carpenter and builder, he became connected with the Art Metal Construction Company, Jamestown, N.Y. During nearly twenty years spent with this company he rose to the position of general superintendent. He helped to develop ornamental works for banks, libraries, and other public buildings; designed and constructed steel furniture approved by the naval constructor in 1909 for use on United States battleships; and invented a process of manufacturing the cold-drawn steel molding used in steel cars and fireproof buildings by various manufacturers.

Mr. Ohnstrand held a number of patents on steel furniture and under his supervision the graining of steel furniture to imitate different kinds of wood was accomplished. In 1906 he organized the Ohnstrand Metal Furniture Company, Falconer, N.Y., which later was reorganized as the Jamestown Metal Furniture Company and finally became Plant No. 2 of the Art Metal Construction Company.

In 1909 Mr. Ohnstrand served as expert engineer for the Art Metal Company and during the next three years was connected with the O. M. Edwards Company of Syracuse, N.Y., in the capacity of general superintendent, developing a metal furniture and office equipment business. He next organized the U.S. Steel Furniture Co., Syracuse, for the manufacture of steel desks and tables according to his designs and patents. In 1914 he became chief engineer of the U.S. Metal Products Co., New York, N.Y., and in 1915 chief engineer of the Library Bureau Division of Remington Rand, Inc., Ilion, N.Y., the position he held until shortly before his death.

Mr. Ohnstrand had been a member of the A.S.M.E. since 1918.

PETER L. O'NEILL (1874–1932)

Peter L. O'Neill, whose death occurred on February 26, 1932, was born in Jersey City, N.J., on May 17, 1874, the son of John and Catherine (Lawless) O'Neill. After completing his high-school course he became head of the Unisol Manufacturing Company, Jersey City, whose product is a preparation for the correction of undesirable boiler feedwater conditions.

Mr. O'Neill became an associate of the A.S.M.E. in 1923. He is survived by his widow, Catherine (Langton) O'Neill, and by three children, John I. and Catherine O'Neill and Mrs. Frederick Yeck, all of Jersey City.

WILLIAM FREDERICK OTTO (1864–1932)

William Frederick Otto, vice-president of the Wilmot Engineering Company, Hazleton and White Haven, Pa., and manager and treasurer of the Weatherly Foundry & Manufacturing Co., Weatherly, Pa., died on January 25, 1932.

Mr. Otto was born in Germany on March 13, 1864. After being graduated in 1879 from the Hoehre Bürger Schule, Hersfeld, Germany, he came to the United States and served a four-year apprenticeship at the Jeanesville (Pa.) Iron Works. Additional experience was secured during the next two years in various sections of New York and Pennsylvania. In 1886 he became erecting engineer of refrigerating machinery for the Consolidated Ice Machinery Company of New York, where he remained for three years. He received his full citizenship papers at Wilkes-Barre, Pa., in 1888.

From 1889 to 1895 he was engineer for A. Pardee & Co., Hazleton, Pa., and during the next seven years was connected with the Lehigh Valley Coal Company, of Wilkes-Barre, as superintendent of outside operations and master mechanic. His duties included redesigning and reconstructing a large pumping plant at Hazleton, the installation of a power plant at the Maltby Colliery, and the design and installation of air haulage systems at two other collieries.

Mr. Otto accepted a position in 1902 with the Eynon-Evans Manufacturing Company, in Philadelphia, designing and selling steam and water specialties for power and pumping plants in anthracite mines. He was connected with the company until 1920. As vice-president of the Wilmot Engineering Company from 1907 until his death, he assisted in the building up of that organization, designing and perfecting coal machinery. He had been associated with the Weatherly Foundry & Manufacturing Co. since 1921.

Mr. Otto became a member of the A.S.M.E. in 1918. He also belonged to the American Society of Military Engineers, the Masonic fraternity, and a number of clubs, including the Engineers and Manufacturers of Philadelphia, Franklyn and Westmoreland of Wilkes-Barre, South Wilkes-Barre Rod and Gun Club, and Izaak Walton League of America. He was affiliated with the Lutheran Church, and served as a school director for the City of Hazleton for eleven years.

Surviving him are his widow, Anna E. Otto, of Hazleton, a daughter, Mrs. Elmo D. French, Miami, Fla., and two sons, George W. Otto, Port Carbon, Pa., and H. H. Otto, Scranton, Pa.

GEORGE ALLEN PAGE (1890–1931)

George Allen Page, consulting engineer and patent attorney of Freehold, N.J., died on December 27, 1931, after a year's illness.

Mr. Page was born in New York, N.Y., the son of Allen H. and Emma (Hauselman) Page, on January 15, 1890. The early training which he received in his father's business, supplemented by extension courses in engineering subjects, enabled him to secure the position of general draftsman and foreman of machine-shop work and manufacturing in the factory of the Tube Bending Machine Company, of Harrison, N.J. in 1908. As superintendent's assistant at the Thos. A. Mack Co., Marion, N.J., in 1909, he had some experience in estimating and cost accounting. During the early part of 1910 he was employed by the Emil Grossman Company, New York, N.Y., at its factory in Newark. Here he had his first contact with patent work, as assistant to the firm's patent attorney, an experience which led him before the close of the year to establish himself in private practice at Hartford, Conn., in partnership with a patent attorney. During the next two years, in addition to the making of patent drawings and serving inventors as engineering counsel on general machine design, he was employed by the J. H. Sessions & Sons, Bristol, Conn., in design and installation work involved in a factory extension; by the Page Brass Company, Elmwood, Conn., in fitting up a brass foundry and manufacturing plant; by the Hart Manufacturing Company, Hartford, to develop experience in the manufacture of electrical goods and in practical electrical laboratory work; and by the Hartford Auto Parts Company as assistant foreman.

From 1912 to 1914 Mr. Page was associated with the Merrow Machine Company, Hartford, as patent attorney and general engineering consultant. He was next employed in a similar capacity by the Bausch & Lomb Optical Co., Rochester, N.Y., for which he established a patent bureau, reorganized the library, and took over certain special engineering work, leading to his appointment as auxiliary engineer of the mechanical division of the company. He resigned this position in 1919 and worked for a short time on machinery improvements for the United States Machinery Company, manufacturers of pressing machines for tailors and factories, with a factory in Syracuse, N.Y., and offices in New York.

In the fall of 1920 Mr. Page severed this connection and went to Detroit, Mich., obtaining a position there as patent attorney with the firm of Barthel, Flanders, and Barthel. Ill health forced him to leave Detroit late in 1921 and he went to Portland, Ore., where he took up private practice again. He helped to develop a fruit grader and did some other experimental work, in addition to handling patents. He returned to Rochester in 1923 and during a year's stay there spent considerable time on the development of an optical invention of his own, for which a patent application had been filed at the time of his death.

Late in 1924 Mr. Page left Rochester and went to Freehold, N.J., where in addition to consulting work, he pursued the development of his own inventions, although ill health restricted his activities. He suffered a complete breakdown early in 1931, while located temporarily in Philadelphia, and was unable to do any work from that time.

Among his inventions which he had not been able to bring to perfection were a special camera film and shutter combination for avoiding double exposures, optical instruments for motorists, and machinery for the tanning industry. He had assisted in the design of a great variety of machinery, including automatic tube polishing and bending machinery, automatic cam-cutting machines, and semi-automatic machines for drilling field glass parts and for finishing special surfaces, as well as automobile wind shields and attachments, annealing furnaces, overseam sewing machine stitching mechanism, and many other inventions.

Mr. Page became an associate member of the A.S.M.E. in 1919. He is survived by his widow, Nanon (Ashcraft) Page, whom he married in 1912, and a daughter, Virginia Nanon Page.

ALFRED BASSETT PATTERSON (1887–1931)

Alfred Bassett Patterson, president and general manager of the Patterson Steel Company, Tulsa, Okla., died on December 12, 1931, at a hospital in Kirksville, Mo., where he was being treated for paralysis caused by the third stroke which he had suffered within two months. He was widely known in Tulsa for his support of a weekday Bible school during the last four years. He made generous donations to the work and interested others in it, building up a school with an enrolment of some 10,000 children in 1931. He was an elder in the First Presbyterian Church, a charter member of the Rotary Club, and active in the work of the Chamber of Commerce. He also was a member and past-president of the Tulsa Traffic Association and of the Manufacturers Bureau, and belonged to the Masonic fraternity. He was associated with the Tulsa Chapter of the American Association of Engineers, past-president of the Mid-West Structural Society, and a member of the American Institute of Steel Construction. He became a member of the A.S.M.E. in 1926.

Mr. Patterson was born at Winslow, Me., on October 1, 1887, the son of Mr. and Mrs. George W. Patterson. He was graduated from the Winslow High School in 1905 and spent the next four years at the University of Maine, securing his B.S. degree in mechanical engineering in 1909. After a few months in machine shops and drafting rooms in New York he went to Houston, Texas, where he worked for a year as draftsman for building internal oil combustion engines for Layne and Bowler. He was next engaged by Halloway and Cathey, patent attorneys, to make Patent Office drawings and to contract drafting in Houston. In January, 1911, he went to Sour Lake, Texas, to do drafting work for the Texas Company, and worked in the Production Department of the company until August of that year. During the remainder of 1911 he was engaged in contracting miscellaneous drawings.

For four years, 1912–1915, Mr. Patterson was chief engineer for the Oklahoma Iron Works, Tulsa, in charge of shops, design of new machinery, and general contracting. He then went into contracting in oil fields, constructing oil refineries, plants, pipe lines, and other heavy work, including gasoline plants for the Standard Oil of Indiana at Drumright, Okla., and work for different oil companies at Ranger and Breckenridge, Texas, and Minden and Homer, La., as well as many other places. The Patterson Steel Company was organized by him and his brother, Nathan R. Patterson, in August, 1920. It handled heavy steel construction for buildings, bridges, refineries, oil-field work, and equipment. Mr. Patterson was responsible for the design of many oil field tools and a great deal of oil-refinery equipment. Shortly before his death he had applied for patents covering steel frame construction for residences and for sectional steel buildings.

Mr. Patterson is survived by his parents, two brothers and a sister, his widow, Myrtle Mae (Reynolds) Patterson, and two children by a former marriage, George W. and Elizabeth May Patterson.

THORLEIF BJERKE PAULSON (1886–1932)

Thorleif Bjerke Paulson, whose death occurred in San Francisco, Calif., on October 12, 1932, was born at Grimstad, Norway, on June 14, 1886. His early education was secured from private tutors and schools in Vestheim. He studied mechanical engineering at the Christiania Technical School from 1901 to 1905. After a year's apprenticeship in the shop of Akers Mekaniske Verksted, Christiania, Mr. Paulson came to the United States. He worked in the East, testing pumps for Henry R. Worthington, Harrison, N.J., and as mechanical draftsman for the Standard Steel Car Company, Butler, Pa., for a short time. The latter company sent him to Hammond, Ind., in 1907 and later in the year he went to San Francisco. For four years he was mechanical draftsman, designing hydraulic machinery and boilers, for the Risdon Iron Works, and then spent about six months on centrifugal pump design for the Yuba Construction Company, Marysville, Calif.

In July, 1910, Mr. Paulson began an association with Chas. C. Moore & Co. of San Francisco which continued until his death. He was chief draftsman for the first fifteen years and since then had been designing engineer, in charge of the design of power stations. Mr. Paulson was responsible for the design of numerous steam electric power and pumping stations on the Pacific Coast and tested a number of them. He directed all test work of the company after 1917. Some of his outstanding work included the design and testing of power plants for the Long Bell Lumber Company, Longview, Wash., Power River Company, in British Columbia, Consolidated Mining Company, Trail, B.C., Calumet & Arizona Copper Mining Co., Ajo, Ariz., and United States Potash Company, Carlsbad, N.M.

Mr. Paulson is survived by his widow, Edith (Erickson) Paulson, whom he married in 1912, and by two daughters, Edith Lillian and Betty Constance Paulson. He became a member of the A.S.M.E. in 1925, and was a past-president of the Norwegian Club of San Francisco, and a member of the Masonic fraternity.

HENRY PILLING (1867–1931)

Henry Pilling, director of Galloways Limited, Manchester, England, died on February 20, 1931, at the age of sixty-four. He was born at Bolton, England, on July 13, 1867, and after completing his early education at the Manchester Grammar School, served an apprenticeship in the erecting shop of John and Edward Wood, of Bolton, makers of slow-speed steam engines. From 1888 to 1895 he worked as draftsman for engineers, boilermakers, and millwrights in Bolton, being with John Musgrave & Sons Limited for five years and Hick, Hargreaves & Co., Limited, for two years. He then became head of the Consulting Engineering and Engine Insurance Departments of the National Boiler & General Insurance Co., Ltd., Manchester, with which he remained until 1904. For the next five years he was technical director of Yates & Thom, Ltd., Blackburn, manufacturers of slow-speed steam engines and boilers. He was appointed general manager of Galloways Limited in 1909 and later elected director of the company. This company, which absorbed the business of John Musgrave & Sons Limited and owns the drawings of John and Edward Wood, with which firms Mr. Pilling had secured his earliest experience, deals in steam and gas engines and repairs, valves and fittings, castings, etc.

Mr. Pilling had an extensive experience in all phases of steam-engine development, and particularly with engines for the tinplate industry, in reversing engines for heavy steel rolling, in blast-furnace engines, both steam and gas, and the like. He possessed a creative and facile mind, and among his many inventions are a single-lever control gear by which the operations of reversing, adjusting the cut-off, and controlling the handling valves of rolling-mill engines were all performed by means of one lever, while at the same time permitting full steam for the full stroke at the beginning of rolling operations. He was also the inventor of a device for reversing winding engines by means of which the stroke of the valves remains constant throughout. He did pioneer work in developing the manufacture of the uniflow steam engine, and invented a hydraulically operated valve gear, which has been successful. He introduced the construction of large gas engines of the continental type and effected various improvements, including a piston with internal diagonal bracing ribs.

Mr. Pilling had presented papers before various technical societies, including the Manchester Association of Engineers, of which he was a past-president. For many years he was a member of the executive committee of the Manchester and District Engineering Trades Employers' Association. He became a member of the A.S.M.E. in 1923, and also belonged to the Institution of Mechanical Engineers and the Order of the British Empire.

WILLIAM DUTTON POMEROY (1874–1932)

William Dutton Pomeroy, general manager, vice-president, and director of Goulds Pumps, Inc., Seneca Falls, N.Y., was born on July 30, 1874, in Utica, N.Y. His parents were George D. and Julia B. (Burritt) Pomeroy. After completing his preparatory education at the Utica Free Academy, he entered Cornell University with the class of 1895 and remained there five years, earning both an M.E. and an E.E. degree. He was elected a member of Sigma Phi fraternity.

Mr. Pomeroy's first position following his graduation was that of draftsman for The Bossert Electrical Contracting Company, in Utica. In January, 1897, he was made shop foreman, and remained with the company in that capacity for another six months. He then worked for a few months as foreman of the wiring gang of the Utica Belt Line Street Railroad. In October he went to Akron, Ohio, where he was connected until 1901 with the Akron Electric Manufacturing Company, first as draftsman and later engaged in construction work and electric mine haulage; during the last two years he was superintendent of the company.

From 1901 to 1907 Mr. Pomeroy was employed by the Bullock Electric Manufacturing Company, of Cincinnati, a subsidiary of the Allis-Chalmers Manufacturing Company. He was advanced from the position of chief draftsman to that of general superintendent, from 1903 to 1907 being in entire charge of the manufacturing department and general plant layout, and supervising the design of plant extensions and special machinery. During this time the number of employees was nearly tripled, increasing from 650 to about 1800.

Mr. Pomeroy went to Seneca Falls as works manager of The Goulds Manufacturing Company, predecessor of Goulds Pumps, Inc., in 1907. He was made general manager in 1915 and for a number of years prior to his death had also served as vice-president and director. Curtailments in the shops necessitated by business conditions and their effects upon employees weighed heavily upon his mind. Depressed by these conditions and suffering from ill health for more than a year, he committed suicide on January 6, 1932.

Civic affairs also claimed much of Mr. Pomeroy's time and interest. He had served as chairman of the Seneca Falls Water Commission and of the Building Committee of Mynderse Academy, and had been a member of the Board of Education of Seneca Falls until shortly before his death. He was director of the Military Census in Seneca County and chairman of the Seneca County War Chest. He served on the executive committee of the Red Cross during the World War. In 1919 he directed the building of the Gould Hotel and for a number of years had been a director and vice-president of the Seneca County Trust Company, resigning in the summer of 1931. In these and many other community activities he gave generously of his time and ability. He belonged to the Masonic fraternity, Elks, and Trinity Church. He was one of the early members of the Seneca Falls Rotary Club, and fostered the formation of the Seneca Falls Country Club. He also belonged to the Owasco Country Club, Auburn, N.Y.

Mr. Pomeroy was likewise an active member of the engineering fraternity. He became a member of the A.S.M.E. in 1908. At the 1930 Annual Meeting of the Society the Melville Award was conferred jointly upon him and Herman Diederichs, of Cornell University, for their paper on "The Occurrence and Elimination of Surge or Oscillating Pressures in Discharge Lines from Reciprocating Pumps." Mr. Pomeroy also belonged to the American Institute of Electrical Engineers, the American Society for Testing Materials, the Institute of Metals, and a number of technical clubs, and had been elected to the honorary engineering fraternity of Sigma Xi about a year before his death.

Automobiling and motor-boating absorbed a good deal of Mr. Pomeroy's leisure. He operated one of the first automobiles in Seneca Falls and launched seven speed-boats on Cayuga Lake.

Surviving Mr. Pomeroy are his widow, Fanny C. (McIntosh) Pomeroy, whom he married in 1901, a daughter Katherine, of New York, N.Y., and a son, William D. Pomeroy, Jr., of Baltimore, Md.

CHARLES TALBOT PORTER (1885–1932)

Charles Talbot Porter died on January 22, 1932, following a very short illness. He is survived by his widow, Anna M. (Newton) Porter, formerly of Norwich, N.Y., whom he married in 1913, and by four sons, Charles Talbot, Howard Newton, John, and Stephen Winthrop Porter.

Mr. Porter was born in Montclair, N.J., on November 13, 1885, the son of John and Elizabeth Keeler (Baker) Porter. He was the grandson and namesake of Charles Talbot Porter, pioneer in the development of the high-speed steam engine and a recipient of the John Fritz Medal. Mr. Porter was graduated from the Sheffield Scientific School of Yale University in 1907 with a Ph.B. degree in mechanical engineering, and received his M.E. degree there in 1913.

During Mr. Porter's early career, from 1907 to 1910, he was in charge of the department of mechanical engineering at the Imperial Polytechnic College at Shanghai, China. Upon his return he did a year of graduate work at Columbia University. In 1911 he took a position as instructor in mechanical engineering at Yale, where he remained until 1918, in charge of work in applied mechanics during the last three years.

From 1918 to 1920 Mr. Porter was an aeronautical engineer at the Naval Aircraft Factory, Philadelphia, Pa. He later was one of the incorporators of the Huff Daland Aircraft Company in Ogdensburg, N.Y., holding the offices of treasurer, vice-president, and chief engineer. This company developed many experimental airplane types for the United States Government.

During 1926 the Huff Daland Company was absorbed by the Keystone Aircraft Corporation, Briston, Pa., and Mr. Porter became vice-president and chief engineer of the Keystone Company, in which capacity he served for more than five years. During his association with the Huff Daland Company and the Keystone Company Mr. Porter became probably the foremost authority in the design and construction of bombardment airplanes. The outstanding achievement of his professional life was the development of the long series of bombers, beginning with the XLB-1 and terminating with the B-4A and B-6A machines, in use at the time of his death as the standard heavy bombers of the Army Air Corps.

Mr. Porter served as a member of the Aeronautical Standards Committee of the Aircraft Division of the Society of Automotive Engineers. He became a junior member of the A.S.M.E. in 1913 and a member six years later. He also belonged to the Society for the Promotion of Engineering Education, the honorary society of Sigma Xi, Engineers Club of Dayton, and Century Club of Ogdensburg, N.Y.

WILLIAM PRELLWITZ (1869–1932)

William Prellwitz, chief engineer of the Ingersoll-Rand Company, died on April 12, 1932, at Easton, Pa., following an operation. He was 63 years old, having been born in New York on February 7,

1869. After completing grammar school he served a four-year apprenticeship in patternmaking, molding, and machine work at the DeLamater Iron Works, where he was subsequently engaged as a draftsman. He also did drafting for the United States Lighthouse Board. He spent his spare time in securing a technical education at the College of the City of New York and Cooper Union, receiving a B.S. degree from the latter in 1893.

It was in 1890, after the death of Mr. DeLamater, that he became an employee of the Sergeant Drill Company, which was located in New York. When the company was merged into the Ingersoll-Sergeant Drill Company, and plans were made to move the manufacturing plant to Easton, Pa., Mr. Prellwitz helped to lay out and to construct the new factory, which was placed in operation in November, 1893. At that time he became chief draftsman and served in that capacity until 1900, when he became chief engineer. He retained that post when the present Ingersoll-Rand Company was formed and held it continuously until his death. In 1905 Mr. Prellwitz had full charge of the design and construction of the Phillipsburg, N.J., plant of the Ingersoll-Rand Company.

Mr. Prellwitz contributed much to the advancement of compressed-air machinery in general, but more especially to the development of the products of the company with which he spent his entire adult life. While he was thoroughly familiar with all Ingersoll-Rand machines, he gave the most of his attention to compressors and rock drills, with the result that many developments in these products are attributable to him. Numerous inventions stand to his credit; and along with his bent for mechanical design he possessed a broadmindedness which allowed him to see merit in the creations of others. Over a span of years he made periodic trips to Europe, and out of his contacts and studies there came the application of various European ideas and methods to American practice. Recognizing the value of plate valves in compressors, he investigated their development abroad and obtained for his company the rights to manufacture the Rogler valve in this country. Similarly, he foresaw the place that turbo-blowers were destined to take in the blast-furnace industry and was quick to improve upon and to help commercialize here the European types of this equipment.

Mr. Prellwitz designed some of the first air compressors for discharge pressures above 1000 lb. These early units served to furnish power for operating street cars in cities and locomotives in mines. He developed the first torpedo-charger compressor used in the United States Navy. It proved so efficient that the Government requested Ingersoll-Rand not to patent it or to supply foreign countries with it. These compressors were originally built for battleships, but were later applied to both cruisers and submarines. The units were designed for 3000 lb pressure. Subsequently, Mr. Prellwitz was closely identified with the development of high-pressure air and gas compressors for industrial purposes.

He was instrumental in perfecting the Sergeant drills which established his company as one of the foremost makers of rock-drilling machinery in the United States. In 1898 he designed the first vertical, 4-stage, 2400-lb-discharge compressor for the Metropolitan Street Railway Company of New York for operating air engines of cross-town street cars.

He was a vital factor in the development of the hammer type of rock drill, of turbo-blowers, and of direct-connected electric-driven compressors. He was responsible for the clearance-control system now used on Ingersoll-Rand compressors. He had a flair for taking hold of new ideas and of making them commercially practicable. When the company was small, he frequently would design and set a price upon a piece of equipment to meet the requirements set forth in an inquiry. He would then call upon the customer, sell the machine, return to the plant, and supervise its construction.

Among his co-workers Mr. Prellwitz was affectionately known as "Pop" Prellwitz. His capacity for teamwork was outstanding and he did much to promote harmony in the organization. He was active in welfare and social work both in the company and in Easton. He was a director in the Phillipsburg Development Corporation, a subsidiary company formed to build homes for employees. As a trustee and member of the building committee, he aided in the construction of the new Easton Hospital.

He became a member of the A.S.M.E. in 1900, belonged to numerous clubs in his home city, and was an ardent fisherman. He was a director in the First National Bank & Trust Co. of Easton.

Mr. Prellwitz is survived by his widow, Mrs. Clara Prellwitz, one daughter, a step-son, a step-daughter, and a brother, Henry Prellwitz, of New York.

REXFORD M. PRUITT (1893–1932)

Rexford M. Pruitt, formerly treasurer of the Indiana Pump & Compressor Co., Indianapolis, Ind., died at his home in that city on February 18, 1932, after a long illness.

Mr. Pruitt was born in Indianapolis on May 25, 1893, the son of Mr. and Mrs. O. M. Pruitt. After four years at the Indianapolis Manual Training High School he entered Butler College, Inadianpolis, from which he received an A.B. degree in 1915. He was then given the position of secretary and sales engineer with the Indiana Air Pump Company, for which he had worked during vacations while in high school and college. He continued with the company throughout his life, becoming treasurer when it was reorganized in 1931 as the Indiana Pump & Compressor Co.

Mr. Pruitt handled a large part of the correspondence, particularly the technical, of the firm. He planned the equipment for hundreds of municipal and industrial water supply systems and supervised many installations. Part of his time was spent in actual selling. His work required familiarity with the fundamentals of hydraulic and pneumatic practice in order to select and install the varied equipment suitable for the needs of each installation. Among the jobs for which he was responsible were equipment for wells at the Cedar Street, Riverside, and Pennsylvania Street stations for Lansing, Mich.; air-lift installations in Rockford, Ill., Winona, Minn., and at the Norton Iron Works, Ashland, Ky., which pumped as much as 6000 gpm from the Ohio River; and many other installations involving a knowledge of air compressors, electric motors, centrifugal pumps, oil engines, etc.

In addition to such work Mr. Pruitt gave air-lift instruction in the sales schools of the Chicago Pneumatic Tool Company at Pittsburgh, Chicago, Detroit, Los Angeles, and San Francisco, the Harris Pump & Supply Co. at Pittsburgh, the Charleston Electrical Supply Company at Charleston, W. Va., and others.

Mr. Pruitt became a member of the A.S.M.E. in 1926. He also belonged to the Wisconsin Engineering Society.

JAMES K. REED (1886–1932)

James K. Reed, design engineer for mechanical and electrical equipment for the Westinghouse Electric & Manufacturing Co., East Pittsburgh, Pa., died at his home in Pittsburgh on April 23, 1932. Mr. Reed had been associated with the Westinghouse company since 1929, when he took a position as mechanical engineer in its Switchboard Engineering Department.

Prior to 1929 he spent 13 years as factory superintendent with the S. Keighley Metal Ceiling & Manufacturing Co. at Follansbee, W. Va., and its successor, the Keighley Manufacturing Company, at Carnegie, Pa. He developed and installed a cost system and new routing schedule at the former plant and designed the equipment necessary for the manufacture of steel lockers, steel ceilings, and other specialties.

Mr. Reed's earlier experience included short periods in drafting work for the Columbia Bridge Company, Carnegie, and the National Tube Company, Pittsburgh, two years in drafting and layouts for firebrick linings of all kinds and for brickyard machinery for the Harbison-Walker Refractories Company, Pittsburgh, and three years designing and testing gas producers, gas engines, steam turbines, thrust bearings, and power plants for the Westinghouse Machine Company, East Pittsburgh.

Mr. Reed was born in Pittsburgh on November 26, 1886, and secured his education there, taking technical subjects in night school for several years and securing a B.S. degree in mechanical engineering at the Carnegie Institute of Technology in 1912. He became a junior member of the A.S.M.E. in 1916, resigned in 1924, and was reinstated as a member in 1930. He is survived by his widow, formerly Miss Blanche Crosbie, whom he married in 1914, and by three daughters, Helen, Margaret, and Mary.

SAMUEL AUSTIN REILLY, JR. (1906–1932)

Samuel Austin Reilly, Jr., whose death occurred at the Presbyterian Hospital in New York, N.Y., on August 20, 1932, was born at Little Falls, N.J., on March 4, 1906, the son of Samuel Austin and Cora (Keefe) Reilly. He attended high school in Newark, N.J., and took a mechanical engineering course at the Stevens Institute of Technology. Following his graduation in 1929 Mr. Reilly taught at the Institute for a year, in the Electrical Engineering Department, and then took a postgraduate course at the Massachusetts Institute of Technology.

At the time of his death Mr. Reilly was a member of the staff of the New York laboratories of the Bell Telephone Company, where he had worked during several vacations while attending Stevens Institute.

Mr. Reilly was a star lacrosse player at Stevens and a member of the track team. He belonged to the Montclair Athletic Club, Tau Beta Pi, honorary engineering fraternity, and Theta Upsilon Omega, and also to Gear and Triangle, a local honorary society at Stevens. He was a teacher in the Sunday School of the Irvington (N.J.)

Methodist Episcopal Church. He became a junior member of the A.S.M.E. in 1929.

Surviving Mr. Reilly are his parents, with whom he made his home in Irvington, and two brothers.

CLAUDE BRYANT ROBERTS (1884–1932)

Claude Bryant Roberts, president and treasurer of the C. B. Roberts Engineering Company, New York, N.Y., died suddenly at his summer residence in Northport, Me., on September 3, 1932.

Mr. Roberts was born at Vinal Haven, Me., on April 10, 1884. He attended the Camden (Me.) High School and took courses in mechanical engineering through the International Correspondence Schools. At the age of nineteen he entered the employ of the Belfast (Me.) Gas & Electric Co., with which he remained for five years, working up to the position of superintendent of operations.

From 1909 to 1919, when he established his own company, Mr. Roberts was connected with Stone & Webster of Boston, Mass. During the first three years he was located at Ponce, Porto Rico, beginning as assistant chief engineer and being promoted to chief engineer in about six months' time. In 1912 he entered the Engineering Department, Power Plant Betterment Division, of the company. For the first three years he was in full charge of betterment work in power plants of several railway, gas, and electric companies in New England. During the remainder of his association with Stone & Webster he directed in an advisory capacity all operations, maintenance, and personnel for about fifteen power plants in Texas, Louisiana, Florida, and Georgia. His last assignment for the company was to assist in a report on the power plants of the Interborough Rapid Transit Company of New York.

Mr. Roberts became an associate of the A.S.M.E. in 1920. He was also a member of the Masonic fraternity and Downtown Athletic Club, New York. He is survived by his widow, Dorothea (Sargent) Roberts, whom he married in 1917, and by a daughter, Emily Ann Roberts.

RALPH LEONARD ROBINSON (1890–1932)

Ralph Leonard Robinson, sales executive for The Babcock & Wilcox Co., New York, N.Y., was killed in an airplane accident on March 19, 1932, when the plane in which he and six other passengers, flying from Phoenix, Ariz., to Los Angeles, Calif., in a fog, struck a high-tension transmission line, near San Bernardino, Calif.

Mr. Robinson was born at Wollaston, Mass., on June 21, 1890. After his graduation in 1912 from Leland Stanford Junior University with an A.B. degree in electrical engineering, he entered the employ of the General Electric Company at Schenectady, N.Y. He did testing work on railway, industrial, and power-plant equipment, assisted in the design of power-plant equipment, and was sales engineer for the power and mining department during the two years he spent with the company.

In 1914 Mr. Robinson was appointed to the New York Public Service Commission, in the First District, New York, and for two years engaged in the inspection of new construction at the 59th and 74th Streets Power Stations of the Interborough Rapid Transit Company and in the appraisal of public utilities. He then became associated with the Griscom-Russell Company, New York, in the design and sale of auxiliary power-plant equipment and heat transfer equipment for ships. He supervised marine engineering and sales on the Pacific Coast. Mr. Robinson took charge of sales of special process equipment for The Babcock & Wilcox Co. on December 1, 1930.

Mr. Robinson became an associate member of the A.S.M.E. in 1919 and also belonged to the National Electric Light Association, American Society of Naval Engineers, and the American Society for Steel Treating. He is survived by his widow Faith (Swift) Robinson.

ROY WINTHROP ROUNSEVILLE (1885–1931)

Roy Winthrop Rounseville, son of Robert and Nellie Rounseville, was born at Neponset, Ill., on February 5, 1885. With his parents he later moved to Kewanee, Ill., and attended the public schools there. After his graduation from the Kewanee High School he studied mechanical engineering at the University of Illinois for three years with the class of 1909.

For a number of years Mr. Rounseville had spent his school vacations in the employ of the National Tube Company, predecessor of the Walworth Manufacturing Company, at the Kewanee Works. In June, 1909, he was engaged as a draftsman and until the first of 1912 worked on the design of products, machinery, and structural-steel and reinforced-concrete construction. The following year was devoted to special work on the design and development of molding and core-making machines. Early in 1913 he was made general foreman of the Iron Valve and Cock Departments, supervising finishing, assembling, and testing operations. After six years in this capacity Mr. Rounseville was promoted to the superintendency of the Finishing Division in charge of the following ten departments: Iron Valve, Brass Valve, Union, Tapping, Blank Stock, Inspection, Forge, Pipe Fabricating, Nipple and Well Point, and Tool Making. Shortly afterward he was also made general superintendent for the company's works at Kewanee, which entailed the supervision of all production and maintenance at this Works, including the Foundry Division, consisting of Malleable, Grey Iron, Steel, and Brass Foundries, and Annealing, Galvanizing, and Pattern Departments; the Finishing Division; and the Maintenance Division with its Machine Repair Shop, Boiler and Tin Shop, Carpenter Shop, Electrical Repair Shop, Power Generating and Distributing Plant, and a number of small maintenance and service departments. At the time of his death he held the title of general manager of the Works.

Mr. Rounseville planned to terminate his connection with the Walworth Company on the first of January, 1932, and to join in the reorganization of the Peters Pump Company, of Kewanee. He died suddenly following a cerebral hemorrhage early in the morning of December 26, 1931. He is survived by his widow, Mrs. Helen (Gunther) Rounseville, and by his mother and a sister, Mrs. Lawrence (Sarah) Bradbury, of Philadelphia.

Mr. Rounseville had been a member of the A.S.M.E. since 1923. He was active in the community work of Kewanee, being a member of the chamber of Commerce, the Rotary Club, Elks, Knights Templar, and First Congregational Church. He was a director and vice-president of the Kewanee Airports, Inc., and a member of the board of governors of the Midland Country Club.

GEORGE ROSS ROWLAND (1867–1932)

George Ross Rowland, supervising engineer of The Texas Company's sales department and an authority on lubrication, died of heart disease at his home in Elizabeth, N.J., on February 10, 1932. He is survived by his widow, Katherine L. (Hirtzel) Rowland, whom he married in 1900, and by a son, Ross.

Mr. Rowland was born at Hampton Junction, N.J., on August 3, 1867, the son of George W. and Mary E. (Johnson) Rowland. He began work for the Central Railroad of New Jersey in 1883 as rivet heater and worked his way up to the position of locomotive engineer, remaining with the railroad until 1910. During the latter part of the time he served as the official representative of the locomotive firemen and engineers on their Board of Adjustment with the officials of the road, and represented both organizations at a number of their conventions.

In November, 1910, Mr. Rowland became demonstrating engineer for The Texas Company, New York, N.Y., and for the next two years was engaged in running comparative tests and demonstrating the products of the company. He was promoted to the position of chief engineer of the Lubricating Division of the Sales Department in January, 1912, superintendent of Street Railway Sales ten years later, and superintendent of Lubricating Sales in April, 1925. He had been supervising engineer since September, 1927. Special lubricants required for modern mechanism were developed, tested, and demonstrated under his direction. He served in an advisory capacity to engine and machine builders in regard to changes in construction to secure more efficient and economical lubrication, as well as to the company's engineers on points relating to the production, characteristics, and application of Texaco products. He wrote many articles pertaining to lubricants and lubrication which have been presented before engineering societies, and others which are in general use by the company for the instruction of employees and for advertising purposes. He served as president of The Lubrication Engineers' Association of the company, which had as its object the standardization of methods and policy concerning lubrication of various types of mechanism with Texaco products, from the time of its organization in April, 1929, until his death.

Mr. Rowland became a member of the A.S.M.E. in 1917, and at the time of his death was serving on the Committee on Lubrication Engineering of the Petroleum Division of the Society. He also belonged to the Society of Automotive Engineers, the American Electric Railway Association, National Association of Stationary Engineers, the Brotherhood of Locomotive Engineers, the Masonic fraternity, and the Knights of Pythias.

GILBERT E. RYDER (1880–1932)

Gilbert E. Ryder, vice-president of The Superheater Company, New York and Chicago, died suddenly of heart failure on May 17, 1932, at his home in Larchmont, N.Y. Mr. Ryder joined The Superheater Company in 1911 as a service engineer and was elected vice-president, in charge of sales and service, in 1921. Since that time the company had broadened its locomotive services and extended its activities to other fields, important among which is the sale of superheaters for stationary power plants, inaugurated under Mr. Ryder's direction.

Mr. Ryder was born on May 29, 1880, in Minneapolis, Minn., the son of Charles Gilbert and Mary L. (Gray) Ryder. His elementary schooling was received in the public schools of Sandwich, Ill., and at Tabor Academy, Marion, Mass., and he studied engineering at the University of Wisconsin and University of Illinois. He served an apprenticeship on the Chicago, Milwaukee and St. Paul Railway (now the Chicago, Milwaukee, St. Paul and Pacific) and was employed for several years as a machinist and draftsman in the Mechanical Department of that road at Dubuque and Ottumwa, Ia., and West Milwaukee, Wis.

In 1906 and 1907, as assistant mechanical engineer in the Fuel Testing Bureau (Briquette Division) of the United States Geological Survey, he had charge of a series of locomotive tests made with briquetted fuel on several railroads. He next served the city of Chicago as deputy smoke inspector in charge of the Railway Department, where his work included investigating and recommending methods and devices for the operation of locomotives without smoke. Following this experience he became associate editor of *Railway and Engineering Review*, where he remained until he joined The Superheater Company.

Mr. Ryder became a member of the A.S.M.E. in 1913. He was a past-president of the Railway Supply Manufacturers' Association and had been active in the work of several other railway associations and clubs. He was well known for his articles and speeches on fuel conservation and increase in power of locomotives through the use of superheated steam. He also belonged to the Engineers Clubs in New York and Boston, Western Universities in New York, and yacht and golf clubs in the vicinity of his home. Surviving him are his widow, the former Miss Lottie [illegible] Cole, whom he married in 1908, a daughter, Mary Evaline, and a son, Charles Gilbert.

MALCOLM P. RYDER (1874–1932)

Malcolm P. Ryder, an associate of the A.S.M.E. since 1901, died on May 24, 1932, at his home in Westfield, Mass. He is survived by his widow, Mrs. Lanette (Corsa) Ryder, whom he married in 1895, a daughter, Mrs. Howard Kling, and two grandchildren.

Mr. Ryder had resided in Westfield for sixteen years and had taken a prominent part in its affairs. He was a member of the Westfield Fire Commission for nearly six years, resigning as chairman early in 1932 to accept an appointment on the Municipal Light Board. He belonged to a number of Masonic groups in Westfield and Springfield, to the Westfield Post of the American Legion, and to the Engineering Society of Western Massachusetts.

Mr. Ryder was born in February 22, 1874, in the township of Ossining, N.Y., the son of Malcolm and Eleanor (Reynolds) Ryder. He began work at the age of fourteen with the Hydromaze Manufacturing Company, New York, N.Y., in toolmaking and brass finishing, and from 1890 to 1892 served an apprenticeship as a machinist at the Edison General Electric Company, Schenectady, N.Y. During the next six years he had a varied experience, doing electrical testing and experimental work at the Lynn, Mass., plant of the General Electric Company, in charge of magnetic ore separators and the lighting plant for Mr. Edison at his concentrating works at Edison, N.J.; in charge of an electric light station at Maracaibo, Venezuela; as superintendent of the North River Electric Light & Power Co., New York; and as foreman of the winding and testing departments of the C. &. C. Electric Co., Garwood, N.J.

In 1898 Mr. Ryder began a connection of about twelve years' duration with the New York Edison Company, in the position of superintendent of the Bronx district. Subsequently for several years he engaged in business for himself as a wiring contractor in New York. He then went to Springfield, Mass., where he was employed by the Wico Electric Company and the Witherbee Igniter Company for some years prior to his retirement from business.

Mr. Ryder perfected numerous inventions and held several patents on radio and electrical-mechanical inventions.

During the World War Mr. Ryder served for a short time in the Air Corps, being stationed at Hempstead, L.I. He also saw service in the Spanish-American War.

One of Mr. Ryder's hobbies was amateur photography, especially motion pictures, and for a number of years he had recorded various events in Westfield and vicinity, including sports and special construction work. He also enjoyed yachting and during the summer spent considerable time on Long Island Sound. He was a member of the Springfield Yacht Club.

JULIAN SALENTINE SCHOLL (1867–1932)

Julian Salentine Scholl, general manager and treasurer of the Julian Scholl Company, Englewood, N.J., died at his home at Tenafly, N.J., on July 27, 1932. Mr. Scholl was born at Henryville, Ind., on April 28, 1867, the son of Charles and Elizabeth (Sulzer) Scholl. He attended high school in Indianapolis and was graduated from Rose Polytechnic Institute in 1888 with a B.S. degree in mechanical engineering. During his vacations he worked for the Sulzer-Vogt Machine Company, Louisville, Ky., and during the three years following his graduation for the Harrisburg Foundry and Machine Works and the Weston Engine Company, Painted Post, N.Y.

In 1891 he established the firm of Julian Scholl & Co., in New York, for designing and erecting complete power plants, designing and perfecting machinery and promoting its manufacture and sale. The name was changed to the Julian Scholl Company in 1910 and the firm has had headquarters in Englewood, N.J., since 1930. During recent years it has dealt in gasoline shovels, sand-washing plants, and contractors' equipment.

Mr. Scholl became a junior member of the A.S.M.E. in 1889 and a member in 1900. He is survived by his widow, Katharine B. (Hargest) Scholl, whom he married in 1893, and by a daughter, Ione S. Eckersen, and three sons, Julian S., Jr., Charles C., and Robert H. Scholl.

CHARLES HENRY SERGEANT (1864–1932)

Charles Henry Sergeant, consulting engineer, Rutherford, N.J., died suddenly of heart failure on January 23, 1932. He is survived by his widow, Dorothy (Bicks) Sergeant, whom he married in 1922.

Mr. Sergeant was born at Columbus, Ohio, on August 25, 1864, the son of Henry Clark Sergeant, a partner in several early firms which later grew into the present Ingersoll-Rand Company. His mother was Caroline (Luckhaupt) Sergeant.

After attending public school in New York, Mr. Sergeant took technical courses at the University of Denver, trained as a machinist with Sergeant & Cullingworth Co., New York, worked as a draftsman with J. W. Jackson, of Denver, and with his father at the Bridgeport Machine Tool Works, secured shop experience as superintendent of a small testing and erecting shop of the Sergeant Drill Company, New York, and spent a season in surveying and making drawings for the Denver and California Short Line Railroad.

Following this varied experience he took a position as draftsman with the Ingersoll Sergeant Drill Company, New York, in 1886. After a short time he was put in charge of the drawing room and occasionally during the six years he remained with the company served temporarily as foreman of the Drill and Compressor Departments. He standardized the company's rock drills and designed special air compressors and tools and supervised drill tests in mines, tunnels, etc.

From 1892 to 1898 Mr. Sergeant was draftsman for the National Meter Company, manufacturers of power and pumping gas engines and water meters of several kinds. He worked on the design of several engines for the Canda Manufacturing Company, Carteret, N.J., a wire opening envelope machine for Munn & Co., New York, air compressors for the McKiernan Drill Company, New York, and other machinery as a consulting engineer. The Merrill-Sergeant Pneumatic Company which he helped to form, dealt in water air lifts and displacement pumps, oil engine compressors, etc. For a time he was engineer for the Fuel Oil Power Company, demonstrating a 12 by 12 in. two-stroke vertical engine. For a year and a half he was superintendent and engineer for the Acme Oil Engine Company, Bridgeport, Conn., engaged in making small-power stationary oil engines, and for a similar period demonstrated his own 2-cycle 6 by 7 in. marine oil engine, running generator and light to secure data. Subsequently he designed a plate air valve of various sizes, a heavy oil engine, convertible to natural gas, and vacuum and air-pressure cylinders for gasoline extraction arranged in powers for one frame. Shortly after the War he went to Bradford, Pa., to work on internal-combustion engines and air compressors for the U.S. & Cuban Allied Works Engineering Corporation, whose main offices are located in New York. He had recently patented a high-speed engine, economical to manufacture and adaptable to automotive, aeronautic, or marine use. He had also recently designed an air-cooled 8-cylinder automobile engine, a radial, air-cooled oil engine, and an automatic automobile clutch.

Mr. Sergeant first became a member of the A.S.M.E. in 1895. He resigned in 1914, not being at the time actively engaged in engineering, but was reinstated in 1921.

JAMES SHEAHAN (1868–1932)

James Sheahan, general superintendent of the Memphis (Tenn.) Artesian Water Department, died of heart failure at his home in that city on June 9, 1932. His widow, formerly Miss Mary Collins of Batavia, Ill., whom he married in 1890, survives him.

Mr. Sheahan was born in Riverton, Va., on December 16, 1868, the son of Mr. and Mrs. John Sheahan. Early in his life the family moved to Vandalia, Ill., and later to Batavia, near Chicago, where he secured the most of his education. At the age of fifteen he began work with the Vandalia Paper Company and was employed by it and the Vannortwick Paper Company, Batavia, until 1887. During the next eight years he was with the United States Wind Engine & Pump Co., Batavia, being in charge of one of the manufacturing departments after completing an apprenticeship as a machinist.

Mr. Sheahan went to Memphis in 1895 and for three years was general superintendent of the Southern Bag & Paper Co., manufacturers of wooden ware. He erected machinery and did some general construction work for the Memphis Artesian Water Company in 1898 and 1899, and from then until 1912 was general superintendent of Scatchard & Son, lumber dealers.

During the first ten years of his connection with the Memphis Water Department Mr. Sheahan held the position of chief mechanical engineer. Under his direction in that capacity and later as general superintendent, the water system was greatly augmented. A recently constructed pumping station was named in Mr. Sheahan's honor.

Mr. Sheahan had been a member of the A.S.M.E. since 1925. He also belonged to the Memphis Engineers Club.

HARRY EALES SMALLBONE (1866–1932)

Harry Eales Smallbone, chief engineer for the Willcox & Gibbs Sewing Machine Co., New York, N.Y., died at St. Luke's Hospital in that city on July 28, 1932, after a brief illness.

Mr. Smallbone was born in England on December 8, 1866, and was educated there. He served a seven-year apprenticeship as an engineer and machinist, and studied drafting and designing at the Science and Art Schools, South Kensington, London. He came to the United States in 1889 and was connected with the Wheeler & Wilson Manufacturing Co., Chicago, Ill., as master mechanic until that company was purchased by the Singer Manufacturing Company in 1905. During the next two years he worked on inventions for the Singer company in Elizabeth, N.J. He returned to Chicago to become president and superintendent of the Smallbone Manufacturing Company, manufacturers of the Smallbone buttonhole attachment and other sewing machine parts, and designers and builders of dies, tools, models, and special machinery.

After ten years in this company Mr. Smallbone went to Buffalo to become assistant superintendent of the King Sewing Machine Company, with which he remained for an equal period. In 1928 he was engaged as consulting engineer by the New Home Sewing Machine Company, Orange, Mass. He entered the employ of the Willcox & Gibbs Sewing Machine Co. late in 1928 in the capacity of assistant superintendent, becoming chief engineer in 1929.

Mr. Smallbone had been a member of the A.S.M.E. since 1914. He also belonged to the Knights of Pythias and the American Order of Sons of St. George. He was a widower.

AUGUSTUS SMITH (1868–1932)

Augustus Smith, vice-president and for many years a member of the New Jersey State Commission of Commerce and Navigation, president of the Bergen Point Iron Works, Bayonne, N.J., died suddenly of heart disease at his home in Roselle, N.J., on February 29, 1932. He had been active in civic affairs in Roselle for many years, and during three years as a member of the Borough Council served as head of the Public Works Department. He was first appointed to the New Jersey State Commission in 1924. He had visited many cities in this country and Europe to increase his knowledge of municipal government, particularly that phase of it which deals with engineering and construction problems, in which he was very keenly interested.

Mr. Smith was born in New York, N.Y., on July 30, 1868, and attended the public schools there, the College of the City of New York, and the School of Mines of Columbia University, from which he received an A.B. degree in 1887 and a C.E. degree two years later. From then until 1893, when he established his own business as engineer and contractor, he was employed by the Link Belt Engineering Company, of New York and Philadelphia, except for a year spent as manager of a saw mill in South Carolina.

The Bergen Point Iron Works was founded by Mr. Smith in 1906. His engineering work included many public projects, among them the construction of naval coaling stations along the Atlantic Coast and at the Balboa and Cristobal terminals of the Panama Canal. He also had a number of inventions to his credit, one of his most important being a type of houseboat on pontoons. He designed and built coal-handling machinery, movable bridges, derricks, cranes, etc.

Mr. Smith had been a member of the A.S.M.E. since 1902 and also belonged to the American Society of Civil Engineers and The Franklin Institute. He is survived by a son, Henry Smith, a student at Princeton University. His wife died several years ago.

CAMERON C. SMITH (1861–1932)

Colonel Cameron C. Smith, founder of the Union Steel Casting Company, Pittsburgh, Pa., died on May 2, 1932, on his way north from Eustis, Fla. He was born on April 24, 1861, at Culmerville, Butler County, Pa., the son of Joseph and Mary (Watson) Smith. He prepared for college at the Sharpsburg (Pa.) Academy and spent three years at Waynesburg College and Lebanon University, where he studied civil engineering.

After leaving college Colonel Smith spent about nine years with Wilson-Walker & Co. and their successor, the Carnegie Steel Company. Here he had experience in the manufacture of railroad forged links, pins, couplers, axles, etc., as well as steel plates, beams, and armor plates.

The Union Steel Casting Company was founded by Colonel Smith in 1899 to manufacture open-hearth and crucible steel and steel castings, and he served as its president and general manager until 1917, when he became chairman of the board. He personally superintended the making of steel castings and took out a number of patents. He also contributed to the perfecting of cast-steel locomotive frames. He was widely consulted on the manufacture of steel.

During the World War he was business manager of the New York Ordnance District and a member of the War Claims Board, and was commissioned Lieutenant-Colonel. He had been chairman of the board of the Pittsburgh Roll Corporation since 1922. He was a director of the Potter Title & Trust Co. and the Potter Mortgage & Guarantee Co., and treasurer of the Duncan Land & Improvement Co. in Pittsburgh. He became a member of the A.S.M.E. in 1906 and held membership in the American Iron and Steel Institute, American Society for Testing Materials, Engineers Society of Western Pennsylvania, Army Ordnance Association, Highland Presbyterian Church, and several clubs in Pittsburgh and vicinity. He was a member of the Masonic fraternity and trustee of Waynesburg College. Colonel Smith had contributed articles to several periodicals, including *Iron Trade Review*, *Better Homes and Gardens*, and the *Literary Digest*.

Surviving Colonel Smith are his widow, formerly Maude Forsaith, of Etna, Pa., whom he married in 1902, and a married daughter, Dorothy (Mrs. J. W.) Badgley, of Dunkirk, N.Y.

HAROLD BABBITT SMITH (1869–1932)

Harold Babbitt Smith, whose study of dielectric phenomena and stress distribution was of inestimable importance in the development of long-distance power transmission, died in Worcester, Mass., on February 9, 1932, after being in ill health for several years. Direct-current generators and motors, alternating-current transformers, and insulators of his design contributed largely to the practical application of electricity in industry and everyday life. In recognition of such achievements, as well as of his long services as an educator, he was honored in 1929 by both Purdue University and Worcester Polytechnic Institute with the degree of doctor of engineering. He was head of the Department of Electrical Engineering at the latter institution for thirty-five years.

Dr. Smith was born at Barre, Mass., on May 23, 1869, the son of Samuel Francis and Julia Asenath (Babbitt) Smith. He prepared for college at the Barre High School and was graduated from Cornell University in June, 1891, with an M.E. degree in electrical engineering. After engaging in post-graduate study there for the remainder of the year, he entered the teaching field as professor of electrical engineering, in charge of the department, at the University of Kansas. In 1893 he became head designer and electrical engineer for the Elektron Manufacturing Company of Springfield, Mass. In the fall of that year he took up the duties of professor and director in the School of Electrical Engineering at Purdue University, where he remained until he went to Worcester in 1896. He was retained as consultant for the Elektron Manufacturing Company until 1902 and served a number of other organizations in a similar capacity. From 1904 to 1911 he was treasurer of the Smith & Rice Co., wholesale lumber manufacturers. In 1905 he became engineer and designer for the Westinghouse Electric & Manufacturing Co., of Pittsburgh, Pa., and since 1913 had been consulting engineer for that company. He retired from the Worcester faculty in 1931. His summer home was at Princeton, Mass.

At the St. Louis Exposition in 1904 Dr. Smith was chairman of the

International Group, Jury of Awards in Electrical Engineering. In 1917–1918 he was an associate member of the Naval Consulting Board and consultant of the special board of the Navy on anti-submarine research. He had traveled extensively in the interest of his profession in Europe, Africa, Japan, China, and India, and had written many papers for engineering organizations and the technical press.

Dr. Smith had belonged to the American Institute of Electrical Engineers since 1891, and had risen through various offices to the presidency of the Institute in 1929–1930. He had been prominent in much of the committee work of the Institute and had represented it on such joint-activity organizations as the American Engineering Council, John Fritz Medal Board of Award, and the United States National Committee of the International Electrotechnical Commission. He became a member of the A.S.M.E. in 1894 and belonged also to the Institution of Electrical Engineers (Great Britain), Society for the Promotion of Engineering Education, American Association for the Advancement of Science, and a number of clubs, including the Worcester Economic Club, Cornell Club of New England, and Cornell Club of New York. He was a member of several fraternities, including the Sigma Xi, Tau Beta Pi, and Beta Theta Pi.

Dr. Smith was twice married. His first wife, the former Miss Laura Bertha Smith, of Ithaca, N.Y., whom he married in 1894, died some years ago. In 1911 he married Miss Persis H. Smith of New York. They were divorced in 1930. He is survived by three children, Miss P. Nancy, Miss Margaret S., and Richard S. Smith, all of New York.

H. COLLIER SMITH (1866–1932)

H. Collier Smith, sole owner of The Quickwork Company, St. Marys, Ohio, died in that city on September 16, 1932.

Mr. Smith was born at Raleigh, N.C., on May 27, 1866, the son of Henry Collier and Laura Ann (Nowell) Smith. Mr. Smith learned the sheet metal business in his father's shop at Raleigh and later as a general mechanic, principally in connection with sheet and plate metal work and as draftsman in the Hull Department of the Newport News Shipbldg. & Dry Dock Co., Newport News, Va. He became president, in 1900, of the Smith-Warren Company, Boston, Mass. This company promoted his system of fireproof, hollow, sheet-metal window frames and sashes, for use in exposed portions of buildings, instead of fire shutters; he secured more than twenty patents on this system and was the pioneer sheet metal window promoter.

In 1906 Mr. Smith went to Brooklyn, N.Y., where for two years he was general assistant to Mr. Grace of the Herman & Grace Co., sheet and metal contractors. Subsequently he held a similar position for about a year with the Moore & Munger Co., in New York, his work relating to automobile bodies and sheet metal work. During this period he designed and built a rotary shear, in addition to a number of other tools and devices.

He designed and built other shears and sheet metal working tools while connected during the next two years with the Springfield (Mass.) Metal Body Company and the Racine (Wis.) Mfg. Co. In 1911 and 1912 he was superintendent of the Sheet Metal Department of the Cadillac Motor Car Company, Detroit, and designed many machines, tools, dies, jigs, and fixtures.

About this time Mr. Smith established his own business in Detroit for building plate and sheet metal working machinery, later removing to St. Marys. He designed and manufactured rotary shears for straight, irregular, and circular cutting, beveling, flanging, and joggling operations in building boilers, ships, cars, tanks, stacks, etc., and in plate mills, as well as many machines for sheet metal work. He contributed articles in his field to the technical press.

Mr. Smith became a member of the A.S.M.E. in 1921. He was also a member of the Society of Automotive Engineers, a 32d degree Mason and Shriner, and a member of the Episcopal Church.

In 1903 Mr. Smith married Miss Agnes T. Flatley, Newark, N.J. He is survived by her and by one son, H. Collier Smith, Jr., under whose direction The Quickwork Company is being continued.

WILLIAM AIKEN STARRETT (1877–1932)

William Aiken Starrett, whose achievements as a builder of skyscrapers were outstanding, died at his home in Madison, N.J., on March 25, 1932, after an illness of three months. The Empire State Building in New York, at the time of its construction the highest building in the world, and the Union Station in Washington were among the many structures for which he and his associates were responsible.

Colonel Starrett was president of The Starrett Corporation, New York, holding company of the Starrett realty and building enterprises, in all of which he was an officer or a director, or both. He was vice-president and director of Starrett Brothers & Eken, Inc., the building affiliate of the varied interests, which erected the Empire State Building and other large buildings of note, including the seventy-story Forty Wall Street Building and the nineteen-story Starrett-Lehigh Terminal Building, in New York, the Carew Tower in Cincinnati, the tallest building in the Ohio Valley, and the forty-story Ramsey Tower, tallest structure in Oklahoma City. Colonel Starrett was also president of the Starrett Investing Corporation, the investing and realty affiliate; the Forty Wall Street Corporation; and the Wall and Hanover Street Realty Corporation; and a director of several contingent interests.

William Starrett was born at Lawrence, Kan., on June 14, 1877, a son of the Reverend William A. and Helen (Ekin) Starrett. He attended the Chicago Preparatory Schools and spent two years at the University of Michigan as a member of the Class of 1897, leaving in 1895. He received his B.S. degree in civil engineering in 1917, as of the Class of 1897, and in 1931 the university conferred the honorary degree of Doctor of Engineering upon him.

After leaving the University, he worked for a time in a large wholesale grocery concern in Chicago and in 1897 went to New York and entered the employ of the Thompson Starrett Company, which his brothers Theodore and Ralph and Henry Thompson had recently organized. He spent about three years with that company, working as timekeeper, field engineer, and building superintendent. After several years as building superintendent on various projects in New York, he took charge of the erection of the Union Station in Washington, and on its completion he was made general superintendent and vice-president of his company. In 1913, Colonel Starrett left the Thompson Starrett Company to become a member of the firm of Starrett & Van Vleck, architects, a connection which continued until 1918.

In 1916 Colonel Starrett spent some time in training work at the Plattsburg Camp and with the Engineers Corps. When the United States entered the World War, he was called to Washington to take charge of emergency construction work for the Council of National Defense and was appointed Chairman of the Emergency Construction Division of the War Industries Board, serving throughout the War. This Division had charge of the building of all cantonments, hospitals, and army bases in the United States. He was commissioned a Captain in the Engineers Reserve Corps of the National Army in May, 1917, and a Major the following month; he was promoted to the rank of Colonel in the Quartermaster Corps in March, 1918, and, when discharged a year later, retained that rank in the Reserve Corps.

After the War, Colonel Starrett was made vice-president of the George A. Fuller Company, an office which he retained until 1921. During this period, he was connected with the erection of several large buildings in Tokyo, Japan. These steel frame buildings which he built then withstood the 1927 quake.

In 1922, together with his brothers Paul and Ralph and Andrew J. Eken, he founded Starrett Brothers, Inc., the firm later becoming Starrett Brothers & Eken, Inc., with Paul Starrett as president and the other members vice-presidents. The Starrett Corporation was formed in 1929 and Colonel Starrett was active in its work up to the time of the illness leading to his death.

Colonel Starrett was called into consultation by President Hoover in August, 1931, in connection with a nation-wide program for enlivening the building trades. He spent the next several months in intensive work as a member of the President's Emergency Committee for Employment and as a director of the Gibson Emergency Committee in New York. He also engaged in public service in Madison, N.J., as its Mayor, on the Republican ticket, from 1920 to 1922. He declined renomination on account of increased building activities at that time.

Colonel Starrett was the author of "Skyscrapers and the Men Who Build Them," published in 1928, as well as a frequent contributor to magazines. He had made several addresses over national broadcasting chains in regard to the utilization in home building of experience secured in the erection of skyscrapers.

He became a member of the A.S.M.E. in 1919 and was a member of its Committee on the Economic Status of the Engineer. He also belonged to the American Society of Civil Engineers, the Society of American Military Engineers, and the Engineers' Club in New York. He was a former member of the American Institute of Architects.

Surviving Colonel Starrett are his widow, formerly Miss Eloise Gedney, of East Orange, N.J., whom he married in 1900, a son David, and a daughter Helen Ruth, as well as his brother Paul and two sisters.

LEWIS STARR STRENG (1876–1931)

Following an illness of several months, Lewis Starr Streng, vice-president in charge of operation for the Louisville Gas & Electric Co., Louisville, Ky., died at his home in that city on December 24, 1931. He is survived by his widow, Mrs. Fannie S. (Henly) Streng, whom he married in 1910, and by two children, John, a student at the Massachusetts Institute of Technology, and Ida Henly Streng, a student at the University of Louisville.

Mr. Streng was a native of Louisville, the son of Manuel J. Streng and Frances (Starr) Streng. He was born on September 19, 1876. He attended the public schools of Louisville, and was a member of the class of 1894 at the du Pont Manual Training School there, the first graduating class of that institution. He was graduated from the Massachusetts Institute of Technology with an S.B. degree in 1898.

His first business connection was in the Testing Department of the General Electric Company at Schenectady, N.Y., for the latter part of 1918. From there he went into the employ of the Public Service Corporation of New Jersey and was with that corporation and its subsidiary organizations until 1906, during the latter part of the time as assistant chief engineer of the Electric Department and in charge of electric design and construction of generating and substations and transmission lines.

In 1906 Mr. Streng returned to Kentucky as chief engineer for the Kentucky Electric Company, designing and building the entire station and lines. Seven years later, when that firm and the Louisville Lighting Company were merged into the Louisville Gas & Electric Co., he was appointed chief engineer and general superintendent. He was elected to the office of vice-president in 1923 and continued in that capacity until his death.

His career at Louisville was marked with a number of engineering achievements. In 1914 he supervised the piping of the first natural gas to the city. He was supervising engineer in the construction of the Bear Grass Gas Plant on the Upper River Road, and of the Ohio Falls Hydro Electric Station, and superintended the enlargement of the Waterside Steam Station at Second Street and the Ohio River.

Mr. Streng was in charge of the purchase of additional power-plant facilities when his company, in 1929, began to furnish power to the Louisville Railway. He also supervised the construction of the transmission line from the hydro plant to the Union Gas & Electric Co. at Cincinnati.

In addition to his membership in the A.S.M.E., which he joined in 1917, Mr. Streng was a Fellow of the American Institute of Electrical Engineers, and was a member of the National Electric Light Association, American Gas Association, and of a number of clubs, including the Engineers and Architects, Electric, Quindecim, and Standard Country clubs of Louisville.

DAVID LONG SUMMEY (1875–1932)

David Long Summey, consulting engineer associated with the United States Metals Refining Company, New York, N.Y., died at his home in that city on November 14, 1932. He was born in Davison, Mich., on March 10, 1875, the son of George E. and Mary (Long) Summey. After studying for a time at the University of Illinois, he secured employment in the Engineers Corps of the Erie Railroad, Buffalo Division. Subsequently he was assistant engineer in the Distribution Department of the Peoples Gas, Light & Coke Co., Buffalo; in charge of a street main construction for the Jenkintown & Cheltenham Gas Co., Jenkintown, Pa., and for the Philadelphia Suburban Gas Company, Darby, Pa.; and superintendent of the River Shore Gas Company, Riverton, N.J.

About 1900 Mr. Summey became associated with the United Gas Improvement Company, Philadelphia, Pa., as erecting engineer and draftsman. In 1903 he was sent to Waterbury, Conn., as assistant superintendent in charge of the operating departments. From 1905 to 1913 he was a designing mechanical engineer, specializing in extrusion processes at the Chase Rolling Mill Co., Inc., of Waterbury, and from 1913 he continued his work on extrusion at the Scovill Manufacturing Company of the same city. Later he became chief engineer of that company.

About five years before his death he was engaged as consultant to the United States Metals Refining Company to design an electric melting furnace as the first step in the development of a process for producing high conductivity oxygen-free copper. This metal is now being produced on a commercial scale at the Carteret, N.J., plant of that company.

Mr. Summey became a member of the A.S.M.E. in 1907 and served on the executive committee of the Waterbury Section in 1923. He also belonged to the Institute of Metals.

Surviving Mr. Summey are his widow, Virginia (Weeks) Summey, whom he married in 1899, and three children, Mrs. Elizabeth (Summey) Roudebush, Virginia Piers Summey, and Richard W. Summey, all of New York.

KARL JOHAN SUNSTRÖM (1851–1932)

Karl Johan Sunström, who died in Stockholm, Sweden, on April 22, 1932, was born in Sunne, Sweden, on November 18, 1851, the son of Jan Henrik and Johanna (Fryxell) Sunström. He attended high school in Karlstad and secured his technical training in Stockholm. He began work in 1870 as draftsman for the Munkfors Iron Works, where he remained for about a year. The next three years were spent in designing and building peat machinery in Stockholm, and from 1874 to 1881 he was connected successively with the Lesjöfors Iron Works, as draftsman, Aker Ordnance Works, as superintendent and mechanical engineer, and Hagfors Iron Works, as chief draftsman, all of these plants being located in Sweden.

Mr. Sunström came to the United States in 1881 and took a position as draftsman with the Washburn & Moen Manufacturing Co. in Worcester, Mass. The next year he went to Providence, R.I., where he worked as draftsman for the Brown & Sharpe Manufacturing Co. until 1886. After another year with the Washburn company he was associated with Charles H. Morgan in developing the continuous rolling mill.

Returning to Sweden in 1890 Mr. Sunström engaged in consulting work for a year and subsequently was associated with the Kopparsbergs-Berglagets Works, Falun, as mechanical engineer, Berglagets Works, as chief engineer, and Degerfors Steel Works, also as chief engineer, until 1906. From then until his retirement he engaged in consulting work in Stockholm.

Mr. Sunström became a member of the A.S.M.E. in 1884 and belonged also to the Iron and Steel Institute, the Verein deutscher Eisenhüttenleute, and other technical organizations. He contributed several articles to *Järnkontorets Annaler* and other periodicals on the manufacture of welded pipes and tubes, the horseshoe nail and its manufacture, old-time rolling mills, and other subjects. The King of Sweden bestowed the Royal Vasaorden upon him.

Since his retirement Mr. Sunström had interested himself in studying and collecting engineering relics. He is survived by a married daughter, Mrs. Agnes Westerberg, of Degerfors, and a son, Rudolf Sunström, of Gunnebobruk, Sweden.

HANS OTTO SWOBODA (1870–1932)

Hans Otto Swoboda, consulting electrical and mechanical engineer, Pittsburgh, Pa., died on June 30, 1932, in that city after a short illness. Mr. Swoboda was born on February 4, 1870, in Buchholz, Saxony, Germany, the son of Herman and Thekla (Eisenstuck) Swoboda. He was educated in Germany, attending technical schools in Dresden, Hanover, and Darmstadt. After two years as electrical engineer with Siemens & Halske, in Berlin, he came to the United States in 1892. Here he was associated successively with the General Incandescent Arc Light Company, absorbed in 1899 by the General Electric Company, the Falcon Electric & Mfg. Co., and the H.O.S. Engineering Company, all of New York, and the Amboy Manufacturing Company, Perth Amboy, N.J. He went to Pittsburgh in 1910 and was connected for two years with the Westinghouse Elec. & Mfg. Co. as superintendent of the electrical department. He then organized the firm of H. O. Swoboda, Inc., consulting electrical and mechanical engineers, of which he was president and treasurer until his death.

Mr. Swoboda was a recognized authority on electric lighting and power plant work and had devoted considerable time to electric heating research. He designed and developed numerous electrical devices for which he received United States and foreign patents, and made frequent contributions to scientific journals. The Falcon electric heat-treating furnaces and bare electric immersion heaters for asphalt and other viscous materials are products of his inventive ingenuity.

Mr. Swoboda became a member of the A.S.M.E. in 1921. He also belonged to the American Institute of Electrical Engineers, American Society for Steel Treating, Technischer Verein, and the Lincoln Club of Pittsburgh and Pittsburgh Athletic Association. He is survived by his widow, Olga (Schmelz) Swoboda, whom he married in 1897, and by two sons, Herman and Walter.

WILLIAM WOLCOTT TEFFT (1882–1932)

William Wolcott Tefft, prominent in the middle-western field of hydroelectric power, died on June 24, 1932, at the Cowie Private Hospital in Ann Arbor, Mich., after an illness of several weeks. His home was in Jackson, Mich., where he was active in church and other local activities. He is survived by his widow, Mrs. Ethel (Foote) Tefft, whom he married in 1910, and by a son, Robert, as well as by one brother, Leo C. Tefft, of Jackson.

Mr. Tefft was born at Milbank, S.D., on February 28, 1882, the son of Levant C. and Ada M. (Wolcott) Tefft. He prepared for college at the Jackson High School and received a B.S. degree in civil engineering from the University of Michigan in 1907. The degree of C.E. was conferred upon him by the University in 1930. During summer vacations while he was in college Mr. Tefft had experience as a rodman in surveying for electric railway construction; as dredging inspector for the Federal Government at the Lime Kiln crossing of the Detroit River at Amherstburg, Ontario, Canada; as chief of party in waterpower surveys on the Muskegon River; as assistant engineer to Gardner S. Williams, consulting engineer of Ann Arbor; and as resident engineer in the construction of a hydroelectric plant at Superior, Mich.

Following his graduation Mr. Tefft spent three years with the Commonwealth Power Company, supervising work on dams, designing reinforced-concrete power houses, and serving for a time as resident engineer at the Cooke Dam on the Au Sable River, Michigan. From 1911 to 1919 he was a member of the firm of the Fargo Engineering Company, Jackson. His work during these eight years included cost estimates and appraisals for hydroelectric developments, in several states. He made a special investigation for his father-in-law, W. A. Foote, founder of the Commonwealth Power Corporation, of power possibilities on the rivers of the Southern Peninsula of Michigan, a survey for the Federal Government during the World War on water-power possibilities in Michigan and Wisconsin, a study of general conditions for the construction of dams along the Chippewa and Menomonie Rivers in Wisconsin, and a survey of the feasibility of substituting water for steam power in Michigan, thereby effecting large savings in coal and railroad haulage. During this period he also invented the Tefft conduit spillway, which reduced hydroelectric construction costs as much as 42 per cent in some instances.

In 1919 Mr. Tefft joined the staff of Hodenpyl, Hardy & Company, of New York, with an office in Jackson. He covered general engineering of large steam electric generating plants, hydroelectric power plants and dams, electric transmission lines, steam generating and electric generating plants, etc. He also became consulting hydraulic and civil engineer to the Consumers Power Company, a subsidiary of the Commonwealth Power Corporation. He was made vice-president of the former in 1922 and of the parent organization in 1924. He served as chief engineer of the Central Illinois Light Company, Southern Indiana Gas & Electric Co., Ohio Edison Company, Illinois Power Company, Illinois Electric Power Company, Northern Ohio Power & Light Co., and Tennessee Electric Power Company from 1924 to 1928, when he entered private practice as a consulting engineer. The following year he rejoined the Fargo Engineering Company as vice-president and since 1930 had also been president of the General Power Corporation.

Among the noteworthy construction achievements of Mr. Tefft were the Alcona Dam on the Au Sable River, built on a quicksand foundation, and the Ox Bow Dam on the Muskegon River, said to be the highest dam in the world on an earth foundation with a spillway through it.

Mr. Tefft was president of the board of trustees of Albion College, Albion, Mich., president of the Methodist Foundation of Michigan, and president of the board of trustees of the First Methodist Church in Jackson. He had served as president of the Jackson Council of the Boy Scouts and was a director of the Y.M.C.A. He had recently accepted the chairmanship of the finance committee of the Michigan George Washington Bicentennial Commission. He was a director of the Union & Peoples National Bank in Jackson and belonged to the Rotary Club there and to a number of local recreational clubs.

Mr. Tefft became a member of the A.S.M.E. in 1928. Other technical organizations to which he belonged were the American Society of Civil Engineers, American Institute of Electrical Engineers, American Association for the Advancement of Science, American Society of Military Engineers, and the National Electric Light Association. He was a director of the Michigan Engineering Society and a member of engineering societies in several other mid-western states. In 1929 he was elected to membership in Sigma Xi for his accomplishments in hydraulic engineering. He was also a member of the American Committee of the World Power Conference.

EDWARD G. THOMAS (1865–1932)

Edward G. Thomas, who had belonged to the A.S.M.E. since 1890, was born at Waltham, Mass., on November 1, 1865, the son of Reuben and Mary Galbraith Thomas. He was graduated in 1887 from the Massachusetts Institute of Technology with an S.B. degree in mechanical engineering. After two months as draftsman with the Ames Manufacturing Company, Chicopee, Mass., he spent a year in drafting and experimental work at the Edison Laboratory at Orange, N.J., and four months with the Thomson Houston Electric Company, San Francisco, Calif. He then became a member of the firm of Thomas, Shepard, and Searing, mechanical and electrical engineers of Denver, Colo., where he remained for two years. Subsequently he was connected for about a year each with the Edison General Electric Company at Butte, Mont., as agent and engineer, and with the Butte General Electric Company, as superintendent of a 1200-hp plant.

In 1894 Mr. Thomas located in Boston, Mass., where for seven years he engaged in general mechanical engineering and the development of automatic weighing machinery. For three years, beginning in 1902, he was engineer of the New York office of the Lamson Consulting Stove Service Company and engineer in the Special Machinery Department at Boston. From 1905 to 1909 he was superintendent of the Ariston Marble Company, Brooklyn, and the Aero Pulverizer Company, New York. During the next two years he was engineer for the Choralcelo Manufacturing Company, Boston.

Mr. Thomas left the East in 1911 to accept a position as mechanical engineer with the Boss Manufacturing Company, Kewanee, Ill., with which he remained until 1915. He spent the following two years with the Wilson Tire & Rubber Co., Springfield, Ill. In 1917 he took a position as mechanical engineer with the Toledo (Ohio) Scale Company, and was in the employ of that company until about two years before his death. Out of work since that time and in ill health he committed suicide on January 19, 1932.

About seventy-five patents were issued to Mr. Thomas, covering weighing and packaging apparatus, conveying machinery, agricultural implements, and other inventions.

Mr. Thomas became a junior member of the A.S.M.E. in 1890 and a member in 1907. He also belonged to the Engineers' Club, New York. He is survived by his widow, Mable Odiorne Thomas, whom he married in 1913, and by one daughter, Mary Galbraith Thomas.

FRED HEGLER THOMAS (1884–1932)

Fred Hegler Thomas died of heart failure on March 27, 1932, at his home in Mt. Vernon, Ohio, following an illness of four months. He was a native of Ohio, having been born at London on July 24, 1884, the son of Madison M. and Cordelia (Hegler) Thomas. After two years in preparatory work at the University School of Columbus, Ohio, he entered the mechanical engineering course at the Case School of Applied Science, Cleveland, Ohio, from which he received a B.S. degree in 1905. For about a year following his graduation he was engaged in drafting and testing work for the Jeffrey Manufacturing Company in Columbus. He then accepted a position in the Engineering Department of the American Steel & Wire Co., at Cleveland, in charge of the layout of all power equipment and the operation of all engine and boiler plants. He also carried on some experimental work for the company.

He resigned in 1907 to become sales agent for The C. & G. Cooper Co., at Mt. Vernon. Subsequently he was advanced through the offices of assistant treasurer and treasurer to that of vice-president and general sales manager of the company, which in 1929 merged with the Bessemer Gas Engine Company of Grove City, Pa., to form The Cooper-Bessemer Corporation. He helped to develop large gas-engine units for oil and gas field service, designed to compress natural gas for pipe-line distribution and to make gasoline from casinghead gas. His company was one of the early builders in this particular field, developing a complete line of engines in different sizes. Mr. Thomas was also associated in the development of mill and uniflow engines. During the World War the company built a large number of special marine engines for the Emergency Fleet Corporation, as well as hydraulic forging presses, etc., and also equipped a complete shop for the manufacture of shells, and built cutting-off machines, etc., used in shell manufacture.

Mr. Thomas became a junior member of the A.S.M.E. in 1909 and was promoted to the grade of member in 1921. He belonged to the Masonic fraternity, in which he was a Shriner, and was a member of the Congregational Church in Mt. Vernon. He is survived by his widow, Irene (Cooper) Thomas, whom he married in 1926, a daughter, Louise, and one brother, Clyde, of London, Ohio.

MAX E. R. TOLTZ (1857–1932)

Max E. R. Toltz, whose death occurred at his home in St. Paul, Minn., on January 11, 1932, was born at Koeslin, Germany, on September 2, 1857, the son of Hermann and Malvine (Beilfuss) Toltz. He attended the Royal Gymnasium at Koeslin and the Royal Polytechnikum in Berlin, receiving a civil engineering degree in 1878. Ramsey Institute of Technology, St. Paul, conferred the degree of Doctor of Engineering upon him in 1924.

Mr. Toltz served a short apprenticeship with a Berlin firm dealing in pumps and water-works equipment, and was connected with the

Prussian government as assistant engineer until he came to the United States in 1882. He became a citizen in 1889.

During the first twenty-five years in the United States Major Toltz was active in the development of railroads, especially in the Northwest. He was connected with the St. Paul, Minneapolis & Manitoba, later the Great Northern Railway, from 1882 to 1904, being promoted through various positions from draftsman to mechanical engineer in charge of motive power. During the next three years he was consulting mechanical engineer at the Angus Shops in Montreal and at the Winnipeg Shops of the Canadian Pacific Railway, and at the Jersey City Shops of the Erie Railroad. He also held the position of vice-president and general manager of the Manistee & Grand Rapids Railroad.

Major Toltz had devoted himself entirely to consulting work since 1907. During the first three years of that time he was engaged in special work on electrification for the Great Northern, Northern Pacific, Butte, Anaconda & Pacific, and Chicago, Milwaukee & St. Paul Railroads, and on ore docks for the Great Northern, Northern Pacific & Soo Lines. In 1910 he organized the Toltz Engineering Company, St. Paul, and was president of it and of its successor, Toltz, King & Day, Inc., formed in 1918, until his retirement from active business in 1928. He specialized in labor-saving machinery, hydroelectric and steam power, grain elevators, and docks, and held patents on steam superheaters, car lighting, and iron-ore docks. He had contributed a number of papers to the technical societies of which he was a member and to the technical press. These dealt with highly superheated steam and its applications, the distillation of peat coke, compressed acetylene gas, and other subjects in his field.

During the World War Major Toltz, who had been a captain in the Minnesota National Guard for many years, received his commission as a major in the Construction Division of the Quartermaster Corps. He supervised the construction of General Hospital No. 2 at Ft. McHenry, Baltimore, Md.

Major Toltz gave much of his time and ability to the advancement of the engineering profession. He was a valued member of the St. Paul Chapter of the American Interprofessional Institute, also a director of its national board. He was a past vice-president of the American Society of Civil Engineers and a member of the American Institute of Electrical Engineers, the American Railway Master Mechanics Association, and the American Society of Military Engineers. He had served as president of both the Engineering Society of St. Paul and the Federation of Architectural and Engineering Societies of Minnesota. He was a member of the Verein deutscher Ingenieure.

Major Toltz became a member of the A.S.M.E. in 1904. He was a manager of the Society from 1914 to 1917 and a vice-president during the next two years. He was one of the organizers and first chairman of the Local Section at St. Paul, and was a member of its executive committee at the time of his death. He was also serving on the 1932 Nominating Committee of the Society and on the Committee on Awards. In 1925 he established a fund of $15,000, the income of which was to be used for loans to students of engineering, under the administration of the A.S.M.E. In his will he has provided similar funds to be administered by the American Society of Civil Engineers and the American Institute of Electrical Engineers.

Among other organizations to which Major Toltz belonged were the St. Paul Engineers' Club, the Minnesota and University Clubs, and the Masonic fraternity. He was an honorary member of Pi Tau Sigma, honorary mechanical engineering fraternity. He was a Christian Scientist, and made bequests to several of its churches and other organizations.

Major Toltz is survived by his widow, Mrs. Elizabeth (Argue) Toltz, whom he married in 1919, and by three grandchildren through a former marriage.

JOHN TRIX (1848–1932)

John Trix, founder and president of the American Injector Company, Detroit, Mich., died at his summer home in Algonac, Mich., on September 26, 1932, after an illness of about nine months.

Mr. Trix was born in New Orleans, La., on December 13, 1848, the son of John and Catherine (Cook) Trix. His father died when he was ten years old and later the family moved north to Buffalo, N.Y., and then to Sandusky, Ohio. After completing work in the public schools there, Mr. Trix served an apprenticeship as machinist, toolmaker, and die worker, and for a time manufactured tobacco in Ohio. In 1870 he went to Detroit, where for sixteen years he was superintendent of the John J. Bagley Tobacco Co. During his leisure hours he worked on several mechanical devices and became interested in a patent for an injector, which led to the establishment of the American Injector Company, manufacturers of injectors, oil and grease cups of all kinds, and many other devices.

Mr. Trix was also president of the Maplewood Land Company, the Dover Court Land Company, the Baldwin Park Land Company, and the Blackstone Land Company; vice-president of the Steere Engineering Company; and a director of the McCleary-Harmon Electric Company, during various periods of his active life. He was one of sixteen men who organized the Detroit Employers' Association, and served the Michigan Manufacturers Association as a director and the National Manufacturers Association as vice-president. In politics he was a Republican and he served as a school inspector in Detroit for a time.

He became a member of the A.S.M.E. in 1913, was a member of the Detroit Athletic Club and the Detroit Board of Commerce, and was very active in the Masonic fraternity, in which he had attained the 33d degree.

Mr. Trix married Harriet Phelps, of Detroit, in 1883, and is survived by her and by four children, John J., Ralph, and Herbert B. Trix, and Caroline (Trix) Bryant.

AMBROSE GILMORE WARREN (1873–1932)

Ambrose Gilmore Warren, who died of heart disease on March 16, 1932, was born at Hubbardstown, Mass., on April 1, 1873, the son of Elijah and Eliza (Wood) Warren. After four years at the Gardner (Mass.) High School he entered Worcester Polytechnic Institute, from which he was graduated in 1895 with an S.B. degree.

Mr. Warren's first position was with the Deane Steam Pump Company, at Holyoke, Mass., where he spent three years in general work and the design of jigs and fixtures and another year in laying out castings. After he left the Deane company he was employed for six months by the Farrell Foundry & Machine Co., Ansonia, Conn. He located in Philadelphia in 1900 and for nearly twenty-five years served the J. W. Paxson Co. as mechanical engineer, designing, manufacturing, and selling foundry machinery, in charge of the drawing room and machine shop. Since 1924 he had been vice-president of the Pennsylvania Bronze & Brass Co., and vice-president and treasurer of the Aetna Foundry Company, both of Philadelphia.

Mr. Warren developed sand-blast machinery and a dust arrester now widely used in foundries.

Mr. Warren became a member of the A.S.M.E. in 1907. He also belonged to the Manufacturers' Club of Philadelphia and the Masonic fraternity, and was a Presbyterian. He is survived by his widow, Mabel P. Warren.

FRANK W. WEARIN (1867–1930)

Frank W. Wearin, engaged in appraisal engineering for the firm of Murrie & Co., Inc., New York, N.Y., since 1925, died on September 20, 1930.

Mr. Wearin was born at Maryborough, Queensland, Australia, on November 7, 1867, and received practical training as machinist and engineer on marine work during five years with Walker's Limited there. He also took some courses at Cooper Institute, New York. He spent three years, 1892–1895, in the United States Navy, and an equal period in the construction and repair of marine engines for the American Line. In 1898 he was appointed chief engineer to the New York Edison Company, to handle the construction and repair of all mechanical apparatus. He returned to naval service in 1906 as master mechanic in the steam engineering department at the Portsmouth (N.H.) Navy Yard, and remained there seven years. From 1915 to 1925 he was engineer for the Selson Engineering Company of London in its New York offices, working on the design and manufacture of machine tools for completely equipping machine shops.

Mr. Wearin became an associate-member of the A.S.M.E. in 1919.

HENRY WEAVER (1879–1932)

Henry Weaver, designer for Warren Webster & Company, Camden, N.J., died suddenly on March 19, 1932, at his home in Maple Shade, N.J. He is survived by his widow, formerly Miss Kate Ellen Colley, of Lincoln, England, whom he married in 1904, and by his father, Edward Weaver, a retired civil engineer, residing in England.

Mr. Weaver was born on June 21, 1879, at Grimsby, England. He spent six years at King Edward the Sixth College, Louth, England, completing his studies there in 1897. He then served a six-year apprenticeship in the machine shops, foundry, and drafting room of Robey & Co., Lincoln, England, at the same time taking night courses in drafting, mathematics, steam, light, and heat, and magnetism and electricity at the Lincoln Technical School. During the next five years he was draftsman at the Engineering Works of Ruston, Proctor & Co., at Lincoln, working chiefly on boilers of different types.

Mr. Weaver came to the United States in 1910 and secured employment at the Baldwin Locomotive Works in Philadelphia. He began work as a detailer in the drafting room, soon being advanced to the position of assistant to the designer on electric locomotives. After two years he was put in charge of the extra order work of the electric locomotive department and in 1914 was selected to check the original drawings with the finished locomotives in the shops, to make sure that any alterations or additions which had been found necessary were recorded on the drawings.

He was connected with the Baldwin Locomotive Works until 1918, with the exception of a few months in 1914 when scarcity of work there caused him to do drafting for several other companies. Since leaving the Baldwin Locomotive Works he had been with Warren Webster & Company, specialists in steam heating, except for a few months during 1920 when he was assistant to the chief in the power, light, and heat department of the Victor Talking Machine Company, designing a new plant to supply steam and water necessary for manufacturing records. His work for Warren Webster & Company was largely designing, though he also had charge of considerable tool work during the first few years.

Mr. Weaver became an associate member of the A.S.M.E. in 1924.

WILLIAM PATTON WESCOTT (1864–1932)

William Patton Wescott, who died at Highland Mills, N.Y., on July 22, 1932, was a native of Philadelphia, Pa., where he was born on November 29, 1864. His parents were William Patton and Sarah P. (Baker) Wescott. His early education was secured in the public schools of Jersey City, N.J., and later he took courses in mechanical and mining engineering through the International Correspondence Schools.

Mr. Wescott was connected with the Galena Signal Oil Company from 1896 until his retirement in 1927. He was located in New York until 1911, in the position of mechanical engineer for the firm. From then until the close of the World War he was managing director of the London branch. He was appointed treasurer in 1922 and during his last three years with the company served both as treasurer and as vice-president.

A mine car invented by Mr. Wescott was adopted as standard equipment by the coal mining department of the D. L. & W. R.R. and was also used in other mines.

Mr. Wescott was a member of both the A.S.M.E., which he joined in 1910, and of the A.I.M.E. He belonged to the Engineers' Club in New York and was a 32d degree Mason. He was an active member of the Protestant Episcopal Church, belonging to St. Johns in Jersey City, where he resided for some years, and more recently to St. Davids in Highland Mills. In 1914, during his residence in London, he served as a member of Ambassador Walter Hines Page's Committee of One Hundred for Relief.

Surviving Mr. Wescott are his widow, Carrie A. (Lothridge) Wescott, of Highland Mills, whom he married in 1887, and two children, Albert L. Wescott and Helen W. Van Winkle, both of Leonia, N.J.

HAROLD SAYRE WHEELER (1884–1932)

Harold Sayre Wheeler, who died in Pasadena, Calif., on November 19, 1932, was born at Manistee, Mich., on July 23, 1884. His parents were Edward D. and Emma A. (Sayre) Wheeler.

Mr. Wheeler received a B.S. degree in mechanical engineering from the University of Michigan in 1906 and was assistant to the head of the mechanical engineering department there during the following year, while working for his M.Sc. degree. He then became head of the designing department of the E. P. Thomas Automobile Co. and in 1908 was consulting engineer to the Chalmers Motor Car Company in Detroit. Because of his work in the automotive field the University of Michigan chapter of Sigma Xi elected him to membership in 1910.

In 1909, following the death of his father, Mr. Wheeler went to Tacoma, Wash., to become associated with a brother in handling clay and timber property which his father had owned there. He took the office of vice-president in both the Far West Lumber Company, a timber-holding corporation, and the Far West Clay Company, of which he also became general manager. A clay plant and machinery for it were designed and built, and the products of the plant steadily were increased and perfected under his supervision. Not only the engineering work but also sales and administration were directed by him.

Mr. Wheeler invented and patented the Wheeler interlocking paving block, a process for the lubrication of bearings, and a means of cooling combustion engines. During the World War he served for a time as a lieutenant in the Engineers Corps, stationed at Camp A. A. Humphries, Va. Prior to his enlistment he was vice-chairman of a Committee of Military Defense at Tacoma to promote the development of Camp Lewis.

Mr. Wheeler became a member of the A.S.M.E. in 1920 and belonged to the Christ Church, the Masonic fraternity, and several clubs in Tacoma and Pasadena. He had built several large homes for sale in Pasadena, where he had a winter residence. He is survived by his widow, Ruth (Anderson) Wheeler, whom he married in 1915, and by two children, Laura and Edward Anderson Wheeler.

JOHN CHARLES FREMONT WHITE (1862–1932)

John Charles Fremont White was born on September 15, 1862, at Wilmington, N.Y., the son of George Clinton and E. A. (Comstock) White. He was graduated from high school in Granville, N.Y., in June, 1879, and during the next three years served a machinist's apprenticeship at the Schenectady Locomotive Works. He then secured employment as assistant master mechanic of the Railroad Repair Shop, at Plattsburg, N.Y. After a year there he opened a general repair shop in Plattsburg, but gave this up in 1887. During the next two years he worked as a machinist at the Watts Campbell Engine Works, Newark, N.J., and Armington & Simms Engine Works, Providence, R.I.

For more than twenty years, beginning in 1890, Mr. White was associated with the Hersey Manufacturing Company, South Boston, Mass., five years as machinist, ten as assistant mechanical engineer, designing and supervising the construction of special sugar, soap, and malting machinery, and seven as efficiency engineer, working on special single purpose duplicating tools, both automatic and semi-automatic, for the rapid production of water meter parts.

In 1912 Mr. White became factory superintendent of the Standard Meter Company, Watervleit, N.Y., where he remained for three years. For part of 1915 he was superintendent of an ammunition factory, later called the Liberty Arms & Fuse Co., in Long Island City, N.Y. The following year he took the position of superintendent of machinery for the A. Kimball Co., New York. He had been foreman of the machine shop of the New York, New Haven & Hartford Railroad Co., Van Nest, N.Y., since 1923. He died on October 9, 1932, following an operation for sinus trouble.

Mr. White became an associate member of the A.S.M.E. in 1918. He also belonged to the Masonic fraternity, the Cable Club, a railroad organization, and the League of American Wheelmen. He was a charter member of the Savin Hill Yacht Club (New Haven, Conn.), when it was reorganized in 1907, and had served on its house committee and as its chairman. He was also active in the Isham Park Yacht Club at Spuyten Duyvil. His own yacht, the *Whitecap*, was well known along the New England Coast.

Mr. White is survived by his widow, Florence Editha (Macdonald) White, whom he married in 1895 in Boston, Mass.

GARDNER STEWART WILLIAMS (1866–1931)

Gardner Stewart Williams, vice-president of the American Engineering Council since 1923, and consulting hydraulic engineer of Ann Arbor, Mich., died in that city on December 12, 1931, after a long illness.

Major Williams had represented the Detroit Engineering Society on the F.A.E.S. and the American Engineering Council since 1921. He was the leader of the group which organized that society, under the name of the Detroit Association of Graduate Engineers of the University of Michigan, in 1895. It is one of a number of technical organizations in which he had taken an active interest. These included the A.S.M.E., which he joined in 1921, the A.S.C.E., of which he was a past vice-president and past director, the American Water Works Association, New England Water Works Association, Western Society of Engineers, Michigan Engineering Society, and Grand Rapids Engineering Society.

The son of Stewart B. and Juliet M. (Ripley) Williams, Gardner S. Williams was born at Saginaw City, Mich., on October 22, 1866. His early education was obtained in the Saginaw schools, from which he entered the Engineering College of the University of Michigan. He received a B.S. degree in civil engineering in 1889, and a C.E. degree was conferred upon him ten years later.

The summer vacations of 1887, 1888, and 1889 were spent by Major Williams in waterworks construction at Bismarck, N.D., and Greenville and Owosso, Mich. For three years following his graduation he was draftsman, designer, and superintendent of erection for the Russel Wheel & Foundry Co. in Detroit. He was civil engineer to the Board of Water Commissioners of Detroit from 1893 to 1898 and during the latter part of that period joined with Messrs. Hubbell and Fenkell in an investigation of the flow of water in pipes, for which they were presented the Norman Medal of the A.S.C.E. in 1901.

In 1899 Major Williams accepted the chair of experimental hydraulics at Cornell University, and took charge of the Hydraulic Laboratory there until 1904. He also conducted a study of the flow of water over dams for the International Waterways Commission, of which he was a member. He designed and built the first dome dam in this country, at Ithaca, in 1902. The Department of the Interior adopted the features of this design in the Coolidge Dam. He also did pioneer work in building multiple-arch dams on soft foundations in 1909, and in 1910 designed underdrained earthen embankments for dams.

After leaving Cornell in 1904, Major Williams taught civil, hydraulic, and sanitary engineering at the University of Michigan until 1911. Since that time he had been engaged in general consulting work, with headquarters at Ann Arbor. He had practised in twenty-one states and in Ontario and Quebec, and his latest multiple arch dam was the Magnitogorsky on the Ural River. Major Williams had also studied water turbines and designed a scroll pit and elbow draft tube for vertical shaft turbines. He was recognized as an authority on the hydraulics of the Great Lakes and was an early advocate of the St. Lawrence Waterway. The last two or three years of his life were devoted mainly to the hydraulics of the Mississippi River, leading him to propose straightening and deepening, as an alternate to levee construction. He was co-author with Allen Hazen of Hydraulic Tables (1905), and he also wrote the chapter on hydraulics in the American Civil Engineers' Handbook.

Major Williams rendered special service to the public and the Government in a number of cases. About 1896 he succeeded in tracing typhoid fever infection from Port Huron to Detroit through the waters of the St. Clair and Detroit Rivers. He appeared before the United States Supreme Court as an expert in the Drainage Canal Case of the State of Missouri vs. the State of Illinois and the Sanitary District of Chicago. He was also an expert witness in the United States Circuit Court of Illinois in the case of the United States vs. the Sanitary District of Chicago. Early in 1927 he appeared in this same case before Charles Evans Hughes, special master for the Supreme Court. Major Williams served in the Officers Reserve Corps in 1917 in connection with camp construction at Alexandria, La.

Surviving Major Williams are his widow, Jessie B. (Wright) Williams, whom he married in 1893, a son, William Wright Williams, and a daughter, Harriet R. (Williams) Waite.

WILLIAM AUGUST TJEENK WILLINK (1859-1932)

William A. T. Willink, who died on April 24, 1932, was born at Zutphen, Netherlands, on July 14, 1859. He studied engineering at the Royal Technical High School and University at Aix-la-Chapelle, Germany, receiving his M.E. degree in 1884.

After a short apprenticeship with a manufacturer of pumps and engines in Burtscheid, Germany, he went to England, where he worked for Butterworth & Dickinson, Burnley, and Woolsume, Rye & Co., Oldham, in 1885. From 1886 to 1890 he was connected with the Zwolle Machine Works, Zwolle, Netherlands, as technical manager. The next two years were spent in the capacity of chief engineer for the Peat Utilization Company and Continental Phosphate & Chemical Manure Co., in London. He then returned to Germany where he worked at the Grevenbroich Machine Works in 1892.

During the years 1893 to 1898 Mr. Willink was in Cuba, holding the position of chief engineer, first at the Santa Lucia Sugar Factory and then at the Vicini Sugar Factories in Santo Domingo. From there he went to Brooklyn, N.Y., spending the next five years at the Pioneer Iron Works. In 1904 he became manager of the Augustin Fuller Company, New York, exporters of sugar machinery. He returned to Cuba in 1905, acting as agent for the Pioneer Iron Works, with office at Havana, and practicing consulting engineering in that city until 1910. He also became a registered patent attorney in 1904.

From 1910 to 1914 Mr. Willink was associated with Lebedjeff & Co., New York, contractors for sugar factories and machinery for Cuba and Porto Rico. He was mechanical engineer in charge of the drafting office of the Arbuckle Brothers Sugar Refinery in Brooklyn for three years, 1914-1916; sugar engineer for the M. H. Treadwell Co., New York, 1917-1921, designing sugar machinery and in 1920-1921 surveying the needs for machinery in Argentina and Brazil; also sugar engineer for the Southwark Foundry & Machine Co. of Philadelphia, 1920-1921; and had practiced consulting engineering in the sugar industry, with an office in Philadelphia, since then.

Mr. Willink became a member of the A.S.M.E. in 1912. Surviving him are his widow, Freda Willink, of Philadelphia, and a son, Lieutenant A. Willink, stationed at Frankford Arsenal.

JOHN P. WINTERS (1876-1932)

John P. Winters was born at Shippenville, Pa., on August 28, 1876, the son of Peter and Sarah L. Winters. He attended Grove City (Pa.) College and in 1916 became superintendent of production in District No. 1, State of Kansas, for the Empire Gas & Fuel Co. From 1919 to 1921 he held a similar position with the Kansas & Gulf Co. and during the next two years with the Skelly Oil Company.

Since 1923 Mr. Winters had been production superintendent for The National Refining Company in the Mid-Continent field, with headquarters at El Dorado, Kan. He was in complete charge of production and of construction of all oil-field equipment. He designed and built casinghead plants, booster stations, compressor plants, and all types of pipe lines. He was a joint patentee of an oil filter and a true-bore-forming guide for rotary drill stems.

Mr. Winters served as a private in the infantry during the Spanish-American War and was a member of the Lawton Camp of Spanish-American War Veterans. He also was postmaster at Pittsville, Pa., for eight years. He became a member of the A.S.M.E. in 1931 and belonged to the American Petroleum Institute. He was a Shriner in the Masonic fraternity and a member of the Presbyterian Church.

Surviving Mr. Winters, whose death occurred on September 26, 1932, at Tulsa, Okla., are his widow, Clementine (Stover) Winters, whom he married in 1899, and two daughters, Miss Jean Winters and Mrs. John E. Howell, both of Bartlesville, Okla.

ALEXANDER WINTON (1860-1932)

Alexander Winton, who in 1898 sold his first "horseless carriage," died in Cleveland, Ohio, on June 21, 1932, after a two weeks' illness. His first "one-lunger" gasoline automobile was repurchased by Mr. Winton after a few years and is now in the Smithsonian Institution at Washington.

Mr. Winton was born in Grangemouth, Scotland, on June 20, 1860, the son of Alexander Winton, a manufacturer of farm implements, and Helen (Fea) Winton. He received a public-school education in Scotland and served an apprenticeship in the shipyards on the Clyde River. He came to the United States in 1880 and for four years was employed by the DeLamater Iron Works, New York. He then went to Cleveland, where he took the position of superintendent of the Phoenix Iron Works.

Mr. Winton's first invention was a bicycle, which was manufactured by the Winton Bicycle Company, established in Cleveland in 1890. He then began experimental work, in the cellar of his home, on a gasoline vehicle. By 1897 he was ready to organize the Winton Motor Carriage Company, later the Winton Motor Car Company, and the first car was sold for $1000 the following year. In the beginning the various parts for his cars were manufactured by hand, but Mr. Winton soon designed special machinery for turning out many pieces. In later years he built the first two-braking system and a Winton car was first to be equipped with internal and external brakes on the one drum. An important phase of his work was done in the development of the storage battery. The difficulty with glass-jar cells in use at the time was that the liquid contents spilled whenever the car struck a rut in the road.

Mr. Winton was the first to devise a successful speed governor and also a completely accessible motor, as well as the first to manufacture four and eight cylinder motors. Recently he had announced the perfection of a light oil-burning motor which he planned to use in airplanes.

Like other pioneer automotive manufacturers, Mr. Winton tested his cars and attracted public attention to them on the race tracks. For several years his cars were winners. In 1903 he established a speed record of 68 miles an hour at Daytona Beach, Florida. In 1905 he built an eight-cylinder racing car, which he drove that year in the James Gordon Bennett Cup race in Ireland. He lost the race, he said later, because someone put candles in the gasoline tanks to "keep away the devils." In those days some people still regarded an automobile as an evil contraption.

Mr. Winton was also the organizer and president of the Winton Gas Engine & Manufacturing Co., established in 1897, and the Winton Marine Oil Engine Works, founded in 1912. The declining popularity of the Winton car caused him to suspend its manufacture in 1924.

Mr. Winton became a member of the A.S.M.E. in 1913. He also belonged to the Cleveland Engineering Society and the Masonic fraternity. He was ex-commander of the Inter-Lake Yachting Association and his club memberships included the Boston Yacht Club, the Civil Engineers Club (Cleveland), and the Chicago, Clifton, and Cleveland Automobile Clubs. He is survived by his fourth wife, Mrs. Mary E. (Avery) Winton, whom he married in 1930, and by six children by his first marriage and one by his second.

GEORGE MONROE WISNER (1870-1932)

George Monroe Wisner was born on February 9, 1870, in Detroit, Mich., the son of George Y. and Carrie (Palmer) Wisner. He attended the public schools of Detroit and the University of Michigan, from which he was graduated in 1892, with a B.S. degree in Civil Engineering. In the same year he accepted a position in the Engineering Department of The Sanitary District of Chicago, and throughout his engineering life of about 40 years he was connected with the work of the District, first with construction and later with operation and maintenance, and the various problems related thereto. He passed through the various grades; as instrument man he had charge of the construction of four rock sections between Lemont and Lockport, Ill.; as assistant engineer he was in charge of cement testing, but was employed chiefly on hydraulic and design work from 1895 to 1897 and during the next four years was in charge of the Chicago River Improvement, consisting of the dredging and docking of the Chicago River and the construction of a "by-pass" between Adams and Van Buren Streets along the west side of the river, the construction of the Des Plaines River Improvement through Joliet, and the construction of the Water Power Development at Lockport. As assistant chief engineer from 1901 to 1907, he directed all construction work, including the building of docks, coffer dams, bridges, both substructures and the superstructures, and the water power development.

Under his direction as chief engineer, to which position he was elected in 1907, the North Shore Channel and the Calumet-Sag Channel, adjuncts to the Main Channel, were planned and built. When Chicago was experiencing its rapid growth both in population and industry, between 1900 and 1910, Mr. Wisner foresaw the necessity of sewage treatment to supplement the existing dilution system. He convinced the Board of Trustees of the need of a thorough study of the sanitary program and early in 1909 secured an appropriation for a testing station on domestic sewage at the 39th Street pumping Station, where the then known methods of sewage treatment were tried. He also began the organization of a sanitary engineering staff, equipped with a laboratory adequate to handle the biological, bacterial, and chemical problems, as well as coal, oil, and other routine analyses. Following this, he directed an intensive study of the Packingtown and Stock Yards wastes of Chicago, the tannery wastes and the corn products wastes, whereby for the first time the magnitude of the industrial waste problem in the Sanitary District was revealed. He developed a keen interest in sewage treatment as then practised in the United States and abroad, visiting England, France, and Germany in 1910 to study foreign practice. In 1911, he made a report to the Board of Trustees on sewage disposal works for the Sanitary District, laying the foundation for later developments. Following these and other investigations, the Des Plaines River Sewage Treatment Works and the Calumet Sewage Treatment works were designed and constructed, the first units of the sewage treatment system. The Morton Grove Sewage Treatment Works, the 32nd Avenue Outlet Sewer, the West 39th Street Conduit, the Stock Yards Intercepting Sewer, the North Shore Intercepting Sewer, the Summit Outfall Sewer, the Evanston Intercepting Sewers and Pumping Station, the Des Plaines Intercepting Sewer and the Calumet Intercepting Sewer and Pumping Station were all designed and built under his direction during his term of office. At the same time, he was following the negotiations and litigation relating to the diversion from Lake Michigan and was one of the principal witnesses in the case of the United States vs. the Sanitary District and later in the hearings before the Rivers and Harbors Committee of Congress, and became an expert in advising the lawyers in such matters.

Mr. Wisner resigned as chief engineer in June, 1920, to enter private consulting practice, but was retained by the District as consulting engineer, a relationship which continued until his death. As a consultant, he proved to be a valuable advisor during the development of the sewage treatment program and the recent Lake level litigation (Wisconsin et al vs. Illinois et al), and was also instrumental in making great savings for the Sanitary District.

Mr. Wisner's private consulting work comprised harbor works in Labrador, dock work and shore protection in Florida, and drainage and road work in Cook County, Illinois. He served one year as Chairman of the Advisory Subway Engineering Commission of the City of Chicago. In spite of total blindness during the last six years of his life he kept up his interest in engineering works, giving particular thought to the transportation problem of the City of Chicago.

In 1902, Mr. Wisner married Edith K. Young, of Chicago, by whom he is survived.

Mr. Wisner became a member of the A.S.M.E. in 1907. He also belonged to the American Society of Civil Engineers and the Western Society of Engineers. His club affiliations included the Beta Theta Pi, Chicago Athletic Association, Chicago Engineers, South Shore Country, and Beverly Country Clubs. He took a great deal of interest in athletic events, playing football when attending the University of Michigan. Throughout his working life, he kept up his skill in swimming. He enjoyed yachting and travel. He died suddenly at his home on August 26, 1932, after a short illness.

FRANK WARREN WOOD (1870–1932)

Frank Warren Wood, whose death occurred on May 18, 1932, was born at Ancora, N.J., on November 9, 1870, the son of Nathan H. and Emmaline (Spaulding) Wood.

In 1903 he became general manager of the Bessemer Coal & Coke Co. of Pittsburgh, Pa. He resigned in 1906 to organized the Cleveland Castings Pattern Company, manufacturers of wood and metal patterns. In 1909 he organized The Wood & Spencer Co., also in Cleveland, manufacturers of taps and automobile and airplane parts. He served as president and general manager in these last two companies until the time of his death.

He was a lieutenant in the Spanish American War, and a major in the Ordnance Department in the World War, in charge of the Ordnance Department at Limoges, France.

He became an associate of the A.S.M.E. in 1924 and also belonged to the Cleveland Engineering Society and the Army Ordnance Association.

SIR ALFRED YARROW (1842–1932)

Sir Alfred Yarrow, shipbuilder, naval engineer, philanthropist, and honorary member, A.S.M.E., who died at the age of ninety on January 24, 1932, was well known for the boiler that bears his name and for the high-speed and shallow-draft vessels made at his works on the River Clyde. He was born into the age of steam that had developed out of the introduction of the engine, the locomotive, and the steamship. Endowed, as his schoolmaster said, with "a talent for engineering and a thirst for affection—to give and to take," and, as he himself once said, with a good constitution and a necessity of working, he made more profitable use of his talents and his opportunities than do most men. He inherited from his mother an ability for affairs unusual in an engineer, good health, and longevity (she lived to be 95), and from both his parents a warmth of human sympathy and understanding which directed the abundant philanthropies made possible by his well-earned prosperity. Starting his apprenticeship to an engineering firm at the age of fifteen, he was more fortunate than most men in being able to crowd into an active three-quarters of a century an extraordinary list of good works. His approach to engineering was a strictly practical one; his school was the shop and drafting room; and no small measure of his success lay in the intrepid pioneering spirit that gave him courage to try new and apparently impossible tasks, such as constructing a steamship that could be taken apart and carried in 50-lb pieces through 60 miles of African jungle, and vision to seek through research the necessary data upon which to base new developments. His specialties, shallow-draft steam yachts, mostly used on rivers in undeveloped countries, and high-speed vessels for the British and other navies, demanded pioneering and research methods, for almost every ship was constructed for an unusual purpose, or to travel at a hitherto unattained speed. It was characteristic of him that he should have been the first to set up and operate a privately owned telegraph in London; that, when less than twenty, he should have constructed a steam-propelled road vehicle which, on its nocturnal travels between Greenwich and Bromley at twenty-five miles an hour, had the misfortune to cause a horse to shy, a mounted policeman to break his leg, and an aroused parliament to pass a bill prohibiting the use of steam upon the road, unless the carriage were preceded by a man carrying a flag; and it was equally characteristic of this same spirit of progress that he should donate £20,000 to the Royal Society in 1911 for an experimental tank for shipbuilders at the National Physical Laboratory at Teddington; and later, in 1923, to offer the same society £100,000 to be used at the discretion of its council in promoting scientific research.

Alfred Fernandez Yarrow was born in London on January 13, 1842, the son of Edgar and Esther (Lindo) Yarrow. His mother was the daughter of Moses Lindo, a Jewish merchant who had been in business on the island of St. Thomas, West Indies, and for whom Edgar Yarrow worked as a clerk. After some schooling, in which he showed an aptitude for mathematics and science, Alfred Yarrow, at the age of 15, was apprenticed for a period of 5 years to Messrs. Ravenhill, marine engineers, builders of marine engines. During his apprenticeship his spare time was spent in shops, in attendance at engineering meetings and lectures (Faraday was demonstrating new-found scientific principles before large audiences during these years), and in working at home. Inventive ability, which had manifested itself in childhood and sometimes led to mischievous pranks, found expression before the lad was twenty in two devices that were developed in cooperation with his chum, James Hilditch: an improved method for steam plowing, and a steam-propelled road carriage, both of which which were taken over by others on a royalty basis; and also gave rise to the building of the steam yacht *Isis*, the first of the long line of vessels that the famous shipbuilder was to produce.

It was the success that attended the building of the *Isis* that finally encouraged Yarrow to undertake the building of small yachts. Ravenhill had held out small inducement for the ambitious boy, and finding a partner and a site for a shop at Poplar, on the Isle of Dogs in the River Thames, the first works with a sign bearing the name Yarrow & Hedley, Engineers, was started. In 1868, after advertising his ability to build steam launches, Yarrow received his first order, a 24-ft steam launch for Colonel Halpin, and thereby established a profitable business. Differences between Yarrow and Hedley terminated the partnership in1875. Up to that time 350 steam launches had been built. Having bought out Hedley, Yarrow continued the shipbuilding business with rapidly growing success to the day of his death, moving his works to Scotstoun, on the Clyde, in 1906.

An impressive list of steam launches have come out of the Yarrow Works. An unusual problem in shipbuilding was successfully solved in the construction of the 55-ft *Ilala*, launched in 1875 on Lake Nyassa, Africa. It had been designed so that no piece weighed more than 50 lb, and was bolted rather than riveted together. After a trip up the Zambesi and Shiré rivers, it was taken apart and carried 60 miles through the jungle and reassembled without loss or injury of a single part.

Between 1877 and 1879 Yarrow, who was specializing in the newly conceived torpedo boat, arranged first for spar torpedoes and subsequently for self-propelled Whiteheads, built torpedo launches for the Argentine, Dutch, French, Russian, Spanish, Austrian, Italian, and Chilean governments. The British Admiralty Torpedo Boat No. 425, built to a guarantee of 18 knots, actually realized 21.9 knots, and led Yarrow into some interesting and valuable experiments on 25 propellers. His first ocean-going torpedo boat, the *Batoom*, built in 1880, made 22 knots. By 1892 these smaller craft had developed into the destroyer class, of which the *Havock* and *Hornet*, 180 ft long and developing 4000 hp, were conspicuous examples. The *Havock* had the usual locomotive type of boiler and made 26.1 knots, but in the *Hornet* had been placed the new Yarrow water-tube boiler. With 11 tons less weight, the *Hornet* made 27.3 knots. Speed was raised again by the Russian yacht *Sokol*, holding a record of 30 knots, and, in 1899, by the Japanese destroyer *Sazanami*, 220 ft long, 6000 hp, which made 31 to 32 knots.

In 1910 Yarrow convinced Lord Jellicoe and subsequently Lord Churchill that, in view of developments elsewhere, the 27-knot destroyer class should be replaced by ships of greater speed, and the *Firedrake*, *Lurcher*, and *Oak* were built, the *Lurcher* attaining a speed of 35.345 knots.

The Yarrow boiler, familiar to all engineers, was developed between 1877 and 1887, and when finally perfected, was used for years with practically no changes in fundamental design. A demand for greater steaming capacity, for which increased speed was responsible, led to the development in 1905 of the double-ended boiler for the Spanish Navy, and in 1908–1910 to two boilers developing 9000 hp for a Brazilian ship. In 1911 with the introduction of superheated steam, the superheated damper was installed in the boilers for the *Archer* and the *Attack*.

With the coming of the World War, Yarrow's speedy destroyers gave valiant aid to the British Navy. Twenty-nine of these ships were built from August 4, 1914, to November 11, 1918, and with the success of the Tigris flotilla, brought Yarrow the baronetcy shortly after. Of these vessles the *Tyrian* made 40 knots.

During a trip to the United States Sir Alfred made an experimental study of ship vibration and subsequently developed the Yarrow-Schlick-Tweedy system of balancing reciprocating engines.

No less famous than the torpedo boats and destroyers were numerous shallow-draft steamers built by Yarrow. In addition to the *Ilala*, a ship of a special sectional construction was built in which Stanley explored the Congo in 1883. The sections could be carried on a steamer and lowered over the ship's side and assembled afloat, and could be carried overland on specially provided carriages. For navigating the upper Nile four boats were built in 1874. Of these no part weighed more than a camel could carry. They were driven by means of a stern wheel. In a fruitless attempt to save Gordon at Khartoum, two shallow-draft gunboats, the *Lotus* and the *Waterlily*, were built in 1884. In 1897 a Nile expedition under Lord Kitchener used the *Sheik*, a 24-in.-draft gunboat with its screws in a tunnel and provided with the Yarrow hinged flap that subsequently became a feature of the ships of the Tigris flotilla. For use on the Yangtze Kiang, in 1903, the gunboat *Widgeon*, 160 ft long and of 27 in. draft, was designed.

The Tigris flotilla consisted of river gunboats built in two sizes; one 250 ft long with 4 ft draft, equipped with twin screws, and the other of the "fly" class, 120 ft long and with 2 ft 6 in. draft and a single screw. They were shipped in pieces to the mouth of the Tigris, assembled at Abadan by native labor, and used in connection with General Townshend's campaign in Mesopotamia.

Aside from his engineering achievements, Sir Alfred's many philanthropies made him a well-known Briton. He established at Broadstairs in 1894 a children's convalescent home, the trusteeship of which passed to the Institution of Civil Engineers in 1903. Among other benefactions he provided funds for the building of the outpatient department of the London Hospital, established a fund for medical research, a nurses' training home in Scotland, as well as a fund to provide nurses in the highlands and islands of Scotland, and a studentship in Assyriology at Cambridge in honor of his son killed during the war, in addition to the two funds for research at the Royal Society already referred to. He was deeply interested in education and in his workmen. During the strike of 1897 he suggested that a delegation of workmen visit the United States at his expense to see for themselves the results that workmen in this country had attained socially and financially, but the suggestion was never carried out.

Sir Alfred was married in 1875 to Minnie Franklin, who died in 1922. Six children were the result of this union: Harold Edgar, now managing director of the Yarrow & Company, Glasgow, who succeeds to the baronetcy; Norman Alfred, managing director, Yarrows, Ltd., Victoria, B.C.; and Eric, killed at Ypres; and three daughters; of whom the eldest is wife of Vice-Admiral P. M. Royds, the second, wife of Alfred Earnest Yarrow of Pinner, and the youngest, wife of Lord Dawson of Penn. Sir Alfred's second wife, who survives him, is Eleanor Barnes, author of "Alfred Yarrow, His Life and Work." Both of Sir Alfred's sons are members of the A.S.M.E.

Sir Alfred was elected an honorary member of the A.S.M.E. in 1914. He had been a member of the Institution of Civil Engineers since 1869 and a member of its council, of the Institution of Mechanical Engineers since 1889, and of the Naval Architects and Marine Engineers, which latter society he served as vice-president in 1896.

WILLIAM FRANKLIN YEAGER (1879–1932)

William Franklin Yeager, consulting engineer for the United Engineers & Constructors, Inc., Philadelphia, Pa., died on February 13, 1932. Mr. Yeager was a native of Philadelphia, having been born there on September 18, 1879. After leaving grammar school he spent two years at the Philadelphia Manual Training School and then three at the Williamson (Pa.) Free School of Mechanical Trades, from which he was graduated in 1899 as an electrical machinist. He followed up this training with practical experience as machinist, electrician, and draftsman in the employ of ten or twelve different Philadelphia companies, including the Brush Electric Company, predecessor of the Philadelphia Electric Company. He also spent about a year with the General Electric Company in Schenectady, engaged in general structural design and drawings for substations, power houses, and other buildings, and pipe lines.

Mr. Yeager was connected with Dodge & Day, an early predecessor of the United Engineers & Constructors, Inc., from 1905 to 1908, making calculations and detail drawings for electrical work in various plants, during the latter part of the time in the capacity of chief draftsman. Subsequently he was associated for five or six years with Frank C. Roberts & Co., and Edgar V. Seeler, Philadelphia, largely in the design, construction, and testing of electrical equipment for the Curtis Publishing Company.

Since early in 1916, when he accepted the position of chief draftsman with Day & Zimmermann, Inc., Mr. Yeager had been in charge of a large volume and variety of design and construction work. Among the contracts to which he was assigned were a factory and auxiliary structures for the Philadelphia Textile Company; several bridge and pipe line structures for the New Process Gear Corporation, Syracuse, N.Y.; a brick, concrete, and steel substation for the Erie (Pa.) Lighting Company; a brick and wood factory for the Chicago Automatic Machine Screw Company; foundry and other buildings for the Toledo Machine Tool Company; and power plant additions for the Penn Central Power Company and other power companies.

In 1917 he was placed in charge of the design of the gun plant at Erie, for which Day & Zimmermann acted as supervising engineers for the Government. Later he handled the general structural design of a plant for the Baltimore Shipbuilding Company and two Government projects, the Quartermaster Terminal at Oregon Avenue, Philadelphia, and the Delaware River, and Motor Transport headquarters in Philadelphia. The latter assignments involved pier construction, warehouses, railroad track and yard, power houses, as well as temporary structures used while the work was in progress. During his last six months on this work his position was that of supervising engineer directing both design and construction.

Since returning to the main offices of Day & Zimmermann in 1920 Mr. Yeager had spent the major portion of his time in surveys and reports on development projects for many clients of the company.

Mr. Yeager became a member of the A.S.M.E. in 1927 and was also an associate of the American Institute of Electrical Engineers.

Mr. Yeager is survived by his widow, Lillie M. (Mandeville) Yeager, whom he married in 1905, and by two sons, William M. and Edward E. Yeager.

WILLIAM ALFRED YOUNG (1870–1931)

William Alfred Young, consulting engineer for the Harnischfeger Corporation, Milwaukee, Wis., died in that city on December 23, 1931.

Mr. Young was born at Cuyahoga Falls, Summit County, Ohio, on October 16, 1870, the son of John and Anne Elizabeth (Davis) Young. He served an apprenticeship as a machinist with the Hughes Steam Pump Company, Cleveland, and studied civil and mechanical engineering through the International Correspondence Schools and Ohio Northern University, from which he received a B.S. degree in civil and mechanical engineering in 1897. His early experience included shop training with the Turner, Vaughn & Taylor Co., Cuyahoga Falls, and the Otis Steel Company, Cleveland. He worked as draftsman for several years for the Whitman & Barnes Manufacturing Co., Akron and Chicago, and the Grant Ball & Machine Co., Cleveland. He was machine-shop foreman for a year for the A. P. Dickey Manufacturing Co., of Racine, Wis., and later chief draftsman for the Falls Rivet & Machinery Co., Cuyahoga Falls, and assistant to the chief draftsman of the Shaw Electric Crane Company, Muskegon, Mich. About the year 1908 he became chief draftsman for the Pawling & Harnischfeger Co., which was reorganized as the Harnischfeger Corporation following the death of Mr. Pawling some fifteen years ago.

A fully enclosed, spur-geared, crane-type trolley was developed by Mr. Young, and one of his most recent contributions to the metal-working industry was a special apparatus for handling material in welderies.

Mr. Young became a junior member of the A.S.M.E. in 1901, an associate in 1905, and a member the following year. He belonged to the Masonic fraternity and the Congregational Church. His widow, Anna Belle (Damp) Young, whom he married in 1899, survives him.

Depositories for A.S.M.E. Transactions in the United States

BOUND copies of the complete Transactions of The American Society of Mechanical Engineers will be found in the libraries in the United States and other countries which are listed on the following pages.
